Theorem 5. *The dual problem of (8) is*

$$\begin{aligned} \max_{Q,W} \quad & \sum_{(i,j)\in\mathcal{T}} \left(Q_{i,j} - \frac{Q_{i,j}^2}{2c}\right) + \sum_{(k,l)\notin\mathcal{T}} \left(|W_{k,l}| - \frac{W_{k,l}^2}{2c}\right) \\ & - \frac{2(m^2-m)}{c}\lambda \quad (9) \\ s.\ t \quad & L \succeq Q \otimes T + W \otimes \bar{T} \\ & \forall (i,j) \in \mathcal{T}, Q_{i,j} \geq 0, \quad \lambda \geq W_{k,l}^2, \forall (k,l) \notin \mathcal{T} \end{aligned}$$

where matrix $\bar{T}$ is defined as

$$\bar{T}_{i,j} = \begin{cases} 0 & (i,j) \in \mathcal{T} \\ 1 & otherwise \end{cases},$$

and $\otimes$ stands for the element wise product of matrices.

The proof can be found in Appendix C. In the dual problem, variables $Q_{i,j}$ and $W_{i,j}$ are the dual variables that indicate the importance of labeled example pairs and unlabeled examples, respectively. We thus will select the unlabeled example pair with the largest $|W_{i,j}|$. To speed up the computation, in our experiment, we first select a subset of example pairs (fixed 200) with smallest $|Z_{i,j}|$ using the current kernel matrix Z. We then set all $W_{k,l}$ to be zero if the corresponding pair is not selected. In this way, we significantly reduce the number of variables in the dual problem in (9), thus simplifying the computation.

3. Experimental Results

In our experiments, we follow the work (Hoi et al., 2007), and evaluate the proposed algorithm for active kernel learning by the experiments of data clustering. More specifically, we first apply the active kernel learning algorithm to identify the most informative example pairs, and then solicit the class labels for the selected example pairs. A kernel matrix will be learned from the labeled example pairs, and the learned kernel matrix will be used by the clustering algorithm to find the right cluster structure.

3.1. Experimental Setup

We use the same datasets as the ones described in (Hoi et al., 2007). Table 1 summarizes the information about the nine datasets used in our study. We adopt the clustering accuracy defined in (Xing et al., 2002) as the evaluation metric. It is defined as follows

$$Accuracy = \sum_{i>j} \frac{\mathbf{1}\{\mathbf{1}\{c_i = c_j\} = \mathbf{1}\{\hat{c}_i = \hat{c}_j\}\}}{0.5n(n-1)}, \quad (10)$$

where $\mathbf{1}\{\cdot\}$ is the indicator function that outputs 1 when the input argument is true and 0 otherwise. c_i and $\hat{c}_i$ denote the true cluster membership and the predicted cluster membership of the ith data point, respectively. n is the number of examples in the dataset. For the graph Laplacian L used by the nonparametric kernel learning, we apply the standard method for all experiments, i.e., by calculating the distance matrix by Euclidean distance, then constructing the adjacency matrix with five nearest neighbors, and finally normalizing the graph to achieve the final Laplacian matrix.

3.2. Performance Evaluation

To evaluate the quality of the learned kernels, we extend the proposed kernel learning algorithm to solve clustering problems with pairwise constraints. In the experiments, we employ the kernel k-means as the clustering method, in which the kernel is learned by the proposed non-parametric kernel learning method. In addition to the proposed active kernel learning method, two baseline approaches are implemented to select informative example pairs for kernel learning. Totally we have:

Table 1. The nine datasets used in our experiments. The first two are the artificial datasets from (Hoi et al., 2007) and the others are from the UCI machine learning repository.

Dataset	#Classes	#Instances	#Features
Chessboard	2	100	2
Double-Spiral	2	100	3
Glass	6	214	9
Heart	2	270	13
Iris	3	150	4
Protein	6	116	20
Sonar	2	208	60
Soybean	4	47	35
Wine	3	178	12

- **Random**: This baseline method randomly samples example pairs from the pool of unlabeled pairs.
- **AKL-min-|Z|**: This baseline method chooses the pair examples with the least $|Z_{k,l}|$, where matrix Z is learned by the non-parametric kernel learning method. As already discussed in the introduction section, this approach may not find the most informative example pairs.
- **AKL-min-H**: This is the proposed AKL algorithm. It selects the example pairs with least $H_{k,l}$ that corresponds to the maximal selection probability $P_{k,l}$.

To examine the performance of the proposed AKL algorithm in a full spectrum, we evaluate the clustering results with respect to different sampling sizes. Specifically, for each experiment, we first randomly sample N_c pairwise constraints as the initially labeled pair examples. We then employ the nonparametric kernel learning method to learn a kernel from the given pairwise constraints. This learned kernel is engaged by the kernel k-means method for data clustering. Next, we apply the AKL method to sample 20 pair examples (i.e. 20 pairwise constraints) for labeling in an iteration, and then examine the clustering results based on the kernel that is learned from the augmented set of example pairs in each iteration.

Each experiment is repeated 50 times with multiple restarts for clustering. Fig. 2 shows the experimental results on the nine datasets with five active kernel learning iterations. First of all, we observe that AKL-min-$|Z|$, i.e., the naive AKL approach that samples the example pairs with the least $|Z|$, does not always outperform the random sampling approach. In fact, it only outperforms the random sampling approach on five out of the nine datasets. It performs noticeably worse than the random approach on dataset "sonar" and "heart". Compared with the two baseline approaches, the proposed AKL algorithm (i.e., AKL-min-H) achieves considerably better performance for most datasets. For example, for the "Double-Spiral" dataset, after 3 active kernel learning iterations, the proposed algorithm is able to achieve the clustering accuracy of 99.6%, but the clustering accuracies of the other two methods are less than 98.8%. These experimental results show the effectiveness of the proposed algorithm as a promising approach for active kernel learning.

4. Conclusion

In this paper we proposed a min-max framework for active kernel learning that specifically addresses the problem of how to identify the informative pair examples for efficient kernel learning. A promising algorithm is presented that approximates the original min-max optimization problem into a convex programming problem. Empirical evaluation based on the performance of data clustering showed that our proposed algorithm for active kernel learning is effective in identifying informative example pairs for the learning of kernel matrix.

Appendix A: Proof of Theorem 3

Proof. First, for any global optimal solution to (6), we have $\sum_{(k,l)\notin\mathcal{T}} p_{k,l} = 1$ though the constraint in (6) is $\sum_{(k,l)\notin\mathcal{T}} p_{k,l} \geq 1$. This is because we can always scale down $p_{k,l}$ if $\sum_{(k,l)\notin\mathcal{T}} p_{k,l} > 1$, which guarantees to reduce the objective function. Second, any extreme point solution (i.e., $p_{k,l} = 1$ for one example pair and zero for other pairs) to (6) is a global optimal solution to (5). This is because (6) is a relaxed version of (5). Third, one of the global optimal solutions to (6) is an extreme point. This is because the first order condition of optimality requires $p^*_{k,l}$ to be a solution to the following problem:

$$\begin{aligned} \min_{p} \quad & \frac{c}{2} \sum_{(k,l)\notin\mathcal{T}} p_{k,l}[\varepsilon^*_{k,l}]^2 \qquad (11) \\ \text{s. t.} \quad & \sum_{(k,l)\notin\mathcal{T}} p_{k,l} \geq 1,\ p_{k,l} \geq 0, \forall (k,l) \notin \mathcal{T} \end{aligned}$$

where $\varepsilon^*_{k,l}$ is the optimal solution for $\varepsilon_{k,l}$. Since (11) is a linear optimization problem, it is well known that one of its global optimal solutions is an extreme point. Combining the above arguments together, we prove there exists a global solution to (5), denoted by $((k,l)^*, Z^*, \varepsilon^*_{i,j})$ that is also a global solution to (6) with $p_{(k,l)^*} = 1$. We extend this conclusion to any other global solution $((k,l)', Z', \varepsilon'_{i,j})$ to (5) because $((k,l)', Z', \varepsilon'_{i,j})$ results in the same value for the problem in (6) as solution $((k,l)^*, Z^*, \varepsilon^*_{i,j})$. This completes our proof. □

Appendix B: Proof of Theorem 4

Proof. To show (8) is a SDP problem, we introduce slack variables for both labeled and unlabeled example pairs, i.e., $\eta_{i,j} \geq \varepsilon^2_{i,j}$ and $\eta_{k,l} \geq \varepsilon^2_{k,l}/h_{k,l}$. We can turn these two nonlinear constraints into LMI constraints, i.e.,

$$\begin{pmatrix} \eta_{i,j} & \varepsilon_{i,j} \\ \varepsilon_{i,j} & 1 \end{pmatrix} \succeq 0, \quad \begin{pmatrix} \eta_{k,l} & \varepsilon_{k,l} \\ \varepsilon_{k,l} & h_{k,l} \end{pmatrix} \succeq 0$$

Using the slack variables, we rewrite (8) as

$$\begin{aligned} \min_{Z\succeq 0, h, \varepsilon} \quad & \mathrm{tr}(LZ) + \frac{c}{2} \sum_{(i,j)\in\mathcal{T}} \eta_{i,j} + \frac{c}{2} \sum_{(k,l)\notin\mathcal{T}} \eta_{k,l} \qquad (12) \\ \text{s. t.} \quad & T_{i,j} Z_{i,j} \geq 1 - \varepsilon_{i,j}, \varepsilon_{i,j} \geq 0,\ \forall (i,j) \in \mathcal{T} \\ & \varepsilon_{k,l} - 1 \geq Z_{k,l} \geq 1 - \varepsilon_{k,l}, \forall (k,l) \notin \mathcal{T} \\ & \sum_{(k,l)\notin\mathcal{T}} h_{k,l} \leq m^2,\ h_{k,l} \geq 1, \forall (k,l) \notin \mathcal{T} \\ & \begin{pmatrix} \eta_{i,j} & \varepsilon_{i,j} \\ \varepsilon_{i,j} & 1 \end{pmatrix} \succeq 0, \forall (i,j) \in \mathcal{T} \\ & \begin{pmatrix} \eta_{k,l} & \varepsilon_{k,l} \\ \varepsilon_{k,l} & h_{k,l} \end{pmatrix} \succeq 0, \forall (k,l) \notin \mathcal{T}, \end{aligned}$$

which is clearly a SDP problem.

To show the second part of theorem, we follow the inequality that a harmonic mean is upper bounded by an arithmetic mean, i.e.,

$$\frac{1}{m} \sum_{(k,l)\notin\mathcal{T}} p_{k,l} \geq \frac{m}{\sum_{(k,l)\notin\mathcal{T}} p^{-1}_{k,l}} = \frac{m}{\sum_{(k,l)\notin\mathcal{T}} h_{k,l}} \geq \frac{1}{m}$$

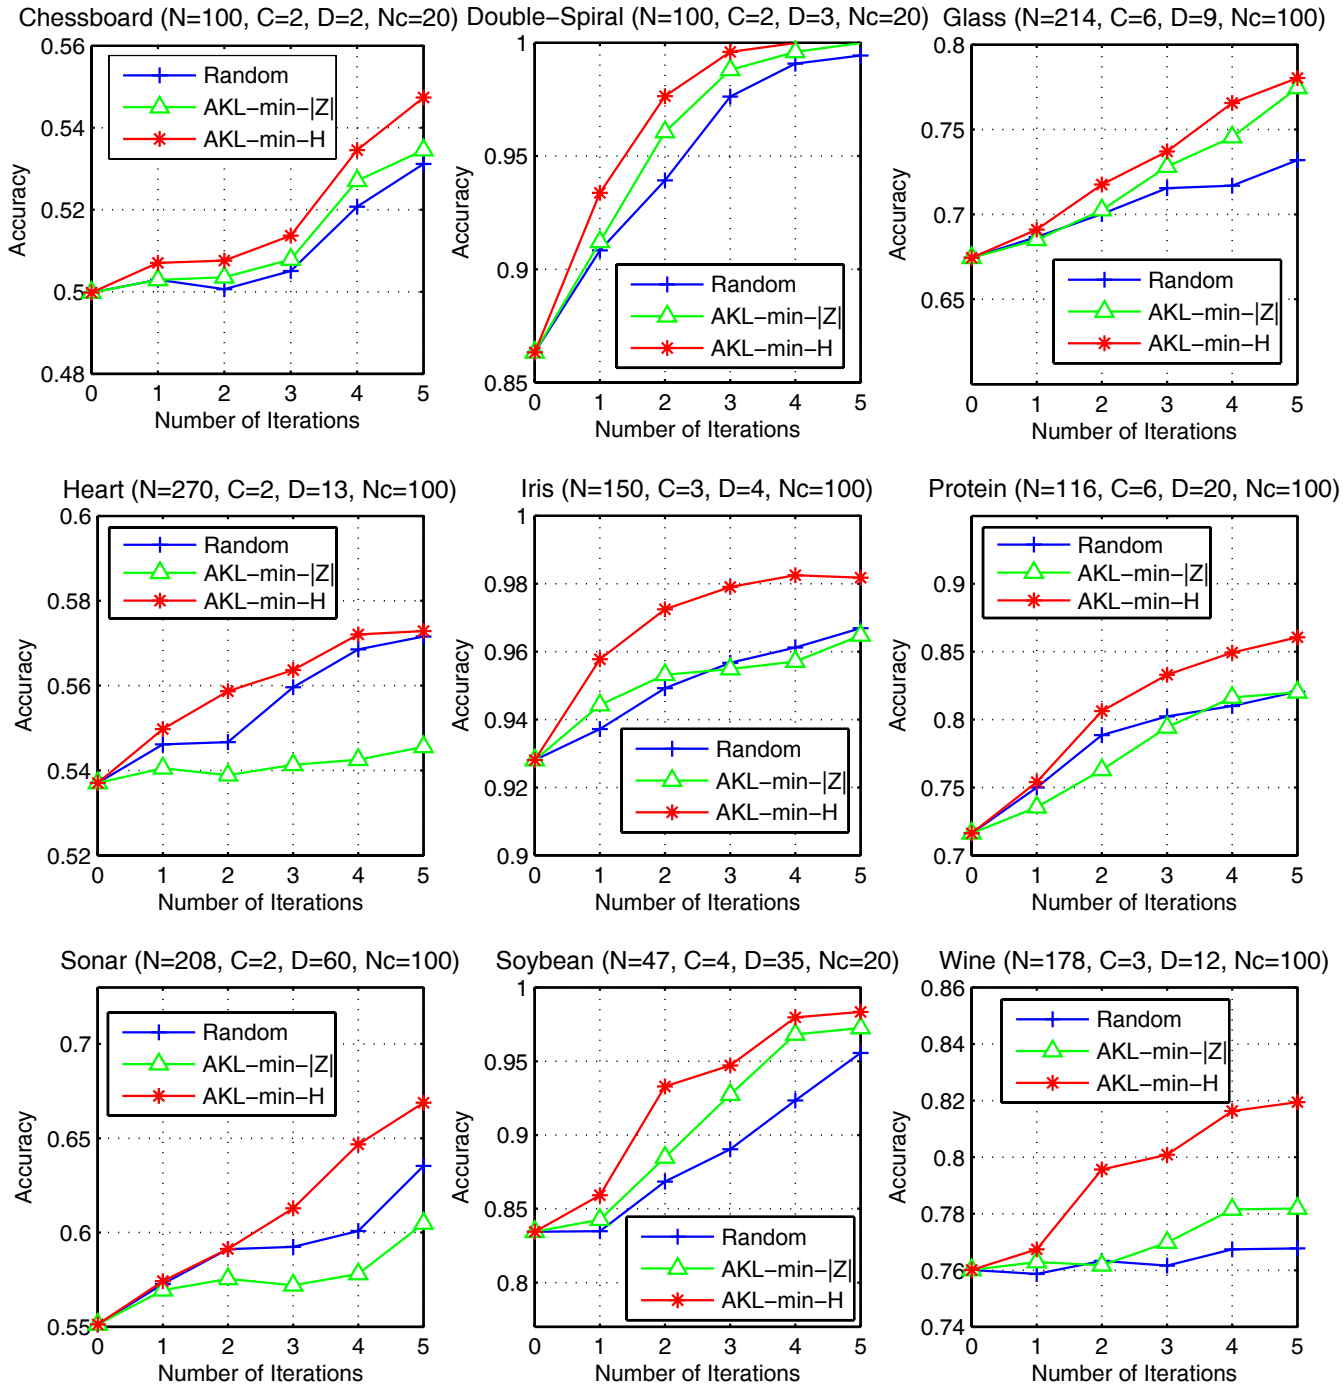

Figure 2. The clustering accuracy of different AKL methods for kernel k-means algorithms with nonparametric kernels learned from pairwise constraints. In each individual diagram, the three curves are respectively the random sampling method, the active kernel learning method for selecting pair examples with the least $|Z_{k,l}|$ (AKL-min-$|Z|$), and the active kernel learning method with minimal H values learned from our proposed algorithm (AKL-min-H). The details of the datasets are also shown in each diagram. In particular, N, C, D, and Nc respectively denote the dataset size, the number of classes, the number of features, and the number of initially sampling pairwise constraints. In each of the five iterations, 20 pair examples are sampled for labeling by the compared algorithms.

Hence, any feasible solution to (8) is also a feasible solution to (6), and (8) is a restricted version of (8), which leads to the conclusion that the optimal output value for (8) provides the upper bound for that of (6). □

Appendix C: Proof of Theorem 5

Proof. We first constructe the Lagrangian function for the above problem

$$\begin{aligned}\mathcal{L} = \mathrm{tr}(L^\top Z) &+ \frac{c}{2}\sum_{(i,j)\in\mathcal{T}}\eta_{i,j} + \frac{c}{2}\sum_{(k,l)\notin\mathcal{T}}\eta_{k,l} \\ &- \sum_{(i,j)\in\mathcal{T}} Q_{i,j}(T_{i,j}Z_{i,j} + \varepsilon_{i,j} - 1) \\ &- \sum_{(i,j)\in\mathcal{T}} (\alpha_{i,j}\eta_{i,j} + \tau_{i,j}/2 - 2\beta_{i,j}\varepsilon_{i,j}) - \mathrm{tr}(MZ) \\ &- \sum_{(k,l)\notin\mathcal{T}} s_{k,l}(h_{k,l} - 1) - \lambda\left(m^2 - \sum_{(k,l)\notin\mathcal{T}} h_{k,l}\right) \\ &- \sum_{(k,l)\notin\mathcal{T}} (\alpha_{k,l}\eta_{k,l} + \tau_{k,l}h_{k,l}/2 - 2\beta_{k,l}\varepsilon_{k,l}) \\ &- \sum_{(k,l)\notin\mathcal{T}} W_{k,l}Z_{k,l} + (\varepsilon_{k,l} - 1)|W_{k,l}|\end{aligned}$$

In the above, we introduce Lagrangian multiplier

$$\begin{pmatrix} \alpha_{i,j} & -\beta_{i,j} \\ -\beta_{i,j} & \tau_{i,j}/2 \end{pmatrix}$$

for constraints

$$\begin{pmatrix} \eta_{i,j} & \varepsilon_{i,j} \\ \varepsilon_{i,j} & 1 \end{pmatrix} \succeq 0 \text{ and } \begin{pmatrix} \eta_{k,l} & \varepsilon_{k,l} \\ \varepsilon_{k,l} & h_{k,l} \end{pmatrix} \succeq 0$$

By setting the derivative to be zero, we have

$$\begin{aligned}\max \quad & \sum_{(i,j)\in\mathcal{T}} \left(Q_{i,j} - \frac{\tau_{i,j}}{2}\right) + \sum_{(k,l)\notin\mathcal{T}} \left(|W_{k,l}| - \frac{\tau_{k,l}}{2}\right) \quad (13) \\ & -(m^2-1)\lambda \\ \text{s. t} \quad & L \succeq Q\otimes T + W\otimes\bar{T} \\ & \begin{pmatrix} c & -Q_{i,j} \\ -Q_{i,j} & \tau_{i,j} \end{pmatrix} \succeq 0, Q_{i,j} \geq 0,\ \forall (i,j)\in\mathcal{T} \\ & 0 \leq \tau_{k,l} \leq 2\lambda,\ \forall (k,l)\notin\mathcal{T} \\ & \begin{pmatrix} c & -|W_{k,l}| \\ -|W_{k,l}| & \tau_{k,l} \end{pmatrix} \succeq 0,\ \forall (k,l)\notin\mathcal{T}\end{aligned}$$

The two LMI constraints can be simplified as

$$\tau_{i,j} \geq 2Q_{i,j}^2/c, \quad \tau_{k,l} \geq 2Q_{k,l}^2/c$$

Substituting the above constraints into (13), we have (9). □

Abstract

In many applications, data appear with a huge number of instances as well as features. Linear Support Vector Machines (SVM) is one of the most popular tools to deal with such large-scale sparse data. This paper presents a novel dual coordinate descent method for linear SVM with L1- and L2-loss functions. The proposed method is simple and reaches an ϵ-accurate solution in $O(\log(1/\epsilon))$ iterations. Experiments indicate that our method is much faster than state of the art solvers such as Pegasos, TRON, SVM$^{\text{perf}}$, and a recent primal coordinate descent implementation.

1. Introduction

Support vector machines (SVM) (Boser et al., 1992) are useful for data classification. Given a set of instance-label pairs $(\boldsymbol{x}_i, y_i), i = 1, \ldots, l,\ \boldsymbol{x}_i \in R^n,\ y_i \in \{-1, +1\}$, SVM requires the solution of the following unconstrained optimization problem:

$$\min_{\boldsymbol{w}} \quad \frac{1}{2}\boldsymbol{w}^T\boldsymbol{w} + C\sum_{i=1}^{l}\xi(\boldsymbol{w}; \boldsymbol{x}_i, y_i), \tag{1}$$

where $\xi(\boldsymbol{w}; \boldsymbol{x}_i, y_i)$ is a loss function, and $C \geq 0$ is a penalty parameter. Two common loss functions are:

$$\max(1 - y_i\boldsymbol{w}^T\boldsymbol{x}_i, 0) \text{ and } \max(1 - y_i\boldsymbol{w}^T\boldsymbol{x}_i, 0)^2. \tag{2}$$

The former is called L1-SVM, while the latter is L2-SVM. In some applications, an SVM problem appears with a bias term b. One often deal with this term by appending each instance with an additional dimension:

$$\boldsymbol{x}_i^T \leftarrow [\boldsymbol{x}_i^T, 1] \qquad \boldsymbol{w}^T \leftarrow [\boldsymbol{w}^T, b]. \tag{3}$$

Problem (1) is often referred to as the primal form of SVM. One may instead solve its dual problem:

$$\begin{aligned} \min_{\boldsymbol{\alpha}} \quad & f(\boldsymbol{\alpha}) = \frac{1}{2}\boldsymbol{\alpha}^T\bar{Q}\boldsymbol{\alpha} - \boldsymbol{e}^T\boldsymbol{\alpha} \\ \text{subject to} \quad & 0 \leq \alpha_i \leq U, \forall i, \end{aligned} \tag{4}$$

where $\bar{Q} = Q + D$, D is a diagonal matrix, and $Q_{ij} = y_i y_j \boldsymbol{x}_i^T\boldsymbol{x}_j$. For L1-SVM, $U = C$ and $D_{ii} = 0,\ \forall i$. For L2-SVM, $U = \infty$ and $D_{ii} = 1/(2C),\ \forall i$.

An SVM usually maps training vectors into a high-dimensional space via a nonlinear function $\phi(\boldsymbol{x})$. Due to the high dimensionality of the vector variable $\boldsymbol{w}$, one solves the dual problem (4) by the kernel trick (i.e., using a closed form of $\phi(\boldsymbol{x}_i)^T\phi(\boldsymbol{x}_j)$). We call such a problem as a nonlinear SVM. In some applications, data appear in a rich dimensional feature space, the performances are similar with/without nonlinear mapping. If data are not mapped, we can often train much larger data sets. We indicate such cases as linear SVM; these are often encountered in applications such as document classification. In this paper, we aim at solving very large linear SVM problems.

Recently, many methods have been proposed for linear SVM in large-scale scenarios. For L1-SVM, Zhang (2004), Shalev-Shwartz et al. (2007), Bottou (2007) propose various stochastic gradient descent methods. Collins et al. (2008) apply an exponentiated gradient method. SVM$^{\text{perf}}$ (Joachims, 2006) uses a cutting plane technique. Smola et al. (2008) apply bundle methods, and view SVM$^{\text{perf}}$ as a special case. For L2-SVM, Keerthi and DeCoste (2005) propose modified Newton methods. A trust region Newton method (TRON) (Lin et al., 2008) is proposed for logistic re-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

gression and L2-SVM. These algorithms focus on different aspects of the training speed. Some aim at quickly obtaining a usable model, but some achieve fast final convergence of solving the optimization problem in (1) or (4). Moreover, among these methods, Joachims (2006), Smola et al. (2008) and Collins et al. (2008) solve SVM via the dual (4). Others consider the primal form (1). The decision of using primal or dual is of course related to the algorithm design.

Very recently, Chang et al. (2007) propose using coordinate descent methods for solving primal L2-SVM. Experiments show that their approach more quickly obtains a useful model than some of the above methods. Coordinate descent, a popular optimization technique, updates one variable at a time by minimizing a single-variable sub-problem. If one can efficiently solve this sub-problem, then it can be a competitive optimization method. Due to the non-differentiability of the primal L1-SVM, Chang et al's work is restricted to L2-SVM. Moreover, as primal L2-SVM is differentiable but not twice differentiable, certain considerations are needed in solving the single-variable sub-problem.

While the dual form (4) involves bound constraints $0 \le \alpha_i \le U$, its objective function is twice differentiable for both L1- and L2-SVM. In this paper, we investigate coordinate descent methods for the dual problem (4). We prove that an ϵ-optimal solution is obtained in $O(\log(1/\epsilon))$ iterations. We propose an implementation using a random order of sub-problems at each iteration, which leads to very fast training. Experiments indicate that our method is more efficient than the primal coordinate descent method. As Chang et al. (2007) solve the primal, they require the easy access of a feature's corresponding data values. However, in practice one often has an easier access of values per instance. Solving the dual takes this advantage, so our implementation is simpler than Chang et al. (2007).

Early SVM papers (Mangasarian & Musicant, 1999; Friess et al., 1998) have discussed coordinate descent methods for the SVM dual form. However, they do not focus on large data using the linear kernel. Crammer and Singer (2003) proposed an online setting for multi-class SVM without considering large sparse data. Recently, Bordes et al. (2007) applied a coordinate descent method to multi-class SVM, but they focus on nonlinear kernels. In this paper, we point out that *dual coordinate descent methods make crucial advantage of the linear kernel and outperform other solvers when the numbers of data and features are both large.*

Coordinate descent methods for (4) are related to the popular decomposition methods for training nonlinear SVM. In this paper, we show their key differences and explain why earlier studies on decomposition methods failed to modify their algorithms in an efficient way like ours for large-scale linear SVM. We also discuss the connection to other linear SVM works such as (Crammer & Singer, 2003; Collins et al., 2008; Shalev-Shwartz et al., 2007).

This paper is organized as follows. In Section 2, we describe our proposed algorithm. Implementation issues are investigated in Section 3. Section 4 discusses the connection to other methods. In Section 5, we compare our method with state of the art implementations for large linear SVM. Results show that the new method is more efficient. Proofs can be found at `http://www.csie.ntu.edu.tw/~cjlin/papers/cddual.pdf`.

2. A Dual Coordinate Descent Method

In this section, we describe our coordinate descent method for L1- and L2-SVM. The optimization process starts from an initial point $\boldsymbol{\alpha}^0 \in R^l$ and generates a sequence of vectors $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty}$. We refer to the process from $\boldsymbol{\alpha}^k$ to $\boldsymbol{\alpha}^{k+1}$ as an outer iteration. In each outer iteration we have l inner iterations, so that sequentially $\alpha_1, \alpha_2, \ldots, \alpha_l$ are updated. Each outer iteration thus generates vectors $\boldsymbol{\alpha}^{k,i} \in R^l$, $i = 1, \ldots, l+1$, such that $\boldsymbol{\alpha}^{k,1} = \boldsymbol{\alpha}^k$, $\boldsymbol{\alpha}^{k,l+1} = \boldsymbol{\alpha}^{k+1}$, and

$$\boldsymbol{\alpha}^{k,i} = [\alpha_1^{k+1}, \ldots, \alpha_{i-1}^{k+1}, \alpha_i^k, \ldots, \alpha_l^k]^T, \ \forall i = 2, \ldots, l.$$

For updating $\boldsymbol{\alpha}^{k,i}$ to $\boldsymbol{\alpha}^{k,i+1}$, we solve the following one-variable sub-problem:

$$\min_d \ f(\boldsymbol{\alpha}^{k,i} + d\boldsymbol{e}_i) \quad \text{subject to} \quad 0 \le \alpha_i^k + d \le U, \quad (5)$$

where $\boldsymbol{e}_i = [0, \ldots, 0, 1, 0, \ldots, 0]^T$. The objective function of (5) is a simple quadratic function of d:

$$f(\boldsymbol{\alpha}^{k,i} + d\boldsymbol{e}_i) = \frac{1}{2}\bar{Q}_{ii}d^2 + \nabla_i f(\boldsymbol{\alpha}^{k,i})d + \text{constant}, \quad (6)$$

where $\nabla_i f$ is the ith component of the gradient ∇f. One can easily see that (5) has an optimum at $d = 0$ (i.e., no need to update α_i) if and only if

$$\nabla_i^P f(\boldsymbol{\alpha}^{k,i}) = 0, \quad (7)$$

where $\nabla^P f(\boldsymbol{\alpha})$ means the projected gradient

$$\nabla_i^P f(\boldsymbol{\alpha}) = \begin{cases} \nabla_i f(\boldsymbol{\alpha}) & \text{if } 0 < \alpha_i < U, \\ \min(0, \nabla_i f(\boldsymbol{\alpha})) & \text{if } \alpha_i = 0, \\ \max(0, \nabla_i f(\boldsymbol{\alpha})) & \text{if } \alpha_i = U. \end{cases} \quad (8)$$

If (7) holds, we move to the index $i+1$ without updating $\alpha_i^{k,i}$. Otherwise, we must find the optimal solution of (5). If $\bar{Q}_{ii} > 0$, easily the solution is:

$$\alpha_i^{k,i+1} = \min\left(\max\left(\alpha_i^{k,i} - \frac{\nabla_i f(\boldsymbol{\alpha}^{k,i})}{\bar{Q}_{ii}}, 0\right), U\right). \quad (9)$$

Algorithm 1 A dual coordinate descent method for Linear SVM

- Given $\boldsymbol{\alpha}$ and the corresponding $\boldsymbol{w} = \sum_i y_i \alpha_i \boldsymbol{x}_i$.
- While $\boldsymbol{\alpha}$ is not optimal

  For $i = 1, \ldots, l$

  (a) $\bar{\alpha}_i \leftarrow \alpha_i$

  (b) $G = y_i \boldsymbol{w}^T \boldsymbol{x}_i - 1 + D_{ii}\alpha_i$

  (c)
  $$PG = \begin{cases} \min(G, 0) & \text{if } \alpha_i = 0, \\ \max(G, 0) & \text{if } \alpha_i = U, \\ G & \text{if } 0 < \alpha_i < U \end{cases}$$

  (d) If $|PG| \neq 0$,
  $\alpha_i \leftarrow \min(\max(\alpha_i - G/\bar{Q}_{ii}, 0), U)$
  $\boldsymbol{w} \leftarrow \boldsymbol{w} + (\alpha_i - \bar{\alpha}_i) y_i \boldsymbol{x}_i$

We thus need to calculate $\bar{Q}_{ii}$ and $\nabla_i f(\boldsymbol{\alpha}^{k,i})$. First, $\bar{Q}_{ii} = \boldsymbol{x}_i^T \boldsymbol{x}_i + D_{ii}$ can be precomputed and stored in the memory. Second, to evaluate $\nabla_i f(\boldsymbol{\alpha}^{k,i})$, we use

$$\nabla_i f(\boldsymbol{\alpha}) = (\bar{Q}\boldsymbol{\alpha})_i - 1 = \sum_{j=1}^{l} \bar{Q}_{ij}\alpha_j - 1. \qquad (10)$$

$\bar{Q}$ may be too large to be stored, so one calculates $\bar{Q}$'s ith row when doing (10). If $\bar{n}$ is the average number of nonzero elements per instance, and $O(\bar{n})$ is needed for each kernel evaluation, then calculating the ith row of the kernel matrix takes $O(l\bar{n})$. Such operations are expensive. However, for a linear SVM, we can define

$$\boldsymbol{w} = \sum_{j=1}^{l} y_j \alpha_j \boldsymbol{x}_j, \qquad (11)$$

so (10) becomes

$$\nabla_i f(\boldsymbol{\alpha}) = y_i \boldsymbol{w}^T \boldsymbol{x}_i - 1 + D_{ii}\alpha_i. \qquad (12)$$

To evaluate (12), the main cost is $O(\bar{n})$ for calculating $\boldsymbol{w}^T \boldsymbol{x}_i$. This is much smaller than $O(l\bar{n})$. To apply (12), $\boldsymbol{w}$ must be maintained throughout the coordinate descent procedure. Calculating $\boldsymbol{w}$ by (11) takes $O(l\bar{n})$ operations, which are too expensive. Fortunately, if $\bar{\alpha}_i$ is the current value and α_i is the value after the updating, we can maintain $\boldsymbol{w}$ by

$$\boldsymbol{w} \leftarrow \boldsymbol{w} + (\alpha_i - \bar{\alpha}_i) y_i \boldsymbol{x}_i. \qquad (13)$$

The number of operations is only $O(\bar{n})$. To have the first $\boldsymbol{w}$, one can use $\boldsymbol{\alpha}^0 = \boldsymbol{0}$ so $\boldsymbol{w} = \boldsymbol{0}$. In the end, we obtain the optimal $\boldsymbol{w}$ of the primal problem (1) as the primal-dual relationship implies (11).

If $\bar{Q}_{ii} = 0$, we have $D_{ii} = 0$, $Q_{ii} = \boldsymbol{x}_i^T \boldsymbol{x}_i = 0$, and hence $\boldsymbol{x}_i = \boldsymbol{0}$. This occurs only in L1-SVM without the bias term by (3). From (12), if $\boldsymbol{x}_i = \boldsymbol{0}$, then $\nabla_i f(\boldsymbol{\alpha}^{k,i}) = -1$. As $U = C < \infty$ for L1-SVM, the solution of (5) makes the new $\alpha_i^{k,i+1} = U$. We can easily include this case in (9) by setting $1/\bar{Q}_{ii} = \infty$.

Briefly, our algorithm uses (12) to compute $\nabla_i f(\boldsymbol{\alpha}^{k,i})$, checks the optimality of the sub-problem (5) by (7), updates α_i by (9), and then maintains $\boldsymbol{w}$ by (13). A description is in Algorithm 1. The cost per iteration (i.e., from $\boldsymbol{\alpha}^k$ to $\boldsymbol{\alpha}^{k+1}$) is $O(l\bar{n})$. The main memory requirement is on storing $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_l$. For the convergence, we prove the following theorem using techniques in (Luo & Tseng, 1992):

Theorem 1 *For L1-SVM and L2-SVM, $\{\boldsymbol{\alpha}^{k,i}\}$ generated by Algorithm 1 globally converges to an optimal solution $\boldsymbol{\alpha}^*$. The convergence rate is at least linear: there are $0 < \mu < 1$ and an iteration k_0 such that*

$$f(\boldsymbol{\alpha}^{k+1}) - f(\boldsymbol{\alpha}^*) \leq \mu(f(\boldsymbol{\alpha}^k) - f(\boldsymbol{\alpha}^*)), \forall k \geq k_0. \quad (14)$$

The global convergence result is quite remarkable. Usually for a convex but not strictly convex problem (e.g., L1-SVM), one can only obtain that any limit point is optimal. We define an ϵ-accurate solution $\boldsymbol{\alpha}$ if $f(\boldsymbol{\alpha}) \leq f(\boldsymbol{\alpha}^*) + \epsilon$. By (14), our algorithm obtains an ϵ-accurate solution in $O(\log(1/\epsilon))$ iterations.

3. Implementation Issues

3.1. Random Permutation of Sub-problems

In Algorithm 1, the coordinate descent algorithm solves the one-variable sub-problems in the order of $\alpha_1, \ldots, \alpha_l$. Past results such as (Chang et al., 2007) show that solving sub-problems in an arbitrary order may give faster convergence. This inspires us to randomly permute the sub-problems at each outer iteration. Formally, at the kth outer iteration, we permute $\{1, \ldots, l\}$ to $\{\pi(1), \ldots, \pi(l)\}$, and solve sub-problems in the order of $\alpha_{\pi(1)}, \alpha_{\pi(2)}, \ldots, \alpha_{\pi(l)}$. Similar to Algorithm 1, the algorithm generates a sequence $\{\boldsymbol{\alpha}^{k,i}\}$ such that $\boldsymbol{\alpha}^{k,1} = \boldsymbol{\alpha}^k$, $\boldsymbol{\alpha}^{k,l+1} = \boldsymbol{\alpha}^{k+1,1}$ and

$$\alpha_t^{k,i} = \begin{cases} \alpha_t^{k+1} & \text{if } \pi_k^{-1}(t) < i, \\ \alpha_t^k & \text{if } \pi_k^{-1}(t) \geq i. \end{cases}$$

The update from $\boldsymbol{\alpha}^{k,i}$ to $\boldsymbol{\alpha}^{k,i+1}$ is by

$$\alpha_t^{k,i+1} = \alpha_t^{k,i} + \arg\min_{0 \leq \alpha_t^{k,i} + d \leq U} f(\boldsymbol{\alpha}^{k,i} + d\boldsymbol{e}_t) \text{ if } \pi_k^{-1}(t) = i.$$

We prove that Theorem 1 is still valid. Hence, the new setting obtains an ϵ-accurate solution in $O(\log(1/\epsilon))$ iterations. A simple experiment reveals that this setting of permuting sub-problems is much faster than Algorithm 1. The improvement is also bigger than that observed in (Chang et al., 2007) for primal coordinate descent methods.

Algorithm 2 Coordinate descent algorithm with randomly selecting one instance at a time

- Given $\boldsymbol{\alpha}$ and the corresponding $\boldsymbol{w} = \sum_i y_i \alpha_i \boldsymbol{x}_i$.
- While $\boldsymbol{\alpha}$ is not optimal
  - Randomly choose $i \in \{1, \ldots, l\}$.
  - Do steps (a)-(d) of Algorithm 1 to update α_i.

3.2. Shrinking

Eq. (4) contains constraints $0 \le \alpha_i \le U$. If an α_i is 0 or U for many iterations, it may remain the same. To speed up decomposition methods for nonlinear SVM (discussed in Section 4.1), the shrinking technique (Joachims, 1998) reduces the size of the optimization problem without considering some bounded variables. Below we show it is much easier to apply this technique to linear SVM than the nonlinear case.

If A is the subset after removing some elements and $\bar{A} = \{1, \ldots, l\} \setminus A$, then the new problem is

$$\begin{aligned} \min_{\boldsymbol{\alpha}_A} \quad & \frac{1}{2}\boldsymbol{\alpha}_A^T \bar{Q}_{AA}\boldsymbol{\alpha}_A + (\bar{Q}_{A\bar{A}}\boldsymbol{\alpha}_{\bar{A}} - \boldsymbol{e}_A)^T\boldsymbol{\alpha}_A \\ \text{subject to} \quad & 0 \le \alpha_i \le U, i \in A, \end{aligned} \tag{15}$$

where $\bar{Q}_{AA}, \bar{Q}_{A\bar{A}}$ are sub-matrices of $\bar{Q}$, and $\boldsymbol{\alpha}_{\bar{A}}$ is considered as a constant vector. Solving this smaller problem consumes less time and memory. Once (15) is solved, we must check if the vector $\boldsymbol{\alpha}$ is optimal for (4). This check needs the whole gradient $\nabla f(\boldsymbol{\alpha})$. Since

$$\nabla_i f(\boldsymbol{\alpha}) = \bar{Q}_{i,A}\boldsymbol{\alpha}_A + \bar{Q}_{i,\bar{A}}\boldsymbol{\alpha}_{\bar{A}} - 1,$$

if $i \in A$, and one stores $\bar{Q}_{i,\bar{A}}\boldsymbol{\alpha}_{\bar{A}}$ before solving (15), we already have $\nabla_i f(\boldsymbol{\alpha})$. However, for all $i \notin A$, we must calculate the corresponding rows of $\bar{Q}$. This step, referred to as the reconstruction of gradients in training nonlinear SVM, is very time consuming. It may cost up to $O(l^2\bar{n})$ if each kernel evaluation is $O(\bar{n})$.

For linear SVM, in solving the smaller problem (15), we still have the vector

$$\boldsymbol{w} = \sum\nolimits_{i\in A} y_i\alpha_i\boldsymbol{x}_i + \sum\nolimits_{i\in\bar{A}} y_i\alpha_i\boldsymbol{x}_i$$

though only the first part $\sum_{i\in A} y_i\alpha_i\boldsymbol{x}_i$ is updated. Therefore, using (12), $\nabla f(\boldsymbol{\alpha})$ is easily available. Below we demonstrate a shrinking implementation so that reconstructing the whole $\nabla f(\boldsymbol{\alpha})$ is never needed.

Our method is related to what LIBSVM (Chang & Lin, 2001) uses. From the optimality condition of bound-constrained problems, $\boldsymbol{\alpha}$ is optimal for (4) if and only if $\nabla^P f(\boldsymbol{\alpha}) = \boldsymbol{0}$, where $\nabla^P f(\boldsymbol{\alpha})$ is the projected gradient defined in (8). We then prove the following result:

Theorem 2 *Let $\boldsymbol{\alpha}^*$ be the convergent point of $\{\boldsymbol{\alpha}^{k,i}\}$.*

1. *If $\alpha_i^* = 0$ and $\nabla_i f(\boldsymbol{\alpha}^*) > 0$, then $\exists k_i$ such that $\forall k \ge k_i,\ \forall s, \alpha_i^{k,s} = 0$.*
2. *If $\alpha_i^* = U$ and $\nabla_i f(\boldsymbol{\alpha}^*) < 0$, then $\exists k_i$ such that $\forall k \ge k_i,\ \forall s,\ \alpha_i^{k,s} = U$.*
3. $\lim_{k\to\infty} \max_j \nabla_j^P f(\boldsymbol{\alpha}^{k,j}) = \lim_{k\to\infty} \min_j \nabla_j^P f(\boldsymbol{\alpha}^{k,j}) = 0$.

During the optimization procedure, $\nabla^P f(\boldsymbol{\alpha}^k) \ne \boldsymbol{0}$, so in general $\max_j \nabla_j^P f(\boldsymbol{\alpha}^k) > 0$ and $\min_j \nabla_j^P f(\boldsymbol{\alpha}^k) < 0$. These two values measure how the current solution violates the optimality condition. In our iterative procedure, what we have are $\nabla_i f(\boldsymbol{\alpha}^{k,i}),\ i = 1, \ldots, l$. Hence, at the $(k-1)$st iteration, we obtain

$$M^{k-1} \equiv \max_j \nabla_j^P f(\boldsymbol{\alpha}^{k-1,j}), m^{k-1} \equiv \min_j \nabla_j^P f(\boldsymbol{\alpha}^{k-1,j}).$$

Then at each inner step of the kth iteration, before updating $\alpha_i^{k,i}$ to $\alpha_i^{k,i+1}$, this element is shrunken if one of the following two conditions holds:

$$\begin{aligned} &\alpha_i^{k,i} = 0 \text{ and } \nabla_i f(\boldsymbol{\alpha}^{k,i}) > \bar{M}^{k-1}, \\ &\alpha_i^{k,i} = U \text{ and } \nabla_i f(\boldsymbol{\alpha}^{k,i}) < \bar{m}^{k-1}, \end{aligned} \tag{16}$$

where

$$\bar{M}^{k-1} = \begin{cases} M^{k-1} & \text{if } M^{k-1} > 0, \\ \infty & \text{otherwise,} \end{cases}$$

$$\bar{m}^{k-1} = \begin{cases} m^{k-1} & \text{if } m^{k-1} < 0 \\ -\infty & \text{otherwise.} \end{cases}$$

In (16), $\bar{M}^{k-1}$ must be strictly positive, so we set it be ∞ if $M^{k-1} = 0$. From Theorem 2, elements satisfying the "if condition" of properties 1 and 2 meet (16) after certain iterations, and are then correctly removed for optimization. To have a more aggressive shrinking, one may multiply both $\bar{M}^{k-1}$ and $\bar{m}^{k-1}$ in (16) by a threshold smaller than one.

Property 3 of Theorem 2 indicates that with a tolerance ϵ,

$$M^k - m^k < \epsilon \tag{17}$$

is satisfied after a finite number of iterations. Hence (17) is a valid stopping condition. We also use it for smaller problems (15). If at the kth iteration, (17) for (15) is reached, we enlarge A to $\{1, \ldots, l\}$, set $\bar{M}^k = \infty, \bar{m}^k = -\infty$ (so no shrinking at the $(k+1)$st iteration), and continue regular iterations. Thus, we do shrinking without reconstructing gradients.

3.3. An Online Setting

In some applications, the number of instances is huge, so going over all $\alpha_1, \ldots, \alpha_l$ causes an expensive outer iteration. Instead, one can randomly choose an index i_k at a time, and update only α_{i_k} at the kth outer iteration. A description is in Algorithm 2. The setting is related to (Crammer & Singer, 2003; Collins et al., 2008). See also the discussion in Section 4.2.

Table 1. A comparison between decomposition methods (Decomp.) and dual coordinate descent (DCD). For both methods, we consider that one α_i is updated at a time. We assume Decomp. maintains gradients, but DCD does not. The average number of nonzeros per instance is $\bar{n}$.

	Nonlinear SVM		Linear SVM	
	Decomp.	DCD	Decomp.	DCD
Update α_i	$O(1)$	$O(l\bar{n})$	$O(1)$	$O(\bar{n})$
Maintain $\nabla f(\boldsymbol{\alpha})$	$O(l\bar{n})$	NA	$O(l\bar{n})$	NA

4. Relations with Other Methods

4.1. Decomposition Methods for Nonlinear SVM

Decomposition methods are one of the most popular approaches for training nonlinear SVM. As the kernel matrix is dense and cannot be stored in the computer memory, decomposition methods solve a sub-problem of few variables at each iteration. Only a small number of corresponding kernel columns are needed, so the memory problem is resolved. If the number of variables is restricted to one, a decomposition method is like the online coordinate descent in Section 3.3, but it differs in the way it selects variables for updating. It has been shown (Keerthi & DeCoste, 2005) that, for linear SVM decomposition methods are inefficient. On the other hand, here we are pointing out that dual coordinate descent is efficient for linear SVM. Therefore, it is important to discuss the relationship between decomposition methods and our method.

In early decomposition methods that were first proposed (Osuna et al., 1997; Platt, 1998), variables minimized at an iteration are selected by certain heuristics. However, subsequent developments (Joachims, 1998; Chang & Lin, 2001; Keerthi et al., 2001) all use gradient information to conduct the selection. The main reason is that maintaining the whole gradient does not introduce extra cost. Here we explain the detail by assuming that one variable of $\boldsymbol{\alpha}$ is chosen and updated at a time[1]. To set-up and solve the sub-problem (6), one uses (10) to calculate $\nabla_i f(\boldsymbol{\alpha})$. If $O(\bar{n})$ effort is needed for each kernel evaluation, obtaining the ith row of the kernel matrix takes $O(l\bar{n})$ effort. If instead one maintains the whole gradient, then $\nabla_i f(\boldsymbol{\alpha})$ is directly available. After updating $\alpha_i^{k,i}$ to $\alpha_i^{k,i+1}$, we obtain $\bar{Q}$'s ith column (same as the ith row due to the symmetry of $\bar{Q}$), and calculate the new whole gradient:

$$\nabla f(\boldsymbol{\alpha}^{k,i+1}) = \nabla f(\boldsymbol{\alpha}^{k,i}) + \bar{Q}_{:,i}(\alpha_i^{k,i+1} - \alpha_i^{k,i}), \quad (18)$$

where $\bar{Q}_{:,i}$ is the ith column of $\bar{Q}$. The cost is $O(l\bar{n})$ for $\bar{Q}_{:,i}$ and $O(l)$ for (18). Therefore, maintaining the whole gradient does not cost more. As using the whole gradient implies fewer iterations (i.e., faster convergence due to the ability to choose for updating the variable that violates optimality most), one should take this advantage. However, the situation for linear SVM is very different. With the different way (12) to calculate $\nabla_i f(\boldsymbol{\alpha})$, the cost to update one α_i is only $O(\bar{n})$. If we still maintain the whole gradient, evaluating (12) l times takes $O(l\bar{n})$ effort. We gather this comparison of different situations in Table 1. Clearly, for nonlinear SVM, one should use decomposition methods by maintaining the whole gradient. However, for linear SVM, if l is large, the cost per iteration without maintaining gradients is much smaller than that with. Hence, the coordinate descent method can be faster than the decomposition method by using many cheap iterations.

An earlier attempt to speed up decomposition methods for linear SVM is (Kao et al., 2004). However, it failed to derive our method here because it does not give up maintaining gradients.

[1]Solvers like LIBSVM update at least two variables due to a linear constraint in their dual problems. Here (4) has no such a constraint, so selecting one variable is possible.

4.2. Existing Linear SVM Methods

We discussed in Section 1 and other places the difference between our method and a primal coordinate descent method (Chang et al., 2007). Below we describe the relations with other linear SVM methods.

We mentioned in Section 3.3 that our Algorithm 2 is related to the online mode in (Collins et al., 2008). They aim at solving multi-class and structured problems. At each iteration an instance is used; then a sub-problem of several variables is solved. They approximately minimize the sub-problem, but for two-class case, one can exactly solve it by (9). For the batch setting, our approach is different from theirs. The algorithm for multi-class problems in (Crammer & Singer, 2003) is also similar to our online setting. For the two-class case, it solves (1) with the loss function $\max(-y_i \boldsymbol{w}^T \boldsymbol{x}_i, 0)$, which is different from (2). They do not study data with a large number of features.

Next, we discuss the connection to stochastic gradient descent (Shalev-Shwartz et al., 2007; Bottou, 2007). The most important step of this method is the following update of $\boldsymbol{w}$:

$$\boldsymbol{w} \leftarrow \boldsymbol{w} - \eta \nabla_{\boldsymbol{w}}(y_i, \boldsymbol{x}_i), \quad (19)$$

where $\nabla_{\boldsymbol{w}}(y_i, \boldsymbol{x}_i)$ is the sub-gradient of the approximate objective function:

$$\boldsymbol{w}^T \boldsymbol{w}/2 + C \max(1 - y_i \boldsymbol{w}^T \boldsymbol{x}_i, 0),$$

and η is the learning rate (or the step size). While our method is dual-based, throughout the iterations we

Table 2. On the right training time for a solver to reduce the primal objective value to within 1% of the optimal value; see (20). Time is in seconds. The method with the shortest running time is boldfaced. Listed on the left are the statistics of data sets: l is the number of instances and n is the number of features.

Data set	Data statistics			Linear L1-SVM			Linear L2-SVM		
	l	n	# nonzeros	DCDL1	Pegasos	SVM$^{\text{perf}}$	DCDL2	PCD	TRON

maintain $\boldsymbol{w}$ by (13). Both (13) and (19) use one single instance $\boldsymbol{x}_i$, but they take different directions $y_i\boldsymbol{x}_i$ and $\nabla_{\boldsymbol{w}}(y_i, \boldsymbol{x}_i)$. The selection of the learning rate η may be the subtlest thing in stochastic gradient descent, but for our method this is never a concern. The step size $(\alpha_i - \bar{\alpha}_i)$ in (13) is governed by solving a sub-problem from the dual.

5. Experiments

In this section, we analyze the performance of our dual coordinate descent algorithm for L1- and L2-SVM. We compare our implementation with state of the art linear SVM solvers. We also investigate how the shrinking technique improves our algorithm.

Table 2 lists the statistics of data sets. Four of them (a9a, real-sim, news20, rcv1) are at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets`. The set astro-physic is available upon request from Thorsten Joachims. Except a9a, all others are from document classification. Past results show that linear SVM performs as well as kernelized ones for such data. To estimate the testing accuracy, we use a stratified selection to split each set to 4/5 training and 1/5 testing. We briefly describe each set below. Details can be found in (Joachims, 2006) (astro-physic) and (Lin et al., 2008) (others). a9a is from the UCI "adult" data set. real-sim includes Usenet articles. astro-physic includes documents from Physics Arxiv. news20 is a collection of news documents. yahoo-japan and yahoo-korea are obtained from Yahoo!. rcv1 is an archive of manually categorized newswire stories from Reuters.

We compare six implementations of linear SVM. Three solve L1-SVM, and three solve L2-SVM.

DCDL1 and DCDL2: the dual coordinate descent method with sub-problems permuted at each outer iteration (see Section 3.1). DCDL1 solves L1-SVM while DCDL2 solves L2-SVM. We *omit the shrinking setting.*

Pegasos: the primal estimated sub-gradient solver (Shalev-Shwartz et al., 2007) for L1-SVM. The source is at `http://ttic.uchicago.edu/~shai/code`.

SVM$^{\text{perf}}$ (Joachims, 2006): a cutting plane method for L1-SVM. We use the latest version 2.1. The source is at `http://svmlight.joachims.org/svm_perf.html`.

TRON: a trust region Newton method (Lin et al., 2008) for L2-SVM. We use the software LIBLINEAR version 1.22 with option `-s 2` (`http://www.csie.ntu.edu.tw/~cjlin/liblinear`).

PCD: a primal coordinate descent method for L2-SVM (Chang et al., 2007).

Since (Bottou, 2007) is related to Pegasos, we do not present its results. We do not compare with another online method Vowpal Wabbit (Langford et al., 2007) either as it has been made available only very recently. Though a code for the bundle method (Smola et al., 2008) is available, we do not include it for comparison due to its closeness to SVM$^{\text{perf}}$. All sources used for our comparisons are available at `http://csie.ntu.edu.tw/~cjlin/liblinear/exp.html`.

We set the penalty parameter $C = 1$ for comparison[2]. For all data sets, the testing accuracy does not increase after $C \geq 4$. All the above methods are implemented in C/C++ with double precision. Some implementations such as (Bottou, 2007) use single precision to reduce training time, but numerical inaccuracy may occur. We do not include the bias term by (3).

To compare these solvers, we consider the CPU time of reducing the relative difference between the primal objective value and the optimum to within 0.01:

$$|f^P(\boldsymbol{w}) - f^P(\boldsymbol{w}^*)|/|f^P(\boldsymbol{w}^*)| \leq 0.01, \qquad (20)$$

where f^P is the objective function of (1), and $f^P(\boldsymbol{w}^*)$ is the optimal value. Note that for consistency, we use primal objective values even for dual solvers. The reference solutions of L1- and L2-SVM are respectively obtained by solving DCDL1 and DCDL2 until the duality gaps are less than 10^{-6}. Table 2 lists the results. Clearly, our dual coordinate descent method

[2]The equivalent setting for Pegasos is $\lambda = 1/(Cl)$. For SVM$^{\text{perf}}$, its penalty parameter is $C_{perf} = 0.01Cl$.

Figure 2. Time versus the difference of testing accuracy between the current model and the reference model (obtained using strict stopping conditions). Time is in seconds.

for both L1- and L2-SVM is significantly faster than other solvers. To check details, we choose astro-physic, news20, rcv1, and show the relative error along time in Figure 1. In Section 3.2, we pointed out that the shrinking technique is very suitable for DCD. In Figure 1, we also include them (DCDL1-S and DCDL2-S) for comparison. Like in Table 2, our solvers are efficient for both L1- and L2-SVM. With shrinking, its performance is even better.

Another evaluation is to consider how fast a solver obtains a model with reasonable testing accuracy. Using the optimal solutions from the above experiment, we generate the reference models for L1- and L2-SVM. We evaluate the testing accuracy difference between the current model and the reference model along the training time. Figure 2 shows the results. Overall, DCDL1 and DCDL2 are more efficient than other solvers. Note that we omit DCDL1-S and DCDL2-S in Figure 2, as the performances with/without shrinking are similar.

Among L1-SVM solvers, SVM$^{\text{perf}}$ is competitive with Pegasos for small data. But in the case of a huge number of instances, Pegasos outperforms SVM$^{\text{perf}}$. However, Pegasos has slower convergence than DCDL1. As discussed in Section 4.2, the learning rate of stochastic gradient descent may be the cause, but for DCDL1 we exactly solve sub-problems to obtain the step size in updating $\boldsymbol{w}$. Also, Pegasos has a jumpy test set performance while DCDL1 gives a stable behavior.

In the comparison of L2-SVM solvers, DCDL2 and PCD are both coordinate descent methods. The former one is applied to the dual, but the latter one to the primal. DCDL2 has a closed form solution for each sub-problem, but PCD has not. The cost per PCD outer iteration is thus higher than that of DCDL2. Therefore, while PCD is very competitive (only second to DCDL1/DCDL2 in Table 2), DCDL2 is even better. Regarding TRON, as a Newton method, it possesses fast final convergence. However, since it takes significant effort at each iteration, it hardly generates a reasonable model quickly. From the experiment results, DCDL2 converges as fast as TRON, but also performs well in early iterations.

Due to the space limitation, we give the following observations without details. First, Figure 1 indicates that our coordinate descent method converges faster for L2-SVM than L1-SVM. As L2-SVM has the diagonal matrix D with $D_{ii} = 1/(2C)$, we suspect that its $\bar{Q}$ is better conditioned, and hence leads to faster convergence. Second, all methods have slower convergence when C is large. However, small C's are usually enough as the accuracy is stable after a threshold. In practice, one thus should try from a small C. More-

over, if $n \ll l$ and C is too large, then our DCDL2 is slower than TRON or PCD (see problem a9a in Table 2, where the accuracy does not change after $C \geq 0.25$). If $n \ll l$, clearly one should solve the primal, whose number of variables is just n. Such data are not our focus. Indeed, with a small number of features, one usually maps data to a higher space and train a nonlinear SVM. Third, we have checked the online Algorithm 2. Its performance is similar to DCDL1 and DCDL2 (i.e., batch setting without shrinking). Fourth, we have investigated real document classification which involves many two-class problems. Using the proposed method as the solver is more efficient than using others.

6. Discussion and Conclusions

We can apply the proposed method to solve regularized least square problems, which have the loss function $(1-y_i \boldsymbol{w}^T \boldsymbol{x}_i)^2$ in (1). The dual is simply (4) without constraints, so the implementation is simpler.

In summary, we present and analyze an efficient dual coordinate decent method for large linear SVM. It is very simple to implement, and possesses sound optimization properties. Experiments show that our method is faster than state of the art implementations.

Abstract

Markov logic networks (MLNs) are an expressive representation for statistical relational learning that generalizes both first-order logic and graphical models. Existing methods for learning the logical structure of an MLN are not discriminative; however, many relational learning problems involve specific target predicates that must be inferred from given background information. We found that existing MLN methods perform very poorly on several such ILP benchmark problems, and we present improved discriminative methods for learning MLN clauses and weights that outperform existing MLN and traditional ILP methods.

1. Introduction

Statistical relational learning (SRL) concerns the induction of probabilistic knowledge that supports accurate prediction for multi-relational structured data (Getoor & Taskar, 2007). Markov Logic Networks (MLNs) are a recently developed SRL model that generalizes both full first-order logic and Markov networks (Richardson & Domingos, 2006). An MLN is represented as a set of weighted clauses in first-order logic, and learning an MLN decomposes into *structure learning*, learning the logical clauses, and *parameter learning*, setting the weight of each clause. Existing structure-learning algorithms for MLNs (Kok & Domingos, 2005; Mihalkova & Mooney, 2007) are non-discriminative and attempt to learn a set of clauses that is equally capable of predicting the truth value of all predicates given an arbitrary set of evidence. However, in many learning problems, there is a specific *target predicate* that must be inferred given evidence data about other *background predicates* used to describe the input data. Most traditional *Inductive Logic Programming* (ILP) methods focus on discriminative relational learning (Dzeroski, 2007); however, they do not address the issue of uncertainty. Discriminative methods have been developed for parameter learning in MLNs (Singla & Domingos, 2005; Lowd & Domingos, 2007); however, they do not address structure learning.

We have found that existing MLN structure learning methods perform very poorly when tested on several benchmark ILP problems on relating the activity of chemical compounds to their structure (King et al., 1995). This led us to develop new discriminative structure and parameter learning algorithms for MLNs whose performance on these problems surpasses that of traditional ILP methods. The overall approach is to use traditional ILP methods to construct a large number of potentially useful clauses, and then use discriminative MLN parameter learning methods to properly weight them, preferring to assign zero weights to clauses that do not contribute significantly to overall predictive accuracy, thereby eliminating them. Our structure learning component utilizes many of the clauses considered during the search conducted by a specific configuration of ALEPH (Srinivasan, 2001). Our parameter learning component utilizes an exact probabilistic inference algorithm for MLNs with only non-recursive definite clauses. Our parameter learner also uses L_1-regularization (Lee et al., 2006) instead of the normal L_2 in order to encourage assigning zero weights to clauses, thereby simplifying the theory. We present experimental results that demonstrate that all three of these enhancements contribute significantly to improving the performance of our system over existing MLN and ILP methods.

The remainder of the paper is organized as follows. Section 2 provides some background on MLNs, ALCHEMY (Kok et al., 2005), and ALEPH. Section 3 presents our new structure and parameter learning algorithms. Section 4 presents our experimental evaluation of these methods. Section 5 discusses related work, and section 6 presents our conclusions.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

2. Background

2.1. ILP and Aleph

Traditional ILP systems discriminatively learn logical Horn-clause rules (logic programs) for inferring a given target predicate given information provided by a set of background predicates. These purely logical definitions are induced from Horn-clause background knowledge and a set of positive and negative tuples of the target predicate.

ALEPH is a popular and effective ILP system primarily based on PROGOL (Muggleton, 1995). The basic ALEPH algorithm consists of four steps. First, it selects a positive example to serve as the "seed" example. Then, it constructs the most specific clause, the "bottom clause", that entails that selected example. The bottom clause is formed by conjoining all known facts about the seed example. Next, ALEPH finds generalizations of this bottom clause by performing a general to specific search. These generalized clauses are scored using a chosen evaluation metric, and the clause with the best score is added to the final theory. This process is repeated

until it finds a set of clauses that covers all the positive examples. ALEPH allows users to customize each of these steps, and thereby supports a variety of specific algorithms.

2.2. MLNs and Alchemy

An MLN consists of a set of weighted first-order formulae (also called clauses or rules). It provides a way of softening first-order logic by making situations in which not all formulae are satisfied less likely but not impossible (Richardson & Domingos, 2006). More formally, let X be the set of all propositions describing a world (i.e. the set of all the ground atoms[1]), $\mathcal{F}$ be the set of all clauses in the MLN, w_i be the weight associated with clause $f_i \in \mathcal{F}$, $\mathcal{G}_{f_i}$ be the set of all possible groundings of clause f_i, and $\mathcal{Z}$ be the normalizing constant. Then the probability of a particular truth assignment x to the variables in X is given by the formula (Richardson & Domingos, 2006):

$$P(X = x) = \frac{1}{\mathcal{Z}} \exp\left(\sum_{f_i \in \mathcal{F}} w_i \sum_{g \in \mathcal{G}_{f_i}} g(x)\right) = \frac{1}{\mathcal{Z}} \exp\left(\sum_{f_i \in \mathcal{F}} w_i n_i(x)\right) \quad (1)$$

where $g(x)$ is 1 if g is satisfied and 0 otherwise, and $n_i(x) = \sum_{g \in \mathcal{G}_{f_i}} g(x)$ is the number of groundings of f_i that are satisfied given the current truth assignments to the variables in X.

[1]Ground atoms are predicates without variables, which are formed by replacing all the variables in predicates by constants.

In order to perform inference for an MLN, L, one needs to produce its corresponding ground Markov network. As described by Richardson and Domingos (2006), this is done by including a node for every possible grounding of the predicates in L and an edge between two nodes if they appear together in a grounding of a clause in L. The nodes appearing together in a ground clause form a clique. In general, exact inference in MLNs is intractable, so to calculate the probability that a ground atom or a set of them has a particular truth assignment given some evidence, one needs to run an approximate inference algorithm such as MCMC on this ground Markov network. MC-SAT (Poon & Domingos, 2006) is currently the best inference method for MLNs.

As previously mentioned, learning an MLN consists of two tasks: structure learning and weight learning. The weight learning component is independent of the structure learning one. It can learn weights for clauses produced by structure learning or written by a human expert. There are two approaches to weight learning: generative and discriminative. The former is used when there is no specific target predicate, and the latter when we know which predicate is to be queried. The current state-of-the-art discriminative weight learner is *preconditioner scaled conjugate gradient* (PSCG) (Lowd & Domingos, 2007). This algorithm uses samples from MC-SAT to approximate the intractable expected counts of satisfied clauses w.r.t. the current model. These counts are needed to compute the gradient and Hessian of the conditional log-likelihood (CLL) of an MLN. The inverse diagonal Hessian is used as the preconditioner in this method.

Regarding structure learning, there are currently two algorithms for learning clauses for MLNs. The first algorithm was proposed by Kok and Domingos (2005). This algorithm uses a top-down approach and can perform either beam-search or shortest-first search over the space of clauses. The candidate clauses are scored using *weighted pseudo log-likelihood* (WPLL) (Kok & Domingos, 2005). In contrast, the second algorithm, BUSL (Mihalkova & Mooney, 2007) follows a more bottom-up approach. It first constructs Markov network templates from the data and then generates candidate clauses from these network templates. All candidate clauses are also evaluated using WPLL, and added to the final MLN in a greedy manner. Both of these algorithms can be constrained to only learn clauses that contain a given target predicate by setting their "ne" (non-evidence) parameter to that predicate. However, they are not designed for discriminative learning since they try to find a set of clauses which maximizes WPLL, a non-discriminative measure.

ALCHEMY (Kok et al., 2005) is an open source software system for MLNs. It has implementations of all the ex-

isting algorithms for structure learning, generative weight learning, discriminative weight learning, and inference for MLNs. It is also a framework for developing new algorithms for MLNs. Our proposed algorithm is implemented in this framework.

3. Discriminative MLN Algorithms

In this section, we describe our two-step process for discriminatively learning both the structure and parameters of an MLN. The first step uses ALEPH to learn a large set of potential clauses. The second step learns the weights for these clauses, preferring to eliminate useless clauses by giving them zero weight.

3.1. Discriminative Structure Learning

Ideally, the search for discriminative MLN clauses would be directly guided by the goal of maximizing their contribution to the predictive accuracy of a complete MLN. However, this would require evaluating every proposed refinement to the existing set of learned clauses by relearning weights for all of the clauses and performing full probabilistic inference to determine the CLL of each of the query atoms. This process is computationally expensive and would have to be repeated for each of the combinatorially large number of potential clause refinements. Evaluating clauses in standard ILP is quicker since each clause can be evaluated in isolation based on the accuracy of its logical inferences about the target predicate. Consequently, we take the heuristic approach of using a standard ILP method to generate clauses; however, since the logical accuracy of a clause is only a rough approximation of its value in a final MLN, we generate a large number of candidates whose accuracy is at least markedly greater than random guessing and allow subsequent weight learning to determine their value to an overall MLN.

In order to find a set of potentially good clauses for an MLN, we use a particular configuration of ALEPH. Specifically, we use the **induce_cover** command and **m-estimate** evaluation function. The **induce_cover** command implements a variant of PROGOL's MDIE greedy covering algorithm (Muggleton, 1995) which does *not* remove previously covered examples when scoring a new clause. The normal ALEPH **induce** command scores a clause based only on its coverage of currently uncovered positive examples. However, this scoring is not reflective of its use in a final MLN, and we found that the **induce_cover** approach produces a larger set of more useful clauses that significantly increases the accuracy of our final learned MLN. The *m*-estimate (Džeroski, 1991) is a Bayesian estimation of the accuracy of a clause (Cussens, 2007). The m parameter defining the underlying prior distribution is automatically set to the maximum likelihood estimate of its best value. The output of **induce_cover** is a theory, a set of high-scoring clauses that cover all the positive examples. However, these clauses were selected based on an *m*-estimate of their accuracy under a purely logical interpretation, and may not be the best ones for an MLN. Therefore, in addition to these clauses, we also save all generated clauses whose *m*-estimate is greater than a predefined threshold (set to 0.6 in our experiments). This provides a large set of clauses of potential utility for an MLN. We use the name ALEPH++ to refer to this version of ALEPH.

3.2. Discriminative Weight Learning

Compared to ALCHEMY's current discriminative weight learning method (Lowd & Domingos, 2007), our method embodies two important modifications: *exact inference* and L_1*-regularization*. This section describes these two modifications.

First, given the restricted nature of the clauses constructed by ALEPH, we can use an efficient exact probabilistic inference method when learning their weights instead of the approximate inference algorithm that ALCHEMY uses to handle the general case. Since these clauses are non-recursive definite clauses in which the target predicate only appears once, multiple query atoms will not appear together in any grounding of any clause. For MLNs, this means that the Markov blanket of a query atom only contains evidence atoms. Consequently, the query atoms are independent given the evidence. Let Y be the set of query atoms and X be the set of evidence atoms, the conditional log likelihood of Y given X in this case is:

$$\log P(Y = y|X = x) = \log \prod_{j=1}^{n} P(Y_j = y_j|X = x)$$
$$= \sum_{j=1}^{n} \log P(Y_j = y_j|X = x)$$

and,

$$P(Y_j = y_j|X = x) = \frac{exp(\sum_{i \in \mathcal{F}_{Y_j}} w_i n_i(x, y_{[Y_j=y_j]}))}{exp(\sum_{i \in \mathcal{F}_{Y_j}} w_i n_i(x, y_{[Y_j=0]})) + exp(\sum_{i \in \mathcal{F}_{Y_j}} w_i n_i(x, y_{[Y_j=1]}))} \quad (2)$$

where $\mathcal{F}_{Y_j}$ is the set of all MLN clauses with at least one grounding containing the query atom Y_j, $n_i(x, y_{[Y_j=y_j]})$ is the number groundings of the ith clause that evaluate to true when all the evidence atoms in X and the query atom Y_j are set to their truth values, and similarly for $n_i(x, y_{[Y_j=0]})$ and $n_i(x, y_{[Y_j=1]})$ when Y_j is set to 0 and 1 respectively. Then the gradient of the CLL is:

$\frac{\partial}{\partial w_i} \log P(Y = y|X = x) =$

$$\sum_{j=1}^{n} [n_i(x, y_{[Y_j=y_j]}) - P(Y_j = 0|X = x) n_i(x, y_{[Y_j=0]}) - P(Y_j = 1|X = x) n_i(x, y_{[Y_j=1]})]$$

Notice that the sum of the last two terms in the gradient is the expected count of the number of true grounding of the i'th formula. In general, computing this expected count requires performing approximate inference under the model. For example, Singla and Domingos (2005) ran MAP inference and used the counts in the MAP state to approximate the expected counts. However, in our case, using the standard closed world assumption for evidence predicates, all the n_i's can be computed without approximate inference since there is no ground atom whose truth value is unknown. This is a result of restricting the structure learner to non-recursive definite clauses. In fact, this result still holds even when the clauses are not Horn clauses. The only restriction is that the target predicate appears only once in every clause. Note that given a set of weights, computing the conditional probability $P(y|x)$, the CLL, and its gradient requires only the n_i counts. So, in our case, the conditional probability $P(Y_j = y_j|X = x)$, the CLL, and its gradient can be computed exactly. In addition, these counts only need to be computed once, and ALCHEMY provides an efficient method for computing them. ALCHEMY also provides an efficient way to construct the Markov blanket of a query atom, in particular it ignores all ground formulae whose truth values are unaffected by the value of the query atom. In our case, this helps reduce the size of the Markov blanket of a query atom significantly since many ground clauses are satisfied by the evidence. As a result, our exact inference is very fast even when the MLN contains thousands of clauses.

Given a procedure for computing the CLL and its gradient, standard gradient-based optimization methods can be used to find a set of weights that optimizes the CLL. However, to prevent overfitting and select only the best clauses, we follow the approach suggested by Lee et al. (2006) and introduce a $Laplacian$ prior with zero mean, $P(w_i) = (\beta/2) \cdot exp(-\beta|w_i|)$, on each weight, and then optimize the posterior conditional log likehood instead of the CLL. The final objective function is:

$$\begin{aligned} \log P(Y|X)P(w) &= \log P(Y|X) + \log P(w) \\ &= \log P(Y|X) + \log(\prod_i P(w_i)) \\ &= CLL + \sum_i \log(\frac{\beta}{2} \cdot exp(-\beta|w_i|)) \\ &= CLL - \beta \sum_i |w_i| + constant \end{aligned}$$

There is now an additional term $\beta \sum_i |w_i|$ in the objective function, which penalizes each non-zero weight w_i by $\beta|w_i|$. So, the larger β is (corresponding to a smaller variance of the prior distribution), the more we penalize non-zero weights. Therefore, placing a $Laplacian$ prior with zero mean on each weight is equivalent to performing an L_1-regularization of the parameters. An important property of L_1-regularization is its tendency to force parameters to zero by strongly penalizing small terms (Lee et al., 2006). In order to learn weights that optimize the L_1-regularized CLL, we use the OWL-QN package which implements the Orthant-Wise Limited-memory Quasi-Newton algorithm (Andrew & Gao, 2007).

This approach to preventing over-fitting contrasts with the standard L_2-regularization used in previous work on learning weights for MLNs, which is equivalent to assuming a Guassian prior with zero mean on each weight and does not penalize non-zero weights as severely. Since ALEPH++ generates a very large number of potential clauses, L_1-regularization encourages eliminating the less useful ones by setting their weights to zero. In agreement with prior results on L_1-regularization (Ng, 2004; Dudík et al., 2007), our experiments confirm that it results in simpler and more accurate learned models compared to L_2-regularization.

4. Experimental Evaluation

In this section, we present experiments that were designed to answer the following questions:

1. How does our method compare to existing methods, specifically:
   (a) Extant discriminative learning for MLNs, viz. ALCHEMY.
   (b) Traditional ILP methods, viz. ALEPH.
   (c) "Advanced" ILP methods, viz. kFOIL (Landwehr et al., 2006), TFOIL (Landwehr et al., 2007), and RUMBLE (Rückert & Kramer, 2008).
2. How does each of our system's major novel components below contribute to its performance:
   (a) Generation of a larger set of potential clauses by using ALEPH++ instead of ALEPH.
   (b) Exact MLN inference for non-recursive definite clauses instead of general approximate inference.
   (c) L_1-regularization instead of L_2.

4.1. Data

We employed four benchmark data sets previously used to evaluate a variety of ILP and relational learning algorithms. They concern predicting the relative biochemical

activity of variants of Tacrine, a drug for Alzheimer's disease (King et al., 1995).[2] The data contain background knowledge about the physical and chemical properties of substituents such as their hydrophobicity and polarity, the relations between various physical and chemical constants, and other relevant information. The goal is to compare various drugs on four important biochemical properties: low **toxicity**, high **acetyl** cholinesterase inhibition, good reversal of scopolamine-induced **memory** impairment, and inhibition of **amine** re-uptake. For each property, the positive and negative examples are pairwise comparisons of drugs. For example, $less\_toxic(d_1, d_2)$ means that drug d_1's toxicity is less than d_2's. These ordering relations are transitive but not complete (i.e. for some pairs of drugs it is unknown which one is better). Therefore, this is a structured (a.k.a. collective) prediction problem since the output labels should form a partial order. However, previous work has ignored this structure and just predicted the examples separately as distinct binary classification problems. In this work, in addition to treating the problem as independent classification, we also use an MLN to perform structured prediction by explicitly imposing the transitive constraint on the target predicate. Table 1 shows some background facts and examples from one of the datasets, and Table 2 summarizes information about all four datasets.

Table 2. Summary statistics for Alzheimer's data sets.

Data set	#Examples	% Positive	# Predicates
Alzheimer acetyl	1326	50%	30
Alzheimer amine	686	50%	30
Alzheimer memory	642	50%	30
Alzheimer toxic	886	50%	30

4.2. Methodology

To answer the above questions, we ran experiments with the following systems:

ALCHEMY**:** Uses the structure learning (Kok & Domingos, 2005) in ALCHEMY and the most accurate existing discriminative weight learning PSCG (Lowd & Domingos, 2007) with the "ne" (non-evidence) parameter set to the target predicate.

BUSL**:** Uses BUSL (Mihalkova & Mooney, 2007) and PSCG discriminative weight learning with the "ne" (non-evidence) parameter set to the target predicate.

ALEPH**:** Uses ALEPH's standard settings with a few modifications. The maximum number of literals in an acceptable clause was set to 5. The minimum number of positive examples covered by an acceptable clause was set to 2. The upper bound on the number of negative examples covered by an acceptable clause was set to 300. The evaluation function was set to **auto_m**, and the minimum score of an acceptable clause was set to 0.6. The **induce_cover** command was used to learn the clauses. We found that this configuration gave somewhat better overall accuracy compared to those reported in previous work.

ALEPH**PSCG:** Uses the discriminative weight learner PSCG to learn MLN weights for the clauses in the final theory returned by ALEPH. Note that PSCG also uses L_2-regularization.

ALEPH**ExactL2** : Uses the limited-memory BFGS algorithm (Liu & Nocedal, 1989) implemented in ALCHEMY to learn discriminative MLN weights for the clauses in the final theory returned by ALEPH. The objective function is CLL with L_2 regularization. The CLL is computed exactly as described in Section 3.2.

ALEPH**++PSCG:** Like ALEPHPSCG, but learns weights for the larger set of clauses returned by ALEPH++.

ALEPH**++ExactL2:** Like ALEPHExactL2, but learns weights for the larger set of clauses returned by ALEPH++.

ALEPH**++ExactL1:** Our full proposed approach using exact inference and L_1-regularization to learn weights on the clauses returned by ALEPH++.

To force the predictions for the target predicate to properly constitute a partial ordering, we also tried adding to the learned MLNs a hard constraint (i.e. a clause with infinite weight) stating the transitive property of the target predicate, and used the MC-SAT algorithm to perform prediction on the test data. This exploits the ability of MLNs to perform collective classification (structured prediction) for the complete set of test examples.

In testing, only the background facts are provided as evidence to ensure that all predictions are based on the chemical structure of a drug. For all systems except ALEPH, a threshold of 0.5 was used to convert predicted probabilities into boolean values. The predictive accuracy of these algorithms for the target predicate were compared using 10-fold cross-validation. The significance of the results were evaluated using a two-tailed paired t-test test with a 95% confidence level. To compare the quality of the predicted probabilities, we also report the average area under the ROC curve (AUC-ROC) for all probabilistic systems by using the AUCCalculator package (Davis & Goadrich, 2006).

[2]Since the current ALCHEMY does not support real valued variables, we could not test our approach on the other standard ILP benchmark data sets in molecular biology.

Table 1. Some background evidence and examples from the Alzheimer toxic dataset.

Background evidence	Examples
r_subst_1(A1,H), r_subst_1(B1,H), r_subst_1(D1,H), x_subst(B1,7,CL), x_subst(D1,6,OCH3), polar(CL,POLAR3), polar(OCH3,POLAR2), great_polar(POLAR3,POLAR2), size(CL,SIZE1), size(OCH3,SIZE2), alk_groups(A1,0), alk_groups(B1,0), alk_groups(D1,0), great_size(SIZE2,SIZE1), flex(CL,FLEX0), flex(OCH3,FLEX1)	less_toxic(B1,A1) less_toxic(A1,D1) less_toxic(B1,D1)

Table 3. Average predictive accuracies and standard deviations for all systems. Bold numbers indicate the best result on a data set.

Data set	ALCHEMY	BUSL	ALEPH	ALEPH **PSCG**	ALEPH **ExactL2**	ALEPH++ **PSCG**	ALEPH++ **ExactL2**	ALEPH++ **ExactL1**
Alzheimer amine	50.1 ± 0.5	51.3 ± 2.5	81.6 ± 5.1	64.6 ± 4.6	83.5 ± 4.7	72.0 ± 5.2	86.8 ± 4.4	$\mathbf{89.4 \pm 2.7}$

4.3. Results and Discussion

Tables 3 and 4 show the average accuracy and AUC-ROC with standard deviation for each system running on each data set. Our complete system (ALEPH++**ExactL1**) achieves significantly higher accuracy than both ALCHEMY and BUSL on all 4 data sets and significantly higher than ALEPH on all except the **memory** data set, answering questions 1(a) and 1(b). In turn, ALEPH has been shown to give higher accuracy on these data sets than other standard ILP systems like FOIL (Landwehr et al., 2007). ALCHEMY's existing non-discriminative structure learners find only a few (3–5) simple clauses. Two of them are unit clauses for the target predicate, such as *great_ne(a1,a1)* and *great_ne(a1,a2)*; the others capture the transitive nature of the target relation. Therefore, even after they are discriminatively weighted, their predictions are not significantly better than random guessing.

The ablations that remove components from our overall system demonstrate the important contribution of each component. Regarding question 2(b), the systems using general approximate inference (ALEPH**PSCG** and ALEPH++**PSCG**) perform much worse than the corresponding versions that use exact inference (ALEPH**ExactL2** and ALEPH++**ExactL2**). Therefore, when there is a target predicate that can be accurately inferred using non-recursive definite clauses, exploiting this restriction to perform exact inference is a clear win.

Regarding question 2(a), ALEPH++**ExactL2** performs significantly better than ALEPH**ExactL2**, demonstrating the advantage of learning a large set of potential clauses and combining them with learned weights in an overall MLN. Across the four datasets, ALEPH++ returns an average of $6,070$ clauses compared to only 10 for ALEPH.

Table 5 presents average accuracies with standard deviations for the MLN systems when we include a transitivity clause for the target predicate. This constraint improves the accuracies of ALEPH**ExactL2**, ALEPH++**ExactL2**, and ALEPH++**ExactL1**, but sometimes decreases the accuracy of other systems, such as ALEPH**PSCG**. This can be explained as follows. Since most of the predictions of ALEPH++**ExactL1** are correct, enforcing transitivity can correct some of the wrong ones. However, ALEPH**PSCG** produces many wrong predictions, so forcing them to obey transitivity can produce additional incorrect predictions. Due to space constraints, we do not report the corresponding AUC-ROC results, which are qualitatively similar.

Regarding question 2(c), using L_1-regularization gives significantly higher accuracy and AUC-ROC than using standard L_2-regularization. This comparison was only performed for ALEPH++ since this is when the weight-learner must choose from a large set of candidate clauses by encouraging zero weights. Table 6 compares the average number of clauses learned (after zero-weight clauses are removed) for L_1 and L_2 regularization. As expected, the final learned MLNs are much simpler when using L_1-regularization. On average, L_1-regularization reduces the size of the final set of clauses by 26% compared to L_2-regularization.

Regarding question 1(c), several researchers have tested "advanced" ILP systems on our datasets. Table 7 compares our best results to those reported for TFOIL (a combination of FOIL and tree augmented naive Bayes), kFOIL (a kernelized version of FOIL), and RUMBLE (a max-margin approach to learning a weighted rule set). Our results are competitive with these recent systems. Additionally, unlike MLNs, these methods do not create "declarative" theories

5. Related Work

Using an off-the-shelf ILP system to learn clauses for MLNs is not a new idea. Richardson and Domingos (2006) used CLAUDIEN, an non-descriminative ILP system that can learn arbitrary first-order clauses, to learn MLN structure and to refine the clauses from a knowledge base. Kok and Domingos (2005) reported experimental results comparing their MLN structure learner to learning clauses using CLAUDIEN, FOIL, and ALEPH. However, since this previous work used the relatively small set of clauses produced by these unaltered ILP systems, the performance was not very good. ILP systems have also been used to learn structures for other SRL models. The SAYU system (Davis et al., 2005) used ALEPH to propose candidate features for a Bayesian network classifier. Muggleton(2000) used PROGOL, another popular ILP system, to learn clauses for Stochastic Logic Programs (SLPs).

When restricted to learning non-recursive clauses for classification, our approach is equivalent to using ALEPH to construct features for use by L_1-regularized logistic regression. Under this view, our approach is closely related to MACCENT (Dehaspe, 1997), which uses a greedy approach to induce clausal constraints that are used as features for maximum-entropy classification. One difference between our approach and MACCENT is that we use a two-step process instead of greedily adding one feature at a time. In addition, our clauses are induced in a bottom-up manner while MACCENT uses top-down search; and our weight learner employs L_1-regularization which makes it less prone to overfitting. Unfortunately, we could not compare experimentally to MACCENT since "only an implementation of a propositional version of MACCENT is available, which only handles data in attribute-value (vector) format" (Landwehr et al., 2007). Additionally, MLNs are a more expressive formalism that also allows for structured prediction, as demonstrated by our results that include a transitivity constraint on the target relation.

6. Conclusions

We have found that existing methods for learning Markov Logic Networks perform very poorly when tested on several benchmark ILP problems in drug design. We have presented a new approach to constructing MLNs that discriminatively learns both their structure and parameters to optimize predictive accuracy for a stated target predicate when given evidence specified with a defined set of background predicates. It uses a variant of an existing ILP system (ALEPH) to construct a large number of potential clauses and then effectively learns their parameters by altering existing discriminative MLN weight-learning methods to utilize exact inference and L_1 regularization. Experimental results show that the resulting system outperforms existing MLN and ILP methods and gives state-of-the-art results for the Alzheimer's-drug benchmarks.

Causal Modelling Combining Instantaneous and Lagged Effects: an Identifiable Model Based on Non-Gaussianity

Abstract

Causal analysis of continuous-valued variables typically uses either autoregressive models or linear Gaussian Bayesian networks with instantaneous effects. Estimation of Gaussian Bayesian networks poses serious identifiability problems, which is why it was recently proposed to use non-Gaussian models. Here, we show how to combine the non-Gaussian instantaneous model with autoregressive models. We show that such a non-Gaussian model is identifiable without prior knowledge of network structure, and we propose an estimation method shown to be consistent. This approach also points out how neglecting instantaneous effects can lead to completely wrong estimates of the autoregressive coefficients.

1. Introduction

Analysis of causal influences or effects has become an important topic in machine learning (Pearl, 2000; Spirtes et al., 1993), and has numerous applications in, for example, neuroinformatics (Roebroeck et al., 2005; Kim et al., 2007) and bioinformatics (Opgen-Rhein & Strimmer, 2007). For continuous-valued variables, such an analysis can basically be performed in two different ways. First, if the time-resolution of the measurements is higher than the time-scale of causal influences, one can estimate a classic autoregressive model with time-lagged variables and interpret the autoregressive coefficients as causal effects. Second, if the measurements have a lower time resolution than the causal influences, or if the data has no temporal structure at all, one can use a model in which the causal influences are instantaneous, leading to Bayesian networks or structural equation models (Bollen, 1989).

While estimation of autoregressive methods can be solved by classic regression methods, the case of instantaneous effects is much more difficult. Most methods suffer from lack of identifiability,[1] because covariance information alone is not sufficient to uniquely characterize the model parameters. Prior knowledge of the structure (fixing some of the connections to zero) of the Bayesian network is then necessary for most practical applications. However, a method was recently proposed which uses the non-Gaussian structure of the data to overcome the identifiability problem (Shimizu et al., 2006): If the disturbance variables (external influences) are non-Gaussian, no prior knowledge on the network structure (other than the ubiquitous assumption of a directed acyclic graph (DAG)) is needed to estimate the model.

Here, we consider the general case where causal influences can occur either instantaneously or with considerable time lags. Such a model is called the structural vector autoregressive (SVAR) model in econometric theory, in which numerous attempts have been made for its estimation, see e.g. (Swanson & Granger, 1997; Demiralp & Hoover, 2003; Moneta & Spirtes, 2006). We propose to use non-Gaussianity to estimate the model. We show that this variant of the model is iden-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] Identifiability is here used in the classic statistical sense: a model is identifiable if no two different values of the parameter vector give the same distribution for the observed data.

tifiable without any other restrictions than acyclicity. To our knowledge, no model proposed for this problem has been shown to be fully identifiable without prior knowledge of network structure. We further propose a computational method for estimating the model based on the theory of independent component analysis or ICA (Hyvärinen et al., 2001).

The proposed non-Gaussian model not only allows estimation of both instantaneous and lagged effects; it also shows that taking instantaneous influences into account can change the values of the time-lagged coefficients quite drastically. Thus, we see that neglecting instantaneous influences can lead to misleading interpretations of causal effects. The framework further leads to a generalization of the well-known Granger causality measure.

The paper is structured as follows. We first define the model and discuss its relation to other models in Section 2. In Section 3 we propose an estimation method, show its consistency, and discuss an intuitive interpretation of the method. Section 4 contains some theoretical examples and a theorem on how including instantaneous effects in the model changes the resulting interpretations. The resulting generalization of Granger causality is discussed in Section 5. The validity of the estimation method is demonstrated by simulations on artificial data in Section 6, and experiments on financial and neuroscientific data in Section 7. Section 8 concludes the paper.

2. Model Combining Lagged and Instantaneous Effects

2.1. Definition and Assumptions

Let us denote the observed time series by $x_i(t), i = 1, \ldots, n, t = 1, \ldots, T$ where i is the index of the variables (time series) and t is the time index. All the variables are collected into a single vector $\mathbf{x}(t)$. Denote by k the number of time-delays used, i.e. the order of the autoregressive model. Denote by $\mathbf{B}_\tau$ the $n \times n$ matrix of the causal effects between the variables x_i with time lag $\tau, \tau = 0 \ldots k$.

The causal dynamics in our model are a combination of autoregressive and structural-equation models. The model is defined as

$$\mathbf{x}(t) = \sum_{\tau=0}^{k} \mathbf{B}_\tau \mathbf{x}(t-\tau) + \mathbf{e}(t) \qquad (1)$$

where the $e_i(t)$ are random processes modelling the external influences or "disturbances". We make the following assumptions on the external influences $e_i(t)$. First, they are mutually *independent*, and *temporally uncorrelated*, which are typical assumptions in autoregressive models. Second, they are assumed to be *non-Gaussian*, which is an important assumption which distinguishes our model from classic models, whether autoregressive models, structural-equation models, or Bayesian networks.

Further, we assume that the matrix modelling instantaneous effects, $\mathbf{B}_0$, corresponds to an *acyclic* graph, as is typical in causal analysis, but this may not be strictly necessary as will be discussed below. The acyclicity is equivalent to the existence of a permutation matrix $\mathbf{P}$, which corresponds to an ordering of the variables x_i, such that the matrix $\mathbf{P}\mathbf{B}_0\mathbf{P}^T$ is lower-triangular (i.e. entries above the diagonal are zero). Acyclicity also implies that the entries on the diagonal are zero, even before such a permutation.

2.2. Relation to Other Models

This model is a generalization of the linear non-Gaussian acyclic model (LiNGAM) proposed in (Shimizu et al., 2006). If the order of the autoregressive part is zero, i.e. $k = 0$, the model is nothing else than the LiNGAM model, modelling instantaneous effects only. As shown in (Shimizu et al., 2006), the assumption of non-Gaussianity of the e_i enables estimation of the model. This is because the non-Gaussian structure of the data provides information not contained in the covariance matrix which is the only source of information in most methods. In this sense the model is similar to independent component analysis, which solves the unidentifiability of factor analytic models using the assumption of non-Gaussianity of the factors (Comon, 1994; Hyvärinen et al., 2001). In fact, the estimation method in (Shimizu et al., 2006) uses an ICA algorithm as an essential part.

On the other hand, if the matrix $\mathbf{B}_0$ has all zero entries, the model in Equation (1) is a classic vector autoregressive model in which future observations are linearly predicted from preceding ones. If we knew in advance that $\mathbf{B}_0$ is zero, the model could thus be estimated by classic regression techniques since we do not have the same variables on the left and right-hand sides of Equation (1).

We emphasize that our model is different from classic autoregressive models two important ways: First, the external influences $e_i(t)$ are non-Gaussian. Second, the lag variable τ takes the value 0 as well, which brings instantaneous effects into the model in the form of the matrix $\mathbf{B}_0$. A coefficient $\mathbf{B}_0(i, j)$ models the instantaneous effect of $x_j(t)$ on $x_i(t)$ as in a linear Bayesian network, or a structural equation model.

2.3. Causality vs. Prediction

An autoregressive model can serve two different goals: prediction and analysis of causality. Our goal here is the latter: We estimate the parameter matrices $\mathbf{B}_\tau$ in order to interpret them as causal effects between the variables. This goal is distinct from simply predicting future outcomes when passively observing the time series, as has been extensively discussed in the literature on causality (Pearl, 2000; Spirtes et al., 1993). Thus, we emphasize that our model is not intended to reduce prediction errors if we want to predict $x_i(t)$ using (passively) observed values of the past $\mathbf{x}(t-1), \mathbf{x}(t-2), \ldots$; for such prediction, an ordinary autoregressive model is likely to be just as good.

Our model is intended to be superior in causal modelling. Causality has an obvious intuitive interpretation, which is typically formalized as the ability to predict the effect of possible new *interventions* on the system (Pearl, 2000). Thus, our model should be better in predicting effects of interventions, which is different from conventional time series prediction.

3. Estimation of the Model

3.1. Combining Least-Squares Estimation and LiNGAM

We propose the following method for estimating our model defined in Section 2.1. The method combines classic least-squares estimation of an autoregressive (AR) model with LiNGAM estimation:

1. Estimate a classic autoregressive model for the data
$$\mathbf{x}(t) = \sum_{\tau=1}^{k} \mathbf{M}_\tau \mathbf{x}(t-\tau) + \mathbf{n}(t) \qquad (2)$$
using any conventional implementation of a least-squares method. Note that here $\tau > 0$, so it is really a classic AR model. Denote the least-squares estimates of the autoregressive matrices by $\hat{\mathbf{M}}_\tau$.

2. Compute the residuals, i.e. estimates of innovations $\mathbf{n}(t)$
$$\hat{\mathbf{n}}(t) = \mathbf{x}(t) - \sum_{\tau=1}^{k} \hat{\mathbf{M}}_\tau \mathbf{x}(t-\tau) \qquad (3)$$

3. Perform the LiNGAM analysis (Shimizu et al., 2006) on the residuals. This gives the estimate of the matrix $\mathbf{B}_0$ as the solution of the instantaneous causal model
$$\hat{\mathbf{n}}(t) = \mathbf{B}_0 \hat{\mathbf{n}}(t) + \tilde{\mathbf{e}}(t) \qquad (4)$$

4. Finally, compute the estimates of the causal effect matrices $\mathbf{B}_\tau$ for $\tau > 0$ as
$$\hat{\mathbf{B}}_\tau = (\mathbf{I} - \hat{\mathbf{B}}_0)\hat{\mathbf{M}}_\tau \text{ for } \tau > 0 \qquad (5)$$

This estimation method is consistent,[2] as will be shown in Section 3.3. First, however, we show the derivation of Equation (5) and discuss its deep meaning.

3.2. Why Autoregressive Matrices Change due to Instantaneous Influences

Equation (5) shows a remarkable fact already mentioned in the Introduction: Consistent estimates of the $\mathbf{B}_\tau$ are not obtained by a simple AR model fit even for $\tau > 0$. Taking instantaneous effects into account changes the estimation procedure for all the autoregressive matrices, if we want consistent estimators as we usually do. Of course, this is only the case if there are instantaneous effects, i.e. $\mathbf{B}_0 \neq 0$; otherwise, the estimates are not changed.

Why do we have (5)? This is because from (1) we have
$$(\mathbf{I} - \mathbf{B}_0)\mathbf{x}(t) = \sum_{\tau=1}^{k} \mathbf{B}_\tau \mathbf{x}(t-\tau) + \mathbf{e}(t) \qquad (6)$$
and thus
$$\mathbf{x}(t) = \sum_{\tau=1}^{k} (\mathbf{I} - \mathbf{B}_0)^{-1} \mathbf{B}_\tau \mathbf{x}(t-\tau) + (\mathbf{I} - \mathbf{B}_0)^{-1} \mathbf{e}(t) \qquad (7)$$
Comparing this with (2), we can equate the autoregressive matrices, which gives $(\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{B}_\tau = \mathbf{M}_\tau$ for $\tau \geq 1$, and thus (5) is justified.

While this phenomenon is, in principle, well-known in econometric literature (Swanson & Granger, 1997; Demiralp & Hoover, 2003; Moneta & Spirtes, 2006), Equation (5) is seldom applied because estimation methods for $\mathbf{B}_0$ have not been well developed. To our knowledge, no estimation method for $\mathbf{B}_0$ has been proposed which is consistent without strong prior assumptions on $\mathbf{B}_0$.

3.3. Consistency and Identifiability

The consistency of our method relies on two facts. First, in the estimation of an AR model as in (2), it is not necessary that the innovation vector $\mathbf{n}(t)$ has independent or even uncorrelated elements (for fixed

[2] Consistency means classic statistical consistency, i.e. the estimator converges in probability to the right parameter values when the data follows the model and sample size grows infinite.

t); least-squares estimation will still be consistent, as is well known. Thus, least-squares estimation of (2), combined with (5), gives consistent estimators of $\mathbf{B}_\tau$ for $\tau \geq 1$, provided we have a consistent estimator of $\mathbf{B}_0$. Second, comparison of (7) with (2) shows that the residuals $\hat{\mathbf{n}}(t)$ are, asymptotically, of the form $(\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{e}(t)$. This means

$$\hat{\mathbf{n}}(t) = (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{e}(t) \Leftrightarrow (\mathbf{I} - \mathbf{B}_0)\hat{\mathbf{n}}(t) = \mathbf{e}(t) \Leftrightarrow \hat{\mathbf{n}}(t) = \mathbf{B}_0\hat{\mathbf{n}}(t) + \mathbf{e}(t) \quad (8)$$

which is the LiNGAM model for $\hat{\mathbf{n}}(t)$. This shows that $\mathbf{B}_0$ is obtained as the LiNGAM analysis of the residuals, and the consistency of our estimator of $\mathbf{B}_0$ follows from the consistency of LiNGAM estimation (Shimizu et al., 2006). Thus, our method is consistent for all the $\mathbf{B}_\tau$. This obviously proves, by construction, the identifiability of the model as well.

We have here assumed that $\mathbf{B}_0$ is acyclic, as is typical in causal analysis. However, this assumption is only made because we do not know very well how to estimate a linear non-Gaussian Bayesian network in the cyclic case. Future work may produce methods which estimate cyclic models, and then we do not need the assumption of acyclicity in our combined model either. We could just use such a new method in Step 3 of the method instead of LiNGAM, and nothing else would be changed. Recent work in that direction is in (Lacerda et al., 2008); see also (Richardson & Spirtes, 1999) for older methods on Gaussian data.

3.4. Interpretation as ICA of Residuals

Another viewpoint on our model is analysis of the correlations of the innovations after estimating a classic AR model. Suppose we just estimate an AR model as in (2), and interpret the coefficients as causal effects. Such an interpretation more or less presupposes that the innovations n_i are independent of each other, because otherwise there is some structure in the model which has not been modelled by the AR model. If the innovations are not independent, the causal interpretation may not be justified. Thus, it seems necessary to further analyze the dependencies in the innovations in cases where they are strongly dependent.

Analysis of the dependency structure in the residuals (which are, by definition, estimates of innovations) is precisely what leads to the present model. As a first approach, one could consider application of something like principal component analysis or independent component analysis on the residuals. The problem with such an approach is that the interpretation of the obtained results in the framework of causal analysis would be quite difficult. Our solution is to fit a causal model like LiNGAM to the residuals, which leads to a straightforward causal interpretation of the analysis of residuals which is logically consistent with the AR model.

4. Interaction of Instantaneous and Lagged Effects

Here we present some theoretical examples of how the instantaneous and lagged effects interact based on the formula in (5).

An instantaneous effect may seem to be lagged Consider first the case where the instantaneous and lagged matrices are as follows:

$$\mathbf{B}_0 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B}_1 = \begin{pmatrix} 0.9 & 0 \\ 0 & 0.9 \end{pmatrix} \quad (9)$$

That is, there is an instantaneous effect $x_2 \to x_1$, and no lagged effects (other than the purely autoregressive $x_i(t-1) \to x_i(t)$). Now, if an AR(1) model is estimated for data coming from this model, without taking the instantaneous effects into account, we get the autoregressive matrix

$$\mathbf{M}_1 = (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{B}_1 = \begin{pmatrix} 0.9 & 0.9 \\ 0 & 0.9 \end{pmatrix} \quad (10)$$

Thus, the effect $x_2 \to x_1$ seems to be lagged although it is, actually, instantaneous.

Spurious effects appear Consider three variables with the instantaneous effects $x_1 \to x_2$ and $x_2 \to x_3$, and no lagged effects other than $x_i(t-1) \to x_i(t)$, as given by

$$\mathbf{B}_0 = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \quad \mathbf{B}_1 = \begin{pmatrix} 0.9 & 0 & 0 \\ 0 & 0.9 & 0 \\ 0 & 0 & 0.9 \end{pmatrix} \quad (11)$$

If we estimate an AR(1) model for the data coming from this model, we obtain

$$\mathbf{M}_1 = (\mathbf{I} - \mathbf{B}_0)^{-1}\mathbf{B}_1 = \begin{pmatrix} 0.9 & 0 & 0 \\ 0.9 & 0.9 & 0 \\ 0.9 & 0.9 & 0.9 \end{pmatrix} \quad (12)$$

This means that the estimation of the simple autoregressive model leads to the inference of a direct lagged effect $x_1 \to x_3$, although no such direct effect exists in the model generating the data, for any time lag.

Causal ordering is not changed A more reassuring result is the following: if the data follows the same causal ordering for all time lags, that ordering is not contradicted by the neglect of instantaneous effect. A rigorous definition of this property is the following.

Theorem 1 *Assume that there is an ordering* $i(j), j = 1 \ldots n$ *of the variables such that no effect goes backward,*[3] *i.e.*

$$\mathbf{B}_\tau(i(j-\delta), i(j)) = 0 \text{ for } \delta > 0, \tau \geq 0, 1 \leq j \leq n \quad (13)$$

Then, the same property applies to the $\mathbf{M}_\tau, \tau \geq 1$ *as well. Conversely, if there is an ordering such that (13) applies to* $\mathbf{M}_\tau, \tau \geq 1$ *and* $\mathbf{B}_0$*, then it applies to* $\mathbf{B}_\tau, \tau \geq 1$ *as well.*

The proof of the theorem is based on the fact that when the variables are ordered in this way (assuming such an order exists), all the matrices $\mathbf{B}_\tau$ are lower-triangular. The same applies to $\mathbf{I} - \mathbf{B}_0$. Now, the product of two lower-triangular matrices is lower-triangular; in particular the $\mathbf{M}_\tau$ are also lower-triangular according to (5), which proves the first part of the theorem. The converse part follows from solving for $\mathbf{B}_\tau$ in (5) and the fact that the inverse of a lower-triangular matrix is lower-triangular.

What this theorem means is that if the variables really follow a single "causal ordering" for all time lags, that ordering is preserved even if instantaneous effects are neglected and a classic AR model is estimated for the data. Thus, there is some limit to how (5) can change the causal interpretation of the results.

5. Towards a Generalization of Granger Causality

The classic interpretation of causality in instantaneous Bayesian network models would be that x_i causes x_j if the (j, i)-th coefficient in $\mathbf{B}_0$ is non-zero. In the time series context, this is related to Granger causality (Granger, 1969), which formalizes causality as the ability to reduce prediction error. A simple operational definition of Granger causality can be based on the autoregressive coefficients $\mathbf{M}_\tau$: If at least one of the coefficients from $x_i(t-\tau), \tau \geq 1$ to $x_j(t)$ is (significantly) non-zero, then x_i Granger-causes x_j. This is because then the variable x_i reduces the prediction error in x_j in the mean-square sense if it is included in the set of predictors, which is the very definition of Granger causality.

In light of the results in this paper, we propose a definition which combines the two aspects: A variable x_i causes x_j if at least one of the coefficients $\mathbf{B}_\tau(j, i)$, giving the effect from $x_i(t-\tau)$ to $x_j(t)$, is (significantly) non-zero for $\tau \geq 0$. The condition for τ is different from Granger causality since the value $\tau = 0$, corresponding to instantaneous effects, is included. Moreover, since estimation of the instantaneous effects changes the estimates of the lagged ones, the lagged effects used in our definition are different from those usually used with Granger causality.

A more general formulation of this definition, which is in line with the general formulation of Granger causality, is that the error in the "prediction" of $x_j(t)$ is reduced when $x_i(t-1), x_i(t-2), \ldots$ *and* $x_i(t)$ are included in the set of predictors. Here, we use a rather unconventional definition of the word "prediction" because we include instantaneous effects.

6. Simulations

To verify the validity of our method, we first performed experiments with artificial data. In the experiments, we created data in the following manner using the LiNGAM code package[4]:

1. We randomly constructed a strictly lower-triangular matrix (i.e. zero entries above and on the diagonal), $\mathbf{B}_0$, for the instantaneous causal model so that the standard deviations of the innovations n_i owing to parent innovations will be in the interval $[0.5, 1.5]$. The number of observed time-series was $n = 10$. Both fully connected (no zeros in the strictly lower triangular part) and sparse networks (many zeros) were created. We also randomly selected the standard deviations of the external influences e_i from the interval $[0.5, 1.5]$.

2. Next, we generated data with various lengths of the time series (300, 500 and 1,000) by independently drawing the external influences e_i from various non-Gaussian distributions with zero mean and unit variance[5]. The values of the innovations n_i were generated according to the assumed instantaneous recursive process. This is straightforward because $\mathbf{B}_0$ is lower-triangular, so we just generate the n_i in the order $n_1, n_2 \ldots$ as is typical in acyclic networks, e.g. (Shimizu et al., 2006).

3. We randomly permuted the order of the innovations n_i to hide the causal order with which the data was generated. We also permuted $\mathbf{B}_0$ as well

[3] In the purely instantaneous case, existence of such an ordering is equivalent to acyclicity of the effects as noted in Section 2.1.

[4] http://www.cs.helsinki.fi/group/neuroinf/lingam/

[5] We first generated a gaussian variable z with zero mean and unit variance and subsequently transformed it to a non-Gaussian variable by $e_i = \text{sign}(z)|z|^q$. The nonlinear exponent q was selected to lie in $[0.5, 0.8]$ or $[1.2, 2.0]$. The former gave a sub-gaussian variable, and the latter a super-gaussian variable. Finally, the transformed variable was standardized to have zero mean and unit variance.

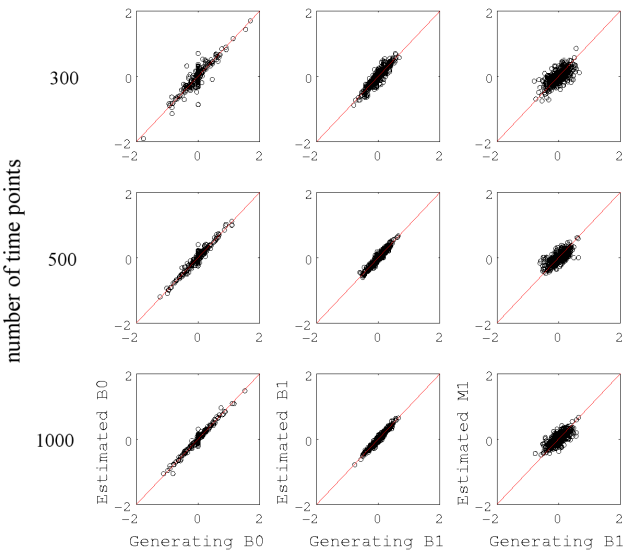

Figure 1. Simulations on artificial data. Left column: Scatterplots of the estimated elements of $\mathbf{B}_0$ versus the generating values. Center column: Scatterplots of the estimated elements of $\mathbf{B}_1$ versus the generating values. Right column: Scatterplots of the estimated elements of $\mathbf{M}_1$ versus those of $\mathbf{B}_1$.The number of observed signals was 10. Five data sets were generated for each scatterplot.

as the variances of the external influences e_i to match the new order.

4. We randomly generated a first-order autoregressive matrix $\mathbf{M}_1$ so that the spectral norm of the matrix was less than 0.99 to ensure the stability of the autoregressive process.

5. The values of the observed signals $x_i(t)$ were generated according to the assumed first-order autoregressive process.

6. Finally, we fed the data to our estimation method. Here we told the method that the generating autoregressive order was 1.

Figure 1 gives the scatterplots of the elements of the estimated parameters versus the generating ones. The left column is for the scatterplots of the estimated causal effects in $\mathbf{B}_0$ versus the generating values. The center column is for the scatterplots of the estimated causal effects in $\mathbf{B}_1$ versus the generating values. The right column is for the scatterplots of the estimated autoregressive coefficients in $\mathbf{M}_1$ versus the generating values of the causal effects in $\mathbf{B}_1$ (here, the estimation was invalid because instantaneous effects were ignored).

For the scatterplots in the left and center columns, the estimation worked well when the sample size grew, as evidenced by the grouping of the data points onto the main diagonal, although for the small sample size 300 the estimation was often inaccurate. On the other hand, the scatterplots in the right column confirmed that the causal effects were not correctly estimated by the ordinary autoregressive coefficients when instantaneous influences existed since the data points were not very close to the main diagonal.

7. Experiments on Real Data

7.1. Financial Data

As a first illustration of the applicability of the method on real data, we analyzed a dataset from a time series repository on the Internet.[6] The data consisted of two observed signals, x_1: weekly closing price of Toyota stock and x_2: weekly closing rate of exchange of Japanese Yen to U.S. Dollar in 2007. The number of time points was 50. The maximum, minimum and mean of x_1 were 8,230, 5,870 and 7,102 (JPY). Those of x_2 were 123.86, 108.51 and 117.72 (JPY).

We analyzed the data using our method with autoregressive order of 1. The estimated first-order autoregressive matrix $\mathbf{M}_1$ and residual correlation matrix were as follows:

$$\mathbf{M}_1 = \begin{pmatrix} 0.95 & -4.22 \\ 0.0008 & 0.78 \end{pmatrix} \tag{14}$$

$$\mathrm{corr}(\mathbf{n}) = \begin{pmatrix} 1.00 & 0.66 \\ 0.66 & 1.00 \end{pmatrix}$$

The relatively strong correlation between the residuals implied that there would be some dependency that had not been modeled by the AR model. Thus, we fitted the instantaneous causal model to the residuals, as proposed above. The estimated instantaneous causal effect matrix $\mathbf{B}_0$ and resulting lagged causal effect matrix $\mathbf{B}_1$ were as follows:

$$\mathbf{B}_0 = \begin{pmatrix} 0 & 56.04 \\ 0.0027 & 0 \end{pmatrix} \tag{15}$$

$$\mathbf{B}_1 = \begin{pmatrix} 0.91 & -48.01 \\ -0.0018 & 0.79 \end{pmatrix} \tag{16}$$

The matrix $\mathbf{B}_0$ is very close to be upper-triangular, which implied that the model was really acyclic (because switching the order of the variables would make $\mathbf{B}_0$ lower-triangular). Further, the instantaneous effect $x_2 \to x_1$ in $\mathbf{B}_0$ was one order of magnitude larger than the lagged effect in $\mathbf{M}_1$ and thus the lagged co-

[6] Yahoo! Japan Finance: http://quote.yahoo.co.jp/

efficients in $\mathbf{M}_1$ are quite different from those in $\mathbf{B}_1$, due to the formula in (5).

Figure 2 shows a graphical representation of the estimated model for financial data. First, it implies that a higher value of the yen (x_2) had a negative lagged effect (-48.01) on the price of Toyota stock (x_1). This would be reasonable since Toyota sells many cars abroad, and a higher value of the yen would increase the cost price and decrease the earning. Interestingly, it was also implied that a higher value of the yen had a positive instantaneous effect (56.04) on the price of Toyota stock. In other words, for weeks where values of the yen one week before were the (approximately) same, if the yen got more expensive (due to some reason other than the value of the yen one week before, perhaps a U.S. recession, for example) then the price of Toyota stock would get more expensive. It would be interesting to further study the economic mechanism with more extensive data.

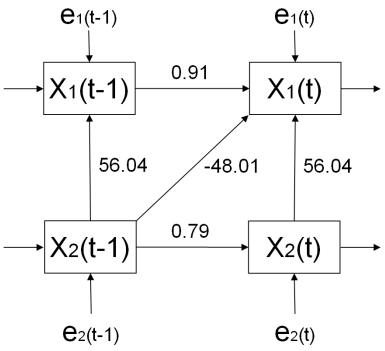

Figure 2. A graphical representation of the model estimated in Section 7.1. The x_1 and x_2 denote weekly closing price of Toyota stock in 2007 and weekly closing rate of exchange of Japanese Yen to U.S. Dollar in 2007, respectively. The arrow from $x_1(t-1)$ to $x_2(t)$ was omitted since the estimated strength was very close to zero (-0.0018).

7.2. Magnetoencephalographic Data

As a second illustration of the applicability of the method on real data, we applied it on magnetoencephalography (MEG), i.e. measurements of the electric activity in the brain. The raw data consisted of the 306 MEG channels measured by the Vectorview helmet-shaped neuromagnetometer (Neuromag Ltd., Helsinki, Finland) in a magnetically shielded room at the Brain Research Unit, Low Temperature Laboratory, Helsinki University of Technology. The sampling frequency was 600 Hz. The measurements consisted of 300 seconds of resting state brain activity from the experiment of (Ramkumar et al., 2007). The subject was sitting with eyes closed, and did not perform any specific task nor was there any specific sensory stimulation. The channels were first linearly projected to the signal space to reduce noise (Uusitalo & Ilmoniemi, 1997). In this illustrative experiment, we only consider a single (gradiometer) channel in the right occipital cortex near the midline.

We considered the interaction of about 10 Hz (alpha) and about 20 Hz (beta) oscillations commonly observed in electromagnetic recordings of spontaneous brain activity. We first computed the amplitudes of the oscillations by dividing the data into windows of length of 0.25 seconds, performing fast Fourier transform inside each of them, and computing the total Fourier amplitudes (unweighted Euclidean norm of the Fourier coefficients) in the frequency ranges of $8 \ldots 12$Hz (alpha range, denoted by x_1) and $15 \ldots 25$Hz (beta range, denoted by x_2). Thus we obtained two time series of 1,200 points.

We fitted our model, with autoregressive order of 1 to the data. The obtained matrices are

$$\mathbf{M}_1 = \begin{pmatrix} 0.23381 & 0.14551 \\ 0.10838 & 0.14314 \end{pmatrix} \tag{17}$$

$$\mathbf{B}_0 = \begin{pmatrix} 0 & -0.65768 \\ 0.56722 & 0 \end{pmatrix} \tag{18}$$

$$\mathbf{B}_1 = \begin{pmatrix} 0.30509 & 0.23965 \\ -0.024244 & 0.060608 \end{pmatrix} \tag{19}$$

What we see is that the instantaneous model is far from trivial: the effects in $\mathbf{B}_0$ are relatively strong. This is also reflected in $\mathbf{B}_1$ which is now rather different from $\mathbf{M}_1$. Thus, the interpretation of the autoregressive matrices using just the autoregressive model (i.e. $\mathbf{M}_1$) or the combined model (i.e. $\mathbf{B}_1$) are quite different. In the classic autoregressive case (based on $\mathbf{M}_1$), the lagged effect $x_1 \to x_2$ is relatively strongly positive whereas in the combined model it is quite weak. In fact, that effect is now modelled as an instantaneous effect in $\mathbf{B}_0$. Even more interesting is that the instantaneous model has a strong negative effect $x_2 \to x_1$ which is not visible at all in the purely autoregressive matrix $\mathbf{M}_1$. Thus, the results illustrate how the interpretation of causal effects (and even of the lagged ones) can change drastically when including the instantaneous effects.

Using an autoregressive order of 2 did not change the results. We also ran the method many times to exclude the problem of the ICA estimation algorithm (used in LiNGAM estimation) getting stuck in local minima (Himberg et al., 2004), and the result was found to be robust with respect to that manipulation.

One problem with this experiment is that the causal model estimated by LiNGAM is far from acyclic. Here, we can justify the procedure by using the theory of cyclic model estimation proposed by (Lacerda et al., 2008); the estimation here gives the only "stable" model according to that theory. Performance of LiNGAM estimation methods in the case of cyclic models, and the possible need for new methods for estimating cyclic models are future research topics of great practical importance. However, as discussed above, they are separate from the main contribution of our paper in the sense that we can use any such new method to estimate the instantaneous model in our framework.

8. Conclusion

We showed how non-Gaussianity enables estimation of a causal discovery model in which the linear effects can be either instantaneous or time-lagged. Like in the purely instantaneous case (Shimizu et al., 2006), non-Gaussianity makes the model identifiable without explicit prior assumptions on existence or non-existence of given causal effects. The classic assumption of acyclicity is sufficient although probably not necessary. From the practical viewpoint, an important implication is that considering instantaneous effects changes the coefficient of the time-lagged effects as well.

Hierarchical Model-Based Reinforcement Learning: R-MAX + MAXQ

Nicholas K. Jong NKJ@CS.UTEXAS.EDU
Peter Stone PSTONE@CS.UTEXAS.EDU
The University of Texas at Austin, 1 University Station, Austin, TX 78712 USA

Abstract

Hierarchical decomposition promises to help scale reinforcement learning algorithms naturally to real-world problems by exploiting their underlying structure. Model-based algorithms, which provided the first finite-time convergence guarantees for reinforcement learning, may also play an important role in coping with the relative scarcity of data in large environments. In this paper, we introduce an algorithm that fully integrates modern hierarchical and model-learning methods in the standard reinforcement learning setting. Our algorithm, R-MAXQ, inherits the efficient model-based exploration of the R-MAX algorithm and the opportunities for abstraction provided by the MAXQ framework. We analyze the sample complexity of our algorithm, and our experiments in a standard simulation environment illustrate the advantages of combining hierarchies and models.

1. Introduction

Reinforcement Learning (RL) algorithms tackle a very challenging problem: how to find rewarding behaviors in unknown environments (Sutton & Barto, 1998). An important goal of RL research is to generalize these algorithms to structured representations and to learn from limited experience. In this paper, we develop an algorithm that integrates two important branches of RL research that, despite their popularity, have rarely been studied in tandem.

The first of these two branches is hierarchical RL. Humans cope with the extraordinary complexity of the real world in part by thinking hierarchically, and we would like to imbue our learning algorithms with the same faculty. In the RL community, this impetus has taken shape as work on temporal abstraction, in which temporally extended abstract actions allow agents to reason above the level of primitive actions (Barto & Mahadevan, 2003). The advantages of such methods include the ability to incorporate prior knowledge and the creation of opportunities for state abstraction. Recent work in the automatic discovery of hierarchy has focused on the ability to focus exploration in novel regions of the state space (Şimşek & Barto, 2004).

The second branch is model-based RL, which directly estimates a model of the environment and then plans with this model. Early work demonstrated that summarizing an agent's experience into a model could be an efficient way to reuse data (Moore & Atkeson, 1993), and later work utilized the uncertainty in an agent's model to guide exploration, yielding the first (probabilistic) finite bounds on the amount of data required to learn near-optimal behaviors in the general case (Kearns & Singh, 1998; Kakade, 2003).

Few RL researchers have tried to combine these two approaches, despite the intuitive appeal of learning hierarchical models of the world. Prior work includes adaptations to the average-reward formulation (Seri & Tadepalli, 2002) and to deterministic domains (Diuk et al., 2006). In this paper, we introduce an algorithm that fully integrates modern hierarchical-decomposition and model-learning methods in the standard setting of discounted rewards and stochastic dynamics. Section 2 details how we decompose high-level models into lower-level models. Section 3 presents our algorithm, which joins our model decomposition with the R-MAX approach to learning primitive models. In Section 4, we formally analyze our algorithm, R-MAXQ. Section 5 describes our empirical results. In Section 6 we discuss related work more fully, and in Section 7 we conclude.

2. Hierarchies of Models

We begin by describing our recursive action decomposition, which defines how we plan at the high level given learned models of primitive actions. Section 3 presents a complete algorithm obtained by combining this decomposition with a particular way of learning primitive models.

We adopt the standard semi-Markov decision process (SMDP) formalism for describing temporally extended actions (Sutton et al., 1999), but we modify the notation to

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

better reflect the recursive nature of hierarchical RL. We define an SMDP as the conjunction $\langle S, A\rangle$ of a finite state space S and a finite action set A. Each action $a \in A$ is associated with a transition function P^a and a reward function R^a. For convenience, we use a *multi-time* model (Sutton et al., 1999), so $P^a(s,s') = \sum_{k=1}^{\infty} \gamma^k \Pr(k, s' \mid s, a)$, where $\gamma \in (0,1)$ is a discount factor and $\Pr(k, s' \mid s, a)$ is the probability that executing action $a \in A$ in state $s \in S$ will take exactly k time steps and terminate in state $s' \in S$. Similarly, $R^a(s) = E\left[\sum_{k=0}^{\infty} \gamma^k r_k\right]$, where r_k is the one-step reward earned during the kth time step executing a.

If $a \in A$ is a *primitive action*, then it will always terminate after exactly one time step, so $\sum_{s'} P^a(s,s') = \gamma$ for all $s \in S$. Since we may construe a discount factor of γ as equivalent to terminating a trajectory with probability $1-\gamma$ after each time step, the "missing" transition probability corresponds to the probability of termination.

In the RL setting, each P^a and R^a is initially unknown, but for each $a \in A$ that is a *composite action*, we assume the agent is given a set of terminal states $T^a \subset S$, a set of child actions A^a, and a goal reward function $\tilde{R}^a : T^a \to \mathbb{R}$. A composite action a may be invoked in any state $s \in S \setminus T^a$, and upon reaching a state $s' \in T^a$ it terminates and earns an internal reward of $\tilde{R}^a(s')$. It executes by repeatedly choosing child actions $a' \in A^a$ to invoke. The child actions a' may be primitive or composite. When a' terminates (and assuming a does not terminate), then a selects another child action. (In contrast to the original MAXQ framework, a composite action a only tests for termination upon the termination of a child action a'.) A composite action a selects child actions to maximize the expected sum of the child action rewards $R^{a'}$ and the goal rewards $\tilde{R}^a$.

Given the transition and reward functions for each of the child actions, the optimal policy for the composite action a may be computed using the following system of Bellman equations, for all $s \in S$ and $a' \in A^a$:

$$Q^a(s,a') = R^{a'}(s) + \sum_{s' \in S} P^{a'}(s,s') V^a(s') \quad (1)$$

$$V^a(s) = \begin{cases} \tilde{R}^a(s), & \text{if } s \in T^a \\ \max_{a' \in A^a(s)} Q^a(s,a'), & \text{otherwise,} \end{cases} \quad (2)$$

where $A^a(s) = \left\{ a' \in A^a \mid \text{primitive}(a') \vee s \notin T^{a'} \right\}$. Then the optimal policy $\pi^a : S \to A^a$ is, for all $s \in S$:

$$\pi^a(s) = \text{argmax}_{a' \in A^a(s)} Q^a(s,a'). \quad (3)$$

Dietterich's MAXQ framework computes $Q^a(s,a')$ by decomposing this quantity into $Q^a(s,a') = R^{a'}(s) + C^a(s,a')$, where C^a is a *completion function* that estimates the reward obtained after executing a' but before completing a. It recursively queries the child action for $R^{a'}$ and learns C^a locally using model-free stochastic approximation. Using the learned π^a, it simultaneously learns an external version of C^a that doesn't include the internal goal rewards $\tilde{R}^a$, so that a can report R^a to its own parents.

The key idea behind our model-based approach is to assume that a composite action a can query a child a' for not just $R^{a'}$ but also $P^{a'}$. Then the only unknown quantity in Equation 1 is V^a, which can be computed using standard dynamic programming methods and stored locally. To satisfy our assumption, each action a, whether primitive or composite, must be able to compute both R^a and P^a. Prior research into option models (Sutton et al., 1999) defined Bellman-like equations, for all $s \in S$ and $x \in T^a$:

$$R^a(s) = R^{\pi^a(s)}(s) + \sum_{s' \in S \setminus T^a} P^{\pi^a(s)}(s,s') R^a(s') \quad (4)$$

$$P^a(s,x) = P^{\pi^a(s)}(s,x) + \sum_{s' \in S \setminus T^a} P^{\pi^a(s)}(s,s') P^a(s',x), \quad (5)$$

and for all $s \in S$ and $x \in S \setminus T^a$, $P^a(s,x) = 0$. Since P^a is a multi-time model, note that $\sum_{s'} P^a(s,s') < \gamma < 1$, where the "missing" transition probability corresponds to the cumulative $1-\gamma$ probability of terminating (the entire trajectory, not just a) marginalized over the random duration of the execution of a. A key strength of our algorithm is that it takes advantage of models to solve Equations 4 and 5 directly using dynamic programming, instead of using these equations to define update rules for stochastic approximation, as in prior work with option models.

Our decomposition provides a way to compute policies and therefore high-level transition and reward models given lower-level transition and reward models. To ground out this process, models of the primitive actions must be available. However, if R^a and P^a are available for each primitive action a, note that we could compute the optimal policy of the system using standard (non-hierarchical) planning algorithms. Nevertheless, we empirically demonstrate the benefit of using hierarchies in Section 5. The next section first presents our learning algorithm.

3. The R-MAXQ Algorithm

Equations 1–5 show how to compute abstract models from primitive models, but a complete model-based RL algorithm must specify how to estimate the primitive models. We propose combining our hierarchical model decomposition, inspired by the MAXQ value function decomposition, with the primitive models defined by the R-MAX algorithm (Brafman & Tennenholtz, 2002), yielding a new algorithm we call R-MAXQ.

R-MAX defines the transition and reward models for primitive actions as follows. Let $n(s,a)$ denote the number of times primitive action a has executed in state s. Let

$n(s,a,s')$ denote the number of times primitive action a transitioned state s to state s'. Finally, let $r(s,a)$ denote the cumulative one-step reward earned by each execution of primitive action a in state s. Then the primitive transition and reward models are given by:

$$R^a(s) = \begin{cases} \frac{r(s,a)}{n(s,a)}, & \text{if } n(s,a) \geq m \\ V^{\max}, & \text{otherwise,} \end{cases} \quad (6)$$

$$P^a(s,s') = \begin{cases} \frac{n(s,a,s')}{n(s,a)}, & \text{if } n(s,a) \geq m \\ 0, & \text{otherwise,} \end{cases} \quad (7)$$

where $V^{\max}$ is an upper bound on the optimal value function and m is a threshold sample size.[1] Given sufficient data, R-MAX uses the maximum likelihood model, but it otherwise uses an optimistic model that predicts a high-reward terminal transition.[2] By backing up these optimistic rewards through the value function, the learned policy effectively plans to visit insufficiently explored states.

R-MAXQ works in the same way, except it computes a hierarchical value function using its model decomposition instead of a monolithic value function using the standard MDP model. Optimistic rewards propagate not only through the value function V^a at a given composite action a but also up the hierarchy, via each action's computed abstract reward function R^a. Each local policy implicitly exploits or explores by choosing a child action with high apparent value, which combines the child's actual value and possibly some optimistic bonus due to some reachable unknown states. No explicit reasoning about exploration is required at any of the composite actions in the hierarchy: as in R-MAX, the planning algorithm is oblivious to its role in balancing exploration and exploitation in a learning agent. A key advantage of R-MAXQ is that its hierarchy allows it to constrain the agent's policy in a fashion that may reduce unnecessary exploratory actions, as illustrated in Section 5.

Algorithms 1–4 give the R-MAXQ algorithm in detail. All variables are global, except for the arguments a and s, which represent the action and state passed to each subroutine. All global variables are initialized to 0, except that $R^a(s)$ is initialized to $V^{\max}$ for all primitive actions a and states s. Algorithm 1 is the main algorithm, invoked with the root action in the hierarchy and the initial state of the system. MAXQ recursively executes an action a in the current state s, returning the resulting state $s' \in T^a$. Primitive actions execute blindly; composite actions first update their policy and then choose a child action to execute, until some child leaves it in a terminal state.

Algorithm 1 R-MAXQ(a,s)

```
if a is primitive then
  Execute a, obtain reward r, observe state s'
  r(s,a) ← r(s,a) + r                    {record primitive data}
  n(s,a) ← n(s,a) + 1
  n(s,a,s') ← n(s,a,s') + 1
  t ← t + 1
  Return s'
else {a is composite}
  repeat
    COMPUTE-POLICY(a,s)
    s ← R-MAXQ(π^a(s), s)                {recursive execution}
  until s ∈ T^a                          {or episode ends}
  Return s
end if
```

Algorithm 2 updates the policy for composite action a given that the agent is in state s. It first constructs a *planning envelope*: all the states reachable from s (at this node of the hierarchy) and thus relevant to the value of s. Once the planning envelope has been computed and all the child actions' models have been updated on the envelope, the value function and policy could be computed using value iteration. Note that our implementation actually uses prioritized sweeping (Moore & Atkeson, 1993) and aggressive memoization, not shown in our pseudocode, to ameliorate the computational burden of propagating incremental model changes throughout the hierarchy.

Algorithm 2 COMPUTE-POLICY(a,s)

```
if timestamp(a) < t then
  timestamp(a) ← t
  envelope(a) ← ∅
end if
PREPARE-ENVELOPE(a,s)
while not converged do {value iteration}
  for all s' ∈ envelope(a) do
    for all a' ∈ A^a(s') do
      Set Q^a(s',a') using Eq. 1
    end for
    Set V^a(s') using Eq. 2
  end for
end while
π^a(s) ← argmax_{a'∈A^a(s)} Q^a(s,a')   {Eq. 3}
```

Algorithm 3 computes the planning envelope for composite action a by examining the given state's successors under any applicable child action's transition model and recur-

[1] The original Prioritized Sweeping algorithm (Moore & Atkeson, 1993) used the same optimistic one-step model, but its name became identified with its method for propagating changes throughout the value function. The primary contribution of the R-MAX algorithm was a derivation of the appropriate value of m given the desired error bounds.

[2] In effect, setting all the transition probabilities to 0 in Equation 5 gives the "missing" probability all to the implicit terminal state. This trick works properly with the Bellman equations since the terminal state has value 0; the optimism is reflected in the reward for transitioning into this state.

sively adding any new states to the envelope. This computation requires that these models be updated, if necessary.

Algorithm 3 PREPARE-ENVELOPE(a, s)

```
if s ∉ envelope(a) then
  envelope(a) ← envelope(a) ∪ {s}
  for all a' ∈ A^a(s) do
    COMPUTE-MODEL(a', s)
    for all s' ∈ S | P^{a'}(s, s') > 0 do
      PREPARE-ENVELOPE(a, s')
    end for
  end for
end if
```

Algorithm 4 updates the model for an action a at some state s. For composite actions, this requires recursively computing the policy and then solving Equations 4 and 5.

Algorithm 4 COMPUTE-MODEL(a, s)

```
if a is primitive then
  if n(s, a) ≥ m then
    R^a(s) ← r(s,a)/n(s,a)                          {Eq. 6}
    for all s' ∈ S do
      P^a(s, s') ← n(s,a,s')/n(s,a)                 {Eq. 7}
    end for
  end if
else {a is composite}
  COMPUTE-POLICY(a, s)
  while not converged do {dynamic programming}
    for all s' ∈ envelope(a) do
      Set R^a(s') using Eq. 4
      for all x ∈ T^a do
        Set P^a(s', x) using Eq. 5
      end for
    end for
  end while
end if
```

4. Analysis of R-MAXQ

We now provide a very rough sketch of our main theoretical result: R-MAXQ probably follows an approximately optimal policy for all but a finite number of time steps. Unfortunately, this number may be exponential in the size of the hierarchy. This section closes with a brief discussion of the implications of this result.

The original R-MAX algorithm achieves efficient exploration by using an optimistic model. Its model of any given state-action pair is optimistic until it samples that state-action m times. By computing a value function from this optimistic model, the resulting policy implicitly trades off exploration (when the value computed for a given state includes optimistic rewards) and exploitation (when the value only includes estimates of the true rewards). Kakade (2003) bounded the sample complexity of RL by first showing that R-MAX probably only spends a finite number of time steps attempting to reach optimistic rewards (exploring). For the remaining (unbounded) number of time steps, the algorithm exploits its learned model, but its exploitation is near-optimal only if this model is sufficiently accurate. Kakade then bounded the values of m necessary to ensure the accuracy of the model with high probability.

To be precise, let an MDP with finite state space S and finite action space A be given. Let ϵ be a desired error bound, δ the desired probability of failure, and γ the discount factor. Then R-MAX applied to an arbitrary initial state will spend $O\left(\frac{m|S||A|L}{\epsilon}\log\frac{|S||A|}{\delta}\right)$ time steps exploring, with probability greater than $1-\frac{\delta}{2}$, where $L = O\left(\frac{\log\epsilon}{1-\gamma}\right)$. Furthermore, there exists an $m \in O\left(\frac{|S|L^2}{\epsilon^2}\log\frac{|S||A|}{\delta}\right)$ such that when the agent is not exploring, $V^{\pi^*}(s_t) - V^{\pi_t}(s_t) \leq \frac{\epsilon}{1-\gamma}(R^{\max} - R^{\min})$ with probability greater than $1-\frac{\delta}{2}$, where s_t and π_t are the current state and policy at time t, and $R^{\max}$ and $R^{\min}$ bound the reward function.

The hierarchical decomposition used by R-MAXQ complicates an analysis of its sample complexity, but essentially the same argument that Kakade used provides a loose bound. We refer the interested reader to the proof of Kakade (2003) for the gross structure of the argument, and we merely sketch the necessary extensions here. A key lemma is Kakade's ϵ-approximation condition (Lemma 8.5.4). The transition model $\hat{P}$ for an action is an ϵ-approximation for the true dynamics P if for all states $s \in S$, $\sum_{s'\in S}\left|\hat{P}(s,s') - P(s,s')\right| < \epsilon$. The ϵ-approximation condition states that if a model has the correct reward function but only an ϵ-approximation of the transition dynamics for each action, then for all policies π and states $s \in S$, $\left|\hat{V}^{\pi}(s) - V^{\pi}(s)\right| < \frac{\epsilon L}{1-\gamma}$.

Essentially, this condition relates the error bounds in the model approximation to the resulting error bounds in the computed value function. It allows the analysis of R-MAX to determine a sufficient value of m to achieve the desired degree of near optimality. We must extend this condition in two ways to adapt the overall proof to R-MAXQ. First, R-MAXQ violates Kakade's assumption of deterministic reward functions. Define a model reward function $\hat{R}$ to be a λ-approximation of the true reward function R if for all states $s \in S$, $\left|\hat{R}(s) - R(s)\right| < \lambda$. Then it is straightforward to adjust Kakade's derivation of the ϵ-approximation condition to show that the computed value function for any given policy satisfies $s \in S$, $\left|\hat{V}^{\pi}(s) - V^{\pi}(s)\right| < \frac{\epsilon L}{1-\gamma} + \lambda$.

Second, for a given composite action a, we must relate error bounds in the approximations of $R^{a'}$ and $P^{a'}$ for each child $a' \in A^a$ to error bounds in the approximations of R^a and P^a. Since R^a is just the value function for π^a but without the goal rewards (Equation 4), we immediately obtain that the estimated R^a will be an $\left(\frac{\epsilon L}{1-\gamma} + \lambda\right)$-approximation. Equation 7 illustrates that for every $s' \in T^a$, $P^a(\cdot, s')$ can be thought of as a value function estimating the expected cumulative discounted probability of transitioning into s'. The total error in $P^a(s, \cdot)$ will be bounded by the sum of the errors for each $s' \in T^a$, so it can be shown that P^a is an $O\left(\frac{|T^a|\epsilon L}{1-\gamma}\right)$-approximation.

These results bound the errors that propagate up from the primitive actions in the hierarchy, but these bounds seem quite loose. In particular, these bounds can't rule out the possibility that each level of the hierarchy might multiply the approximation error by a factor of $\frac{|T^a|L}{1-\delta}$. Since the amount of data required varies as the inverse square of ϵ, if R-MAX requires m samples of each action at each state to achieve a certain error bound, R-MAXQ may require $m' = O\left(m\left(\frac{TL}{1-\delta}\right)^{2h}\right)$ samples of each primitive action at each state to achieve the same error bound at the root of the hierarchy, where T is the maximum number of reachable terminal states for any composite action and h is the height of the hierarchy: the number of composite tasks on the longest path from the root of the hierarchy to a primitive action (not including the root itself).

By adapting the remainder of Kakade's proof, we can establish that R-MAXQ will probably converge to a (recursively) near-optimal policy, although this guarantee requires exponentially more data than R-MAX in the worst case. We note that this guarantee applies to any choice of hierarchy. It remains to be seen whether it might be possible to derive tighter bounds for specific classes of action hierarchies. Furthermore, as Kakade (2003) notes in his derivation, the ϵ-approximation condition is perhaps unnecessarily stringent, since it gives the worst possible degradation in approximation quality over all possible policies.

In practice, implementations of R-MAX use far smaller values of m than would be required to achieve useful theoretical guarantees. In this vein, we note that running R-MAXQ will result in no more time spent in exploration than running R-MAX with the same value for m. The hierarchical decomposition only weakens the guarantees on the near-optimality of the policy that R-MAXQ exploits. The experiments described in the next section show that a good hierarchy can even reduce the amount of time spent exploring, with no appreciable deterioration in solution quality.

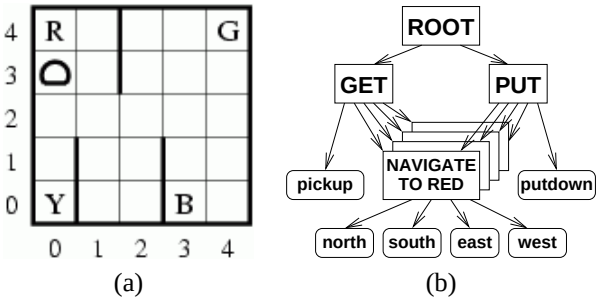

Figure 1. (a) Taxi domain, and (b) an action hierarchy for Taxi

5. Experiments

This section presents our empirical results, which show that R-MAXQ outperforms both of its components, R-MAX and MAXQ-Q. We discuss our findings in detail, to reveal how precisely our algorithm benefits from combining model-based learning and hierarchical decomposition.

For our experiments, we use the familiar Taxi domain (Dietterich, 2000). This domain consists of a 5×5 gridworld with four landmarks, labeled `red`, `blue`, `green`, and `yellow`, illustrated in Figure 1a. The agent is a taxi that must navigate this gridworld to pick up and deliver a passenger. The system has four state variables and six primitive actions. The first two state variables, `x` and `y`, give the coordinates of the taxi in the grid. The third, `passenger`, gives the current location of the passenger as one of the four landmarks or as `taxi`, if the passenger is inside the taxi. The final state variable, `destination`, denotes the landmark where the passenger must go. Four primitive actions, `north`, `south`, `east`, and `west`, each move the taxi in the indicated direction with probability 0.8 and in each perpendicular direction with probability 0.1. The `pickup` action transfers the passenger into the taxi if the taxi is at the indicated landmark. The `putdown` action ends an episode if the passenger is in the taxi and the taxi is at the desired destination. Each episode begins with the taxi in a random location, the passenger at a random landmark, and a destination chosen randomly from the remaining landmarks. Each action incurs a -1 penalty, except that unsuccessful `pickup` and `putdown` actions cost -10, and a successful `putdown` action earns a reward of 20.

The structure of the Taxi domain makes it conducive for research into hierarchical RL. The optimal policy may be described abstractly in four steps. First, navigate to the landmark where the passenger is. Second, pick up the passenger. Third, navigate to the destination landmark. Finally, put down the passenger. Navigation to each of the landmarks constitute reuseable subtasks that hierarchical algorithms can exploit. Dietterich (2000) expressed this domain knowledge in the task hierarchy shown in Figure 1b. This hierarchy defines a navigational composite action for

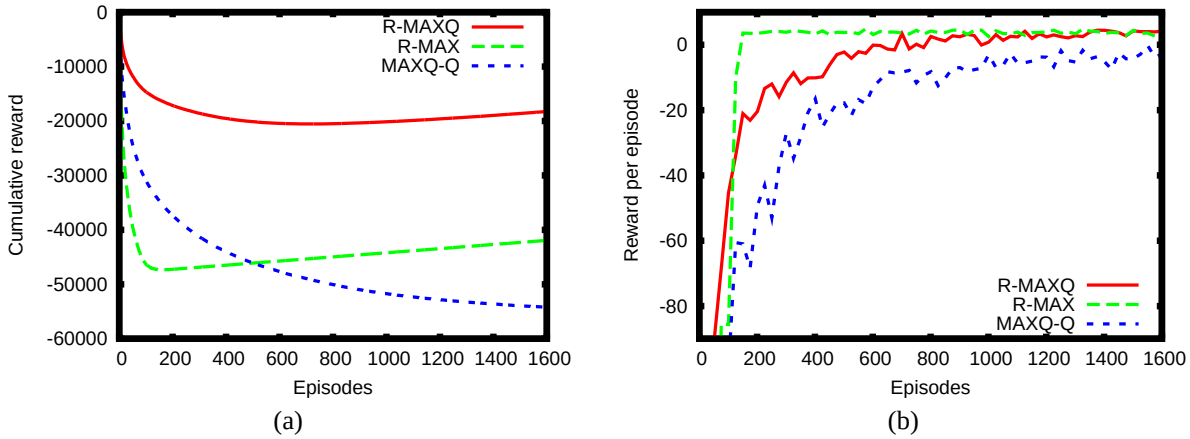

Figure 2. (a) Cumulative and (b) asymptotic performance of R-MAXQ, R-MAX, and MAXQ-Q on the Taxi domain, averaged over 100 independent trials. R-MAXQ and MAXQ-Q utilize the hierarchy shown in Figure 1b, but they do not use any explicit state abstraction.

each of the four landmarks. These actions include the four primitive movement actions as children, and they terminate upon reaching the coordinates corresponding to the respective landmark. The `GET` and `PUT` composite actions each have all four of their navigational composite actions as children, as well as `pickup` or `putdown`, respectively. `GET` terminates when the passenger is in the taxi, and `PUT` terminates only when the episode does. The `ROOT` action only includes `GET` and `PUT` as children, and like `PUT` it defines no terminal states beyond those intrinsic to the domain. All goal reward functions give 0 reward; each action simply minimizes the costs earned before reaching their subgoals.

In our experiments with R-MAX and R-MAXQ we set the threshold sample size at $m = 5$. Preliminary experiments showed that larger values of m did not signicantly improve the final policy, although of course they led to more time spent estimating the model. The only other parameter for these algorithms is the stopping criterion for the dynamic programming steps in Algorithms 2 and 4. In all cases, we ran value iteration until the largest change was smaller than $\epsilon = 0.001$. We provided R-MAXQ and the original MAXQ-Q algorithm with the hierarchy shown in Figure 1b as prior knowledge. For our implementation of MAXQ-Q, we used precisely the hand-tuned parameters Dietterich (2000) optimized for the initial value function, learning rates, and temperature decay (for Boltzmann exploration) for each action in the hierarchy. We conducted 100 independent trials of each condition of our experiments.

5.1. R-MAXQ versus R-MAX

We begin by comparing the performance of R-MAXQ and R-MAX on the Taxi task. Our initial hypothesis was that R-MAXQ would perform no better than R-MAX in the absence of state abstraction, since the model-based ability to plan to explore might subsume the exploratory role that options have played in many model-free RL implementations (Şimşek & Barto, 2004; Singh et al., 2005). Figure 2 reveals that in fact the two algorithms exhibit very different learning curves. In particular, although R-MAX requires many fewer episodes to converge to an optimal policy, R-MAXQ earns much greater total reward.

We had overlooked the fact that the hierarchy used by R-MAXQ doesn't so much guide exploration as it constrains it. In particular, note that the hierarchical agent can never attempt the `putdown` action except at one of the four landmark locations, since the `PUT` action only becomes available when the agent is already at one of these locations, and the four navigational actions keep the agent in this reduced set of states. The agent thus only attempts the `putdown` action in 12 incorrect states, instead of the 396 explored by R-MAX. In addition, R-MAX attempts the `pickup` action in 100 states in which R-MAXQ doesn't, when the passenger is already in the car. Since the penalty for incorrect usage of these actions is -10, R-MAX loses $10(396 - 12 + 100)m = 24200$ reward due to its wasted exploration, accounting for the difference between the two algorithms in Figure 2a. Furthermore, since the `GET` action cannot navigate to an arbitrary location, R-MAXQ can't attempt the `pickup` action in a non-landmark location until some episode randomly starts the agent there. In this case the hierarchy can only postpone, not prevent, wasted exploration. This effect explains the delayed convergence relative to R-MAX: in later episodes R-MAXQ spends time on exploration that R-MAX performed more eagerly.

5.2. R-MAXQ versus MAXQ-Q

Figure 2 also compares R-MAXQ with the original MAXQ-Q algorithm. Of course, this comparison isn't very fair,

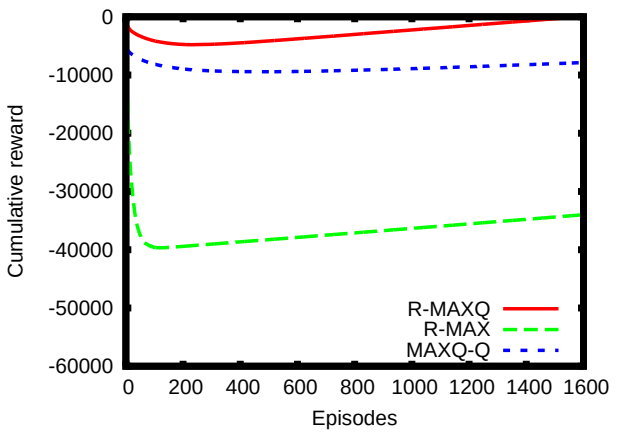

Figure 3. Cumulative performance of R-MAXQ, R-MAX, and MAXQ-Q on the Taxi domain, using state abstraction. (The asymptotic performance is qualitatively similar to that shown in Figure 2b, although with faster convergence.)

since a primary goal of the MAXQ framework was to create opportunities for state abstraction (Dietterich, 2000), which we did not initially exploit. In fact, Dietterich identified the condition described in Section 5.1, which he called shielding, as one that permits abstraction. For a more fair comparison, we allowed our implementation of MAXQ-Q to use all the state abstractions in the Taxi domain identified by Dietterich (2000), along with his optimized parameters.

We applied Dietterich's notion of max node irrelevance to allow R-MAXQ also to enjoy an explicit form of state abstraction as prior knowledge. Each action in the hierarchy abstracts away state variables when our domain knowledge indicates that doing so would not compromise the learned model. However, whereas in MAXQ-Q an action a only reports its abstract reward function R^a to its parents, in R-MAXQ it must also convey the abstract transition function P^a. Thus we only allow a composite action to ignore a state variable if all of its children also ignore that state variable.

In the hierarchy shown in Figure 1b, the four primitive movement actions and the four navigational actions can abstract away the `passenger` and `destination` state variables. `GET` and `pickup` ignore `destination`, and `PUT` and `putdown` ignore `passenger`. However, `ROOT` cannot ignore any state variables. When a child's transition function was more abstract than a parent's model, the parent assumed a very simple dynamic Bayes network (DBN) factorization (Boutilier et al., 1995). For example, $P^{\texttt{north}}$ sets `x` and `y` (each conditional on the previous values of both variables), but `passenger` and `destination` remain constant. Figure 3 compares the performance of the resulting algorithms. Both MAXQ-Q and R-MAXQ learn much faster with state abstraction, with the model-based nature of R-MAXQ continuing to give it an edge.

It is worthwhile to examine more closely how the hierarchy interacts with state abstraction in the Taxi domain. Consider how MAXQ-Q learns the `ROOT` action. The only values stored locally are the completion functions $C^{\texttt{root}}(\cdot, \texttt{GET})$ and $C^{\texttt{root}}(\cdot, \texttt{PUT})$, which have different abstract representations. The latter function is always equal to 0, since after `PUT` terminates there is nothing to complete, since the entire episode has terminated. Meanwhile, to evaluate $C^{\texttt{root}}(s, \texttt{GET})$ the algorithm need only inspect the `passenger` and `destination` variables of s, since the values of these two variables before executing `GET` completely determine the remaining cost of completing `ROOT` after `GET` terminates. Hence, MAXQ-Q only learns 16 values at the `ROOT` node; to compute the value of a state it recursively queries R^a and adds the appropriate completion function (Dietterich, 2000).

R-MAXQ doesn't apply any explicit state abstraction to `ROOT`, but note that after executing either of its two child actions, the result must be one of 12 nonterminal states: with the taxi at one of four landmarks, the passenger in the taxi, and the destination at one of the other three landmarks. Hence, the planning envelope computed in Algorithm 2 will always contain some subset of these 12 states plus the current state. As with MAXQ-Q, the result distribution irrelevance of `GET` allows R-MAXQ to store only a small number of values locally. To compute the value of a state, R-MAXQ also queries one-step values from its children and then adds the appropriate successor state values. In this sense, these 12 states can be thought of as the *completion set* of `ROOT`.

Figure 3 also shows the performance of standard R-MAX with the same DBN factorization as R-MAXQ applied to most of its actions (which are all primitive). Note that in the absence of shielding, `putdown` cannot safely ignore the `passenger` variable. The ability to abstract the primitive models does reduce the amount of exploration that R-MAX must perform, but the improvement is significantly smaller than that of the other algorithms. This result gives more support for motivating hierarchical decomposition with opportunities for state abstraction.

Some preliminary further experiments support the arguments of Jong et al. (2008), who used model-free hierarchical algorithms to suggest that composite actions more reliably improve RL performance when they replace instead of augment primitive actions. We ran R-MAXQ with a hierarchy in which the root's children included all six primitive actions as well as the four navigational composite actions, producing learning curves indistinguishable from those of standard R-MAX in Figure 2. When the root action can execute every primitive action, the planning envelope grows to include too many states. Formalizing the properties of a composite action's completion set may help us understand

how hierarchies can constrain planning envelopes without sacrificing learning performance.

6. Related Work

Other algorithms have combined hierarchical RL with a model-based approach, but not in the standard framework of discounted rewards and stochastic dynamics. Diuk et al. (2006) developed a model-based MAXQ algorithm for deterministic domains, allowing them to quickly sample the effect of a composite action recursively: every action's effect can be represented as a scalar reward and a single successor state. Their algorithm also uses Dietterich's approach to state abstraction, occasionally forcing it to replan, since the effect of a child action may depend on state variables not visible to the parent, making it seem nondeterministic. In contrast, R-MAXQ does not employ explicit state abstraction, allowing it to save the value functions and policies computed during one time step for all future time steps. Our algorithm relies on the choice of hierarchy to yield small planning envelopes, automatically achieving an effective reduction in the size of the state space considered during any one time step.

Seri and Tadepalli (2002) extended the MAXQ framework to average-reward reinforcement learning, resulting in an algorithm that learns a model to facilitate the computation of the bias for each state from the average reward of the current policy. However, the computation of the average reward itself relies on stochastic approximation techniques, and their algorithm does not have any formal guarantees regarding its sample complexity.

7. Conclusions

The R-MAXQ algorithm combines the efficient model-based exploration of R-MAX with the hierarchical decomposition of MAXQ. Although our algorithm does not improve upon the known formal bounds on the sample complexity of RL, it retains a finite-time convergence guarantee. An empirical evaluation demonstrates that even a relatively simple hierarchy can improve the cumulative reward earned by constraining the exploration that the agent performs, both within individual episodes of learning and throughout an agent's experience with its environment. Even in the absence of explicit state abstraction, the structure of an action hierarchy can drastically reduce the effective state space seen by a given composite action during a single episode. This implicit concept of a reduced completion set, mirroring Dietterich's explicitly abstracted completion function, suggests future avenues of research, both for improving the theoretical guarantees on the sample complexity of R-MAXQ and for guiding the discovery of more useful hierarchies.

Abstract

This paper introduces the Banditron, a variant of the Perceptron [Rosenblatt, 1958], for the multiclass bandit setting. The multiclass bandit setting models a wide range of practical supervised learning applications where the learner only receives partial feedback (referred to as "bandit" feedback, in the spirit of multi-armed bandit models) with respect to the true label (e.g. in many web applications users often only provide positive "click" feedback which does not necessarily fully disclose a true label). The Banditron has the ability to learn in a multiclass classification setting with the "bandit" feedback which only reveals whether or not the prediction made by the algorithm was correct or not (but does not necessarily reveal the true label). We provide (relative) mistake bounds which show how the Banditron enjoys favorable performance, and our experiments demonstrate the practicality of the algorithm. Furthermore, this paper pays close attention to the important special case when the data is linearly separable — a problem which has been exhaustively studied in the full information setting yet is novel in the bandit setting.

1. Introduction

In the conventional supervised learning paradigm, the learner has access to a data set in which the true labels of the inputs are provided. While attendant learning algorithms in this paradigm are enjoying wide ranging success, their effective application to a number of domains, including many web based applications, hinges on being able to learn in settings where the true labels are not fully disclosed, but rather the learning algorithm only receives some partial feedback. Important domains include both the (financially important) sponsored advertising on webpages and recommender systems. The typical setting is: first, a user queries the system; then using the query and other potentially rich knowledge the system has about the user (e.g. past purchases, their browsing history, etc.) the system makes a suggestion (e.g. it presents the user with a few ads they might click on or songs they might buy); finally, the user either positively or negatively responds to the suggestion. Crucially, the system does not learn what would have happened had other suggestions been presented.

We view such problems as naturally being online, "bandit" versions of multiclass prediction problems, and, in this paper, we formalize such a model. In essence, this multiclass bandit problem is as follows: at each round, the learner receives an input $\mathbf{x}$ (say the users query, profile, and other high dimensional information); the learner predicts some class label $\hat{y}$ (the suggestion); then the learner receives the limited feedback of only whether the chosen label was correct or not. In the conventional, "full information" supervised learning model, a true label y (possibly more than one or none at all) is revealed to the learner at each round — clearly unrealistic in the aforementioned applications. In both cases, the learner desires to make as few mistakes as possible. The bandit version of this problem is clearly more challenging, since, in addition to the issues ones faces for supervised learning (e.g. learning a mapping from a high dimensional input space to the label space), one also faces balancing exploration and exploitation.

This paper considers the workhorse of hypothesis spaces, namely linear predictors, in the bandit setting. Somewhat surprisingly, while there has been a staggering number of results on (margin based) linear predictors and much recent work on bandit models, the

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

intersection of these two settings is novel and opens a number of interesting (both theoretical and practical) questions, which we consider. In particular, we pay close attention to the important case where the data are linearly separable, where, in the full information setting, the (efficient) Perceptron algorithm makes a number of mistakes that is asymptotically bounded (so the actual error rate will rapidly converge to 0).

There are a number of related results in the bandit literature. The Exp4 algorithm (for the "experts" setting) of Auer et al. [1998] and the contextual bandit setting of Langford and Zhang [2007] are both bandit settings where the learner has side information (e.g. the input "x") when making a decision — in fact, our setting can be thought of as a special case of the contextual bandit setting[1]. However, these settings consider abstract hypothesis spaces and do not explicitly consider efficient algorithms. Technically related are the bandit algorithms for online convex optimization of Flaxman et al. [2005], Kleinberg [2004], which attempt to estimate a gradient (for optimization) with only partial feedback. However, these algorithms do not apply due to the subtleties of using the non-convex classification loss, which we discuss at the end of Section 2.

This paper provides an *efficient* bandit algorithm, the Banditron, for multiclass prediction using linear hypothesis spaces, which enjoys a favorable mistake bound. We provide empirical results showing our algorithm is quite practical. For the case where the data is linearly separable, our mistake bound is $O(\sqrt{T})$ in T rounds. We also provide results toward characterizing the optimal achievable mistake bound for the linearly separable case (ignoring efficiency issues here) and introduce some important open questions regarding this issue. In the Extensions section, we also discuss update rules which generalize the Winnow algorithm (for L1 margins) and margin-mistake based algorithms to the bandit setting. We also discuss how our algorithm can be extended to ranking and settings where more than one prediction $\hat{y}$ can be presented to the user (e.g. an advertising setting where multiple ads may be presented).

2. Problem Setting

We now formally define the problem of online multiclass prediction in the bandit setting. Online learning is performed in a sequence of consecutive rounds. On round t, the learner is given an instance vector $\mathbf{x}_t \in \mathbb{R}^d$ and is required to predict a label out of a set of k predefined labels which we denote by $[k] = \{1, \ldots, k\}$. We denote the predicted label by $\hat{y}_t$. In the full information case, after predicting the label, the learner receives the correct label associated with $\mathbf{x}_t$, which we denote by $y_t \in [k]$. We consider a bandit setting, in which the feedback received by the learner is $\mathbf{1}[\hat{y}_t \neq y_t]$, where $\mathbf{1}[\pi]$ is 1 if predicate π holds and 0 otherwise. That is, the learner knows if it predicted an incorrect label, but it does not know the identity of the correct label. The learner's ultimate goal is to minimize the number of prediction mistakes, M, it makes along its run, where:

$$M = \sum_{t=1}^{T} \mathbf{1}[\hat{y}_t \neq y_t] \quad .$$

To make M small, the learner may update its prediction mechanism after each round so as to be more accurate in later rounds.

The prediction of the algorithm at round t is determined by a hypothesis, $h_t : \mathbb{R}^d \to [k]$, where h_t is taken from a class of hypotheses $\mathcal{H}$. In this paper we focus on the class of margin based linear hypotheses. Formally, each $h \in \mathcal{H}$ is parameterized by a matrix of weights $W \in \mathbb{R}^{k \times d}$ and is defined to be:

$$h(\mathbf{x}) \;=\; \operatorname*{argmax}_{j \in [k]} \; (W\mathbf{x})_j \quad , \tag{1}$$

where $(W\mathbf{x})_j$ is the jth element of the vector obtained by multiplying the matrix W with the vector $\mathbf{x}$. Since each hypothesis is parameterized by a weight matrix, we refer to a matrix W also as a hypothesis — by that we mean that the prediction is defined as given in Eq. (1). To evaluate the performance of a weight matrix W on an example $(\mathbf{x}, y)$ we check whether W makes a prediction mistake, namely determine if $\arg\max_j (W\mathbf{x})_j \neq y$.

The class of margin based linear hypotheses for multiclass learning has been extensively studied in the full information case [Duda and Hart, 1973, Vapnik, 1998, Weston and Watkins, 1999, Elisseeff and Weston, 2001, Crammer and Singer, 2003]. Our starting point is a simple adaptation of the Perceptron algorithm [Rosenblatt, 1958] for multiclass prediction in the full information case (this adaptation is called Kesler's construction in [Duda and Hart, 1973, Crammer and Singer, 2003]). Despite its age and simplicity, the Perceptron has proven to be quite effective in practical problems, even when compared to state-of-the-art large margin algorithms [Freund and Schapire, 1999]. We denote by W^t the weight matrix used by the Perceptron at round t. The Perceptron starts with the all

[1] The contextual bandit setting can be thought of as a general cost sensitive classification problem with bandit feedback. While their setting is an i.i.d. one, we make no statistical assumptions.

zero matrix $W^1 = \mathbf{0}$ and updates it as follows

$$W^{t+1} \;=\; W^t + U^t \quad , \tag{2}$$

where $U^t \in \mathbb{R}^{k\times d}$ is the matrix defined by

$$U^t_{r,j} \;=\; x_{t,j}\left(\mathbf{1}[y_t = r] - \mathbf{1}[\hat{y}_t = r]\right) . \tag{3}$$

In other words, if there is no prediction mistake (i.e. $y_t = \hat{y}_t$), then there is no update (i.e. $W^{t+1} = W^t$), and if there is a prediction mistake, then $\mathbf{x}_t$ is added to the y_tth row of the weight matrix and subtracted from the $\hat{y}_t$th row of the matrix.

A relative mistake bound can be proven for the multiclass Perceptron algorithm. The difficulty with providing mistake bounds for any (efficient) algorithm in this setting stems from the fact that the classification loss is non-convex. Hence, performance bounds are commonly evaluated using the multiclass *hinge-loss* — what might be thought of as a convex relaxation of the classification loss. In particular, the hinge-loss of W on $(\mathbf{x}, y)$ is defined as follows:

$$\ell(W;(\mathbf{x},y)) \;=\; \max_{r\in[k]\setminus\{y\}} [1 - (W\mathbf{x})_y + (W\mathbf{x})_r]_+ \quad , \tag{4}$$

where $[a]_+ = \max\{a, 0\}$ is the hinge function. The hinge-loss will be zero only if $(W\mathbf{x})_y - (W\mathbf{x})_r \geq 1$ for all $r \neq y$. The difference $(W\mathbf{x})_y - (W\mathbf{x})_r$ is a generalization of the notion of *margin* from binary classification. Let $\hat{y} = \text{argmax}_r (W\mathbf{x})_r$ be the prediction of W. Note that if $\hat{y} \neq y$ then $\ell(W;(\mathbf{x},y)) \geq 1$. Thus, the hinge-loss is a convex upper bound on the zero-one loss function, $\ell(\mathbf{w};(\mathbf{x},y)) \geq \mathbf{1}[\hat{y} \neq y]$.

The Perceptron mistake bound holds for any sequence of examples and compares the number of mistakes made by the Perceptron with the cumulative hinge-loss of any fixed weight matrix $W^\star$, even one defined with prior knowledge of the sequence. Formally, let $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$ be a sequence of examples and assume for simplicity that $\|\mathbf{x}_t\| \leq 1$ for all t. Let $W^\star$ be any fixed weight matrix. We denote by

$$L = \sum_{t=1}^{T} \ell(W^\star;(\mathbf{x}_t, y_t)) \quad , \tag{5}$$

the cumulative hinge-loss of $W^\star$ over the sequence of examples and by

$$D = 2\,\|W^\star\|_F^2 = 2\sum_{r=1}^{k}\sum_{j=1}^{d}(W^\star_{i,j})^2 \quad , \tag{6}$$

the *complexity* of $W^\star$. Here $\|\cdot\|_F^2$ denotes the Frobenius norm. Then the number of prediction mistakes of the multiclass Perceptron is at most,

$$M \;\leq\; L + D + \sqrt{L\,D} \quad . \tag{7}$$

Algorithm 1 The Banditron

Parameters: $\gamma \in (0, 0.5)$
Initialize $W^1 = \mathbf{0} \in \mathbb{R}^{k\times d}$
for $t = 1, 2, \ldots, T$ **do**
  Receive $\mathbf{x}_t \in \mathbb{R}^d$
  Set $\hat{y}_t = \arg\max_{r\in[k]} (W^t\mathbf{x}_t)_r$
  $\forall r \in [k]$ define $P(r) = (1-\gamma)\mathbf{1}[r = \hat{y}_t] + \frac{\gamma}{k}$
  Randomly sample $\tilde{y}_t$ according to P
  Predict $\tilde{y}_t$ and receive feedback $\mathbf{1}[\tilde{y}_t = y_t]$
  Define $\tilde{U}^t \in \mathbb{R}^{k\times d}$ such that:
    $\tilde{U}^t_{r,j} = x_{t,j}\left(\frac{\mathbf{1}[y_t=\tilde{y}_t]\mathbf{1}[\tilde{y}_t=r]}{P(r)} - \mathbf{1}[\hat{y}_t = r]\right)$
  Update: $W^{t+1} = W^t + \tilde{U}^t$
end for

A proof of the above mistake bound can be found for example in Fink et al. [2006]. The mistake bound in Eq. (7) consists of three terms: the loss of $W^\star$, the complexity of $W^\star$, and a sub-linear term which is often negligible. In particular, when the data is separable (i.e. $L = 0$), the number of mistakes is bounded by D.

Unfortunately, the Perceptron's update cannot be implemented in the bandit setting as we do not know the identity of y_t. One direction is to work directly with the hinge-loss (which is convex) and try to use the bandit algorithms for online convex optimization of Flaxman et al. [2005], Kleinberg [2004]. In this work, they attempt to find an unbiased estimate of the gradient using only bandit feedback (i.e. using only the loss received as feedback). However, since the only feedback the learner receives is $\mathbf{1}[\hat{y}_t \neq y_t]$, one does not necessarily even know the hinge-loss for the chosen decision, $\hat{y}_t$, due to dependence of the hinge loss on the true label y_t. Hence, the results of Flaxman et al. [2005], Kleinberg [2004] are not directly applicable.

3. The Banditron

We now present the Banditron in Algorithm 1, which is an adaptation of the multiclass Perceptron for the bandit case.

Similar to the Perceptron, at each round we let $\hat{y}_t$ be the best label according to the current weight matrix W^t, i.e. $\hat{y}_t = \text{argmax}_r (W^t\mathbf{x}_t)_r$. Most of the time the Banditron exploits the quality of the current weight matrix by predicting the label $\hat{y}_t$. Unlike the Perceptron, if $\hat{y}_t \neq y_t$, then we can not make an update since we are blind to the identity of y_t. Roughly speaking, it is difficult to learn when we exploit using W^t. For this reason, on some of the rounds we let the algorithm explore (with probability $1-\gamma$) and uniformly predict a random label from $[k]$. We denote by $\tilde{y}_t$ the

predicted label. On rounds in which we explore, (so $\tilde{y}_t \neq \hat{y}_t$), if we additionally receive a positive feedback, i.e. $\tilde{y}_t = y_t$, then we indirectly obtain the full information regarding the identity of y_t, and we can therefore update our weight matrix using this positive instance. The parameter γ controls the exploration-exploitation tradeoff.

The above intuitive argument is formalized by defining the update matrix $\tilde{U}^t$ to be a function of the randomized prediction $\tilde{y}_t$. We emphasize that $\tilde{U}^t$ accesses the correct label y_t only through the indicator $\mathbf{1}[y_t = \tilde{y}_t]$ and is thus adequate for the Bandit setting. As we show later in Lemma 4, the expected value of the Banditron's update matrix $\tilde{U}^t$ is exactly the Perceptron's update matrix U^t. While there a number of other variants which also perform unbiased updates, we have found this one provides the most favorable performance (empirically speaking).

The following theorem provides a bound on the expected number of mistakes the Banditron makes.

Theorem 1. *(Mistake Bound). Assume that for the sequence of examples, $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)$, we have, for all t, $\mathbf{x}_t \in \mathbb{R}^d$, $\|\mathbf{x}_t\| \leq 1$, and $y_t \in [k]$. Let $W^\star$ be any matrix, let L be the cumulative hinge-loss of $W^\star$ as defined in Eq. (5), and let D be the complexity of $W^\star$ (i.e. $D = 2||W^\star||_F^2$). Then the number of mistakes M made by the Banditron satisfies*

$$\mathbb{E}[M] \;\leq\; L + \gamma\, T + 3 \max\left\{ \tfrac{k\, D}{\gamma}\,,\, \sqrt{D\, \gamma\, T} \right\} + \sqrt{\tfrac{k\, D\, L}{\gamma}} \quad .$$

where expectation is taken with respect to the randomness of the algorithm.

Before turning to the proof of Thm. 1 let us first optimize the exploration-exploitation parameter γ in different scenarios. First, assume that the data is separable, that is $L = 0$. In this case, we can obtain a mistake bound of $O(\sqrt{T})$. In fact the following corollary shows that an $O(\sqrt{T})$ bound is achievable whenever the cumulative hinge-loss of $W^\star$ is small enough.

Corollary 2 (Low noise)**.** *Assume that the conditions stated in Thm. 1 hold and that there exists $W^\star$ with fixed complexity D and loss $L \leq O(\sqrt{D\, k\, T})$. Then, by setting $\gamma = \sqrt{k\, D/T}$ we obtain the bound $\mathbb{E}[M] \leq O(\sqrt{k\, D\, T})$.*

Next, let us consider the case where we have a constant (average) noise level of ρ, i.e. there exists $\rho \in (0, 1)$ such that $L \leq \rho T$. In this case,

Corollary 3 (High noise)**.** *Assume that the conditions stated in Thm. 1 hold and that there exists $W^\star$ with fixed complexity D and loss $L \leq \rho\, T$ for a constant $\rho \in (0, 1)$. Then, by setting $\gamma = \rho\, (k\, D/T)^{1/3}$ we obtain the bound $\mathbb{E}[M] \leq \rho T\, (1+\epsilon)$ where $\epsilon = O((k\, D)^{1/3}\, T^{-1/3})$.*

We note that the bound in the above corollary can be also written in an additive form as: $\mathbb{E}[M] - L \leq O(T^{2/3})$. However, since we are not giving proper regret bounds as we compare mistakes to hinge-loss we prefer to directly bound $\mathbb{E}[M]$.

Analysis: To prove Thm. 1 we first show that the random matrix $\tilde{U}^t$ is an unbiased estimator of the update matrix U^t used by the Perceptron. Formally, let $\mathbb{E}_t[\tilde{U}^t]$ be the expected value of $\tilde{U}^t$ conditioned on $\tilde{y}_1, \ldots, \tilde{y}_{t-1}$. Then:

Lemma 4. *Let $\tilde{U}^t$ be as defined in Algorithm 1 and let U^t be as defined in Eq. (3). Then, $\mathbb{E}_t[\tilde{U}^t] = U^t$.*

Proof. For each $r \in [k]$ and $j \in [d]$ we have

$$\begin{aligned} \mathbb{E}_t[\tilde{U}^t_{r,j}] \;&=\; \sum_{i=1}^{k} P(i) x_{t,j} \left(\tfrac{\mathbf{1}[i=y_t]\mathbf{1}[i=r]}{P(r)} - \mathbf{1}[\hat{y}_t = r] \right) \\ &=\; x_{t,j}\, (\mathbf{1}[y_t = r] - \mathbf{1}[\hat{y}_t = r]) \;=\; U^t_{r,j} \quad , \end{aligned}$$

which completes the proof. □

Next, we bound the expected squared norm of $\tilde{U}^t$.

Lemma 5. *Let $\tilde{U}^t$ be as defined in Algorithm 1. Then,*

$$\mathbb{E}_t[\, \|\tilde{U}^t\|_F^2\,] \leq 2\, \|\mathbf{x}_t\|^2 \left(\tfrac{k}{\gamma}\, \mathbf{1}[y_t \neq \hat{y}_t] + \gamma\, \mathbf{1}[y_t = \hat{y}_t] \right) \quad .$$

Proof. We first observe that

$$\|\tilde{U}^t\|_F^2 \;=\; \begin{cases} \|\mathbf{x}_t\|^2 \left(\frac{1}{P(y_t)^2} + 1 \right) & \text{if } \tilde{y}_t = y_t \neq \hat{y}_t \\ \|\mathbf{x}_t\|^2 \left(\frac{1}{P(y_t)} - 1 \right)^2 & \text{if } \tilde{y}_t = y_t = \hat{y}_t \\ \|\mathbf{x}_t\|^2 & \text{if } \tilde{y}_t \neq y_t \end{cases}$$

Therefore, if $y_t \neq \hat{y}_t$ then

$$\begin{aligned} \frac{\mathbb{E}_t[\|\tilde{U}^t\|_F^2]}{\|\mathbf{x}_t\|^2} \;&=\; P(y_t) \left(\tfrac{1}{P(y_t)^2} + 1 \right) + (1 - P(y_t)) \\ &=\; 1 + \tfrac{1}{P(y_t)} = 1 + \tfrac{k}{\gamma} \leq \tfrac{2k}{\gamma} \quad , \end{aligned}$$

and if $y_t = \hat{y}_t$ then

$$\begin{aligned} \frac{\mathbb{E}_t[\|\tilde{U}^t\|_F^2]}{\|\mathbf{x}_t\|^2} \;&=\; P(y_t) \left(\tfrac{1}{P(y_t)} - 1 \right)^2 + (1 - P(y_t)) \\ &=\; \tfrac{1}{P(y_t)} - 1 \leq \tfrac{1}{1-\gamma} - 1 \leq \tfrac{\gamma}{1-\gamma} \leq 2\gamma \quad . \end{aligned}$$

Combining the two cases concludes our proof. □

Equipped with the above two lemmas, we are ready to prove Thm. 1.

Proof of Thm. 1. Throughout the proof we use the notation $\langle W^\star, W^t \rangle := \sum_{r=1}^{k} \sum_{j=1}^{d} W^\star_{r,j} W^t_{r,j}$. We prove the theorem by bounding $\mathbb{E}[\langle W^\star, W^{T+1} \rangle]$ from above and from below starting with a lower bound. We can first use the fact that $W^1 = \mathbf{0}$ to rewrite $\mathbb{E}[\langle W^\star, W^{T+1} \rangle]$ as $\sum_{t=1}^{T} \Delta_t$ where

$$\Delta_t := \mathbb{E}[\langle W^\star, W^{t+1} \rangle] - \mathbb{E}[\langle W^\star, W^t \rangle] \ .$$

Expanding the definition of W^{t+1} and using Lemma 4 we obtain that for all t, $\Delta_t = \mathbb{E}[\langle W^\star, \tilde{U}^t \rangle] = \mathbb{E}[\langle W^\star, U^t \rangle]$. Next, we note that the definition of the hinge-loss given in Eq. (4) implies that the following holds regardless of the value of $\hat{y}_t$

$$\ell(W^\star, (\mathbf{x}_t, y_t)) \ \geq \ \mathbf{1}[\hat{y}_t \neq y_t] - \langle W^\star, U^t \rangle \ .$$

Therefore $\Delta_t \geq \mathbb{E}[\, \mathbf{1}[\hat{y}_t \neq y_t] \,] - \ell(W^\star, (\mathbf{x}_t, y_t))$. Summing over t we obtain the lower bound

$$\mathbb{E}[\langle W^\star, W^{T+1} \rangle] \ = \ \sum_{t=1}^{T} \Delta_t \ \geq \ \mathbb{E}[\hat{M}] - L \ , \qquad (8)$$

where $\hat{M} := \sum_{t=1}^{T} \mathbf{1}[\hat{y}_t \neq y_t]$ and L is as defined in Eq. (5). Next, we show an upper bound on $\mathbb{E}[\langle W^\star, W^{T+1} \rangle]$. Using Cauchy-Schwartz inequality we have $\langle W^\star, W^{T+1} \rangle \leq \|W^\star\|_F \, \|W^{T+1}\|_F$. To ease our notation, we use the shorthand $\|\cdot\|$ for denoting the Frobenius norm. Using the definition of D given in Eq. (6), the concavity of the sqrt function, and Jensen's inequality we obtain that

$$\mathbb{E}[\langle W^\star, W^{T+1} \rangle] \leq \sqrt{\tfrac{D \, \mathbb{E}[\, \|W^{T+1}\|^2 \,]}{2}} \ . \qquad (9)$$

We therefore need to upper bound the expected value of $\|W^{T+1}\|^2$. Expanding the definition of W^{T+1} we get that

$$\begin{aligned} \mathbb{E}[\|W^{T+1}\|^2] &= \mathbb{E}[\|W^T\|^2 + \langle W^T, \tilde{U}^T \rangle + \|\tilde{U}^T\|^2] \\ &= \sum_{t=1}^{T} \Big(\mathbb{E}[\langle W^t, \tilde{U}^t \rangle] + \mathbb{E}[\, \|\tilde{U}^t\|^2 \,] \Big) \ . \end{aligned}$$

Using Lemma 4 we obtain that $\mathbb{E}[\langle W^t, \tilde{U}^t \rangle] = \mathbb{E}[\langle W^t, U^t \rangle] \leq 0$, where the second inequality follows from the definition of U^t and $\hat{y}_t$. Combining this with Lemma 5 and with the assumption $\|\mathbf{x}_t\| \leq 1$ for all t we obtain that

$$\begin{aligned} \mathbb{E}[\|W^{T+1}\|^2] &\leq \sum_{t=1}^{T} \mathbb{E}\left(\tfrac{2k}{\gamma} \mathbf{1}[y_t \neq \hat{y}_t] + 2\gamma \mathbf{1}[y_t = \hat{y}_t] \right) \\ &\leq \tfrac{2k}{\gamma} \, \mathbb{E}[\hat{M}] + 2\,\gamma\, T \ . \end{aligned}$$

Plugging the above into Eq. (9) and using the inequality $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$ we get the upper bound

$$\mathbb{E}[\langle W^\star, W^{T+1} \rangle] \leq \sqrt{\tfrac{D\,k\,\mathbb{E}[\hat{M}]}{\gamma}} + \sqrt{D\,\gamma\,T} \ .$$

Comparing the above upper bound with the lower bound given in Eq. (8) and rearranging terms yield

$$\mathbb{E}[\hat{M}] - \sqrt{\tfrac{D\,k\,\mathbb{E}[\hat{M}]}{\gamma}} - \left(L + \sqrt{D\,\gamma\,T} \right) \leq 0 \ .$$

Standard algebraic manipulations give the bound

$$\mathbb{E}[\hat{M}] \ \leq \ L + \sqrt{\tfrac{D\,k\,L}{\gamma}} + 3 \max\left\{ \tfrac{D\,k}{\gamma} \, , \, \sqrt{D\,\gamma\,T} \right\} \ .$$

Finally, our proof is concluded by noting that in expectation we are exploring no more than γT of the rounds and thus $\mathbb{E}[M] \leq \mathbb{E}[\hat{M}] + \gamma T$. □

4. Mistake Bounds Under Separability

In this section we present results towards characterizing the optimal achievable rate for the case where the data is separable. Here, in the full-information setting, the mistake bound of the Perceptron algorithm is finite and bounded by D. We now present an (inefficient) algorithm showing that the achievable mistake bound in the bandit setting is also finite — thus the Banditron's mistake bound of $O(\sqrt{T})$ leaves significant room for improvement (though the algorithm is quite simple and has reasonable performance, which we demonstrate in the next section).

First, as a technical tool, we make the interesting observation that the halving algorithm (generalized to the multiclass setting) is also applicable to the bandit setting. The algorithm is as follows: Let $\mathcal{H}'$ be the current set of "active" experts, which is initialized to the full set, i.e. $\mathcal{H} = \mathcal{H}'$ at $t = 1$. At each round t, we predict using the majority prediction r (i.e. the prediction $r \in [k]$ which the most hypotheses in $\mathcal{H}'$ predict). If we are correct, we make no update. If we are incorrect, we remove from the active set, $\mathcal{H}'$, those $h \in \mathcal{H}'$ which predicted the incorrect label r. Crucially, this (generalized) halving algorithm is implementable with only the bandit feedback that we receive. This algorithm enjoys the following mistake bound.

Lemma 6. *(Halving Algorithm). The halving algorithm (in the bandit setting) makes at most $k \ln |\mathcal{H}|$ mistakes on any sequence in which there exists some hypothesis in $\mathcal{H}$ which makes no mistakes.*

Proof. Whenever the algorithm makes a mistake, the size of active set is reduced by at least a $1 - 1/k$ fraction, since majority prediction uses a fraction of hypothesis (from the active set) that is at least $1/k$. Since the algorithm never removes a perfect hypothesis from the active set, the maximal number of mistakes, M, that can occur until $\mathcal{H}'$ consists of only perfect

hypotheses satisfies $(1-1/k)^M|\mathcal{H}| \geq 1$. Using the inequality $(1-1/k) \leq e^{-1/k}$ and solving for M leads to the claim. □

Using this, the following theorem shows that the achievable bound for the number of mistakes is asymptotically finite. Unfortunately, the result has a dimensionality dependence on d. The algorithm essentially uses the margin condition to construct an appropriately sized cover for $\mathcal{H}$, the set of all linear hypotheses, and runs the halving algorithm on this cover.

Theorem 7. *There exists a deterministic algorithm (in the bandit setting), taking D as input, which makes at most $O(k^2 d \ln(Dd))$ mistakes on any sequence (where $\|\mathbf{x}_t\| \leq 1$) that is linearly separable at margin 1 by some $W^\star$, with $2||W^\star||_F^2 \leq D$.*

Proof. (sketch) Since the margin is 1, it is straightforward to show that if W is a perturbation of $W^\star$ which satisfies $||W^\star - W||_\infty \leq O(\frac{1}{\sqrt{d}})$, then the data is still linearly separable under W. By noting that each coordinate in $W^\star$ is (rather crudely) bounded by $\sqrt{D}$, there exists a discretized grid of $\mathcal{H}$ of size $O(\sqrt{Dd})^{kd}$ which contains a linear separator. The algorithm simply runs the halving algorithm on this cover. □

This result is in stark contrast to the Perceptron mistake bound which has no dependence on the dimension d. We now provide a mistake bound with no dependence on the dimension. Unfortunately, it is not asymptotically finite, as it is has a rather mild dependence on the time — it is $O(D \ln T)$ (ignoring k and higher order terms), while the Perceptron mistake bound is $O(D)$.

Theorem 8. *There exists a randomized algorithm (in the bandit setting), taking as inputs D, T and $\delta > 0$, such that with probability greater than $1-\delta$ the algorithm makes at most $O(k^2 D \ln \frac{T+k}{\delta}(\ln D + \ln\ln \frac{T+k}{\delta}))$ mistakes on any T length sequence (where $\|\mathbf{x}_t\| \leq 1$) that is linearly separable at margin 1 by some $W^\star$, with $2||W^\star||_F^2 \leq D$.*

The algorithm first constructs a random projection operator which projects any $\mathbf{x}$ into a space of dimension $d' = O(D \ln \frac{T+k}{\delta})$, and then it runs the previous algorithm in this lower dimensional space. The proof essentially consists of using the results in Arriaga and Vempala [2006] to argue that the (multiclass) margin is preserved under this random projection.

Proof. (sketch) It is simpler to rescale $W^\star$ such that $||W^\star||_F = 1$ and the margin is $1/\sqrt{D}$. Consider the $T+k$ points x_1 to x_T and the (row) vectors $W_1^\star, \ldots W_k^\star$, whose norms are all bounded by 1. Let P be a matrix of dimension $d' \times d$, where each entry of P is independently sampled from $U(-1,1)$. Define the projection operator $\Pi(v) = \frac{1}{\sqrt{d'}} Pv$. Corollary 2 of Arriaga and Vempala [2006] (essentially a result from the JL lemma) shows that if $d' = O(D \ln \frac{T+k}{\delta})$ then this projection additively preserves the inner products of these points up to $\frac{1}{3\sqrt{D}}$, i.e. $|\Pi(W_r^\star)\cdot\Pi(\mathbf{x}_t) - W_r^\star \cdot \mathbf{x}_t| \leq \frac{1}{3\sqrt{D}}$. It follows that, after the projection, the data is linearly separable with margin at least $\frac{1}{3\sqrt{D}}$. Letting $\Pi(W^\star)$ denote the matrix where each row of $W^\star$ has been projected, then, also by the JL lemma, the norm $||\Pi(W^\star)||_F$ will (rather crudely) be bounded by 2 (recall $||W^\star||_F = 1$). Hence, the projected data is linearly separable at margin $1/(3\sqrt{D})$ by a weight matrix that has norm $O(1)$, which is identical to being separable at margin 1 with weight vector of complexity $O(D)$. The algorithm is to first create a random projection matrix (which can be constructed without knowledge of the sequence) and then we can run the previous algorithm on the lower dimensional space d'. Since we have shown that the margin is preserved (up to a constant) in the lower dimensional space, the result follows from the previous Theorem 7, with d' as the dimensionality. □

We discuss open questions in the Extensions section.

5. Experiments

In this section, we report some experimental results for the Banditron algorithm on synthetic and real world data sets. For each data set, we ran Banditron for a wide range of values of the exploration parameter γ. For each value of γ, we report the average error rate, where the averaging is over 10 independent runs of Banditron.

The results are shown on Fig. 1. Each column corresponds to one data set. The top figures plot the error rates of Banditron (for the best value of γ) and Perceptron as a function of the number of examples seen. We show these on a log-log scale to get a better visual indication of the asymptotics of these algorithms. The bottom figures plot the final error rates on the complete data set as a function of γ. As expected, setting γ too low or too high leads to higher error rates.

The first data set, denoted by SynSep, is a 9-class, 400-dimensional synthetic data set of size 10^6. The idea is to have a simple simulation of generating a text document. The coordinates represent different words in a small vocabulary of size 400. See the caption of Figure 1 for details. We ensure, by construction, that

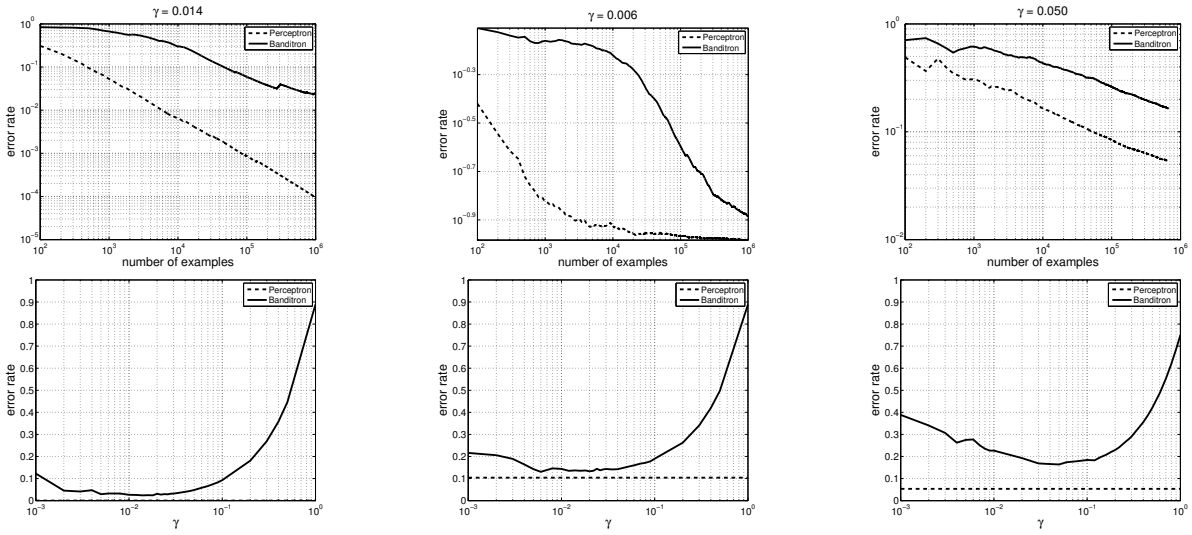

Figure 1. Error rates of Perceptron (dashed) and Banditron (solid) on the SYNSEP (left), SYNNONSEP (middle), and REUTERS4 (right) data sets. The 9-class synthetic data sets are generated as follows. We fix 9 bit-vectors $v_1, \ldots, v_9 \in \{0,1\}^{400}$ each of which has 20 to 40 bits turned on in its first 120 coordinates. The supports of some of these vectors overlap. The vectors v_i correspond to 9 topics where topic i has "keywords" that correspond to the bits turned on in v_i. To generate an example, we randomly choose a v_i and randomly turn off 5 bits in its support. Further, we randomly turn on 20 additional bits in the last 280 coordinates. The last 280 coordinates thus correspond to common words that can appear in a document from any topic.

SYNSEP is linearly separable. The left plots in Figure 1 show the results for this data set. Since this is a separable data set, Perceptron makes a bounded number of mistakes and its error rate plot falls at a rate of $1/T$ yielding a slope of -1 on a log-log plot. Corollary 2 predicts that error rate for Banditron should decay faster than $1/\sqrt{T}$ and we indeed see a slope of approximately -0.55 on the log-log plot. The second data set, denoted by SYNNONSEP, is constructed in the same way as SYNSEP except that we introduce 5% label noise. This makes the data set non-separable. The middle plots in Fig. 1 show the results for SYNNONSEP. The Perceptron error rate decays till it drops to 10% and then becomes constant. Banditron does not decay appreciably till 10^4 examples after which it falls rapidly to its final value of $10^{-0.89} = 13\%$.

We construct our third data set REUTERS4 from the Reuters RCV1 collection. Documents in the Reuters data set can have more than one label. We restrict ourselves to those documents that have exactly one label from the following set of labels: {CCAT, ECAT, GCAT, MCAT}. This gives us a 4-class data set of size 673,768 which includes about 84% of the documents in the original Reuters data set. We do this because the model considered in this paper assumes that every instance has a single true label. See the Extensions section for a discussion about dealing with multiple labels. We represent each document using bag-of-words, which leads to 346,810 dimensions. The right plots in Fig. 1 show the results for REUTERS4. The final error rates for Perceptron and Banditron ($\gamma = 0.05$) are 5.3% and 16.3% respectively. However, it is clear from the top plot that as the number of examples grows, the error rate of Banditron is dropping at a rate comparable to that of Perceptron.

6. Extensions and Open Problems

We now discuss a few extensions of the Banditron algorithm and some open problems. These extensions may possibly improve the performance of the algorithm and also broaden the set of applications that can be tackled by our approach. Due space constraints, we confine ourselves to a rather high level overview.

Label Ranking: So far we assumed that each instance vector is associated with a *single* correct label and we must correctly predict this particular label. In many applications this binary dichotomy is inadequate as each label is associated with a degree of relevance, which reflects to what extent it is relevant to the instance vector in hand. Furthermore, it is sometime natural to predict a subset of the labels rather than a single label. For example, consider again the problem of sponsored advertising on webpages described in the Introduction. Here, the system presents the user with a few ads. If the user positively responds to one

of the suggestions (say by a "click"), this implies that the user prefers this suggestion over the other suggestions, but it does not necessarily mean that the other suggestions are completely wrong.

We now briefly discuss a possible extension of the Banditron algorithm for this case (using techniques from Crammer et al. [2006]). On each round, we first find the r top ranked labels (where ranking is according to $\langle \mathbf{w}_r, \mathbf{x}_t \rangle$). With probability $1-\gamma$ we exploit and predict these labels. With probability γ we explore and randomly change one of the top ranked labels with another label which is ranked lower by our model. If we are exploring and the user chooses the replaced label, then we obtain a feedback that can be used for improving our model. The Banditron analysis can be generalized to this case, leading to bounds on the number of rounds in which the user negatively responds to our advertisement system.

Multiplicative Updates and Margin-Based Updates: While deriving the Banditron algorithm, our starting point was the Perceptron, which is an extremely simple online learning algorithm for the full information case. Over the years, many improvements of the Perceptron were suggested (see for example Shalev-Shwartz and Singer [2007] and the references therein). It is therefore interesting to study which algorithms can be adapted to the Bandit setting. We conjecture that it is relatively straightforward to adapt the multiplicative update scheme [Littlestone, 1988, Kivinen and Warmuth, 1997] to the bandit setting while achieving mistake bounds similar to the mistake bounds we derived for the Banditron. It is also possible to adapt margin-based updates (i.e. updating also when there is no prediction mistake but only a margin violation) to the bandit setting. Here, however, it seems that the resulting mistake bounds for the low noise case are inferior to the bound we obtained for the Banditron.

Achievable Rates and Open Problems: The immediate question is how to improve our rate of $O(T^{2/3})$ to $O(\sqrt{T})$ in the general setting with an efficient algorithm. We conjecture this is at least possible by some (possibly inefficient) algorithm. Important open questions in the separable case are: What is the optimal mistake bound? In particular, does there exist a finite mistake bound which has no dimensionality dependence? Furthermore, are there efficient algorithms which achieve the mistake bound of $O(D \ln T)$, provided in Theorem 8 (or better)? Practically speaking, this last question is of the most importance, as then we would have an algorithm that actually achieves a very small mistake bound in certain cases.

Abstract

We show how the regularizer of Transductive Support Vector Machines (TSVM) can be trained by stochastic gradient descent for linear models and multi-layer architectures. The resulting methods can be trained *online*, have vastly superior training and testing speed to existing TSVM algorithms, can encode prior knowledge in the network architecture, and obtain competitive error rates. We then go on to propose a natural generalization of the TSVM loss function that takes into account neighborhood and manifold information directly, unifying the two-stage Low Density Separation method into a single criterion, and leading to state-of-the-art results.

1. Introduction

Several methods for improving discriminative classifiers using unlabeled data have been developed in the last few years. Perhaps the two most popular ways of utilizing the unlabeled data are:

(i) maximizing the *margin* on the unlabeled data as in Transductive Support Vector Machines (TSVM) so that the decision rule lies in a region of low density; and

(ii) learning the *cluster* or *manifold* structure from the unlabeled data as in cluster kernels (Chapelle et al., 2003), label propagation (Zhu & Ghahramani, 2002), and Laplacian SVMs (Belkin et al., 2006).

Both approaches can be seen as making the same *structure assumption* on the data, that the cluster or manifold structure in the data is correlated with the class labels of interest.

The Low Density Separation algorithm (LDS) (Chapelle & Zien, 2005) is a two-stage algorithm that combines both of these approaches, with improved results over using only one of the techniques, however the combination method is somewhat *ad-hoc*.

A serious problem with all these methods is that they suffer from an inability to scale to very large datasets, apart from in the linear case (Sindhwani & Keerthi, 2006). This is ironic because the potential gain of semi-supervised learning lies in the vast amounts of readily available unlabeled data. This performance gain is never attained simply because of the computational burden of calculating the result. In the conclusion of the article describing the LDS algorithm the authors state:

"We observe that the time (and to some degree, also space) complexities of all methods investigated here prohibit the application to really large sets of unlabeled data, say, more than a few thousand. Thus, work should also be devoted to improvements of the computational efficiency of algorithms, ideally of LDS."

In this work we propose a new method for semi-supervised learning which features the following improvements over existing approaches:

- A new regularizer for semi-supervised learning is proposed, that is a unification of the approaches in both *margin-based* and *manifold-based* regularization. As such it represents a clean version of

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

the LDS method in a single objective, rather than an *ad-hoc* two-stage approach. Experimental results show its good performance.

- We train our system using stochastic gradient descent and choose linear or multi-layer architectures rather than kernel methods. This results in far faster training and testing times than existing methods, and also allows semi-supervised learning to be performed *online*. Our method can easily scale to *millions* of examples.

- We show it is also possible to encode domain knowledge into our multi-layer architecture approach, resulting in excellent generalization performance. This is demonstrated by training semi-supervised convolutional networks for image data.

The rest of the article is as follows. Section 2 describes in detail existing margin and manifold based regularization approaches, and scalability of the resulting algorithms. Section 3 describes our proposed approach, Section 4 compares it experimentally to existing methods, and Section 5 concludes.

2. Existing Approaches

As stated in the introduction, two of the most popular loss functions (regularizers) for using unlabeled data are *margin*-based regularization as in TSVMs and *manifold*-based regularization. We will discuss each of these in turn.

2.1. TSVMs

The Transductive Support Vector Machine (TSVM) is an algorithm originally proposed by Vapnik (1998) to take advantage of both a labeled training set and an unlabeled test set during prediction time. It was named that way because Vapnik proved bounds on generalization performance given the availability of the test set that were superior to induction based on using the labeled training set alone. The idea of the algorithm was:

(i) Choose a nested set of functions $\mathcal{F}_1 \subset \mathcal{F}_2 \subset \ldots$ of increasing capacity.

(ii) For each possible labeling of the test examples, find the smallest subset $\mathcal{F}_k$ that can classify both training and testing data correctly.

(iii) Choose the labeling which required the smallest index k.

In terms of actual implementation it is known that the notion of margin – the distance of examples from the classifier's decision rule – is connected to the concept of capacity (Vapnik, 1998), so a simple algorithm is the following: *choose the decision rule that maximizes the margin on both labeled and unlabeled examples.*

The Support Vector Machine (Vapnik, 1998) for two-class classification already implements a margin based capacity control on *labeled* examples, using an optimization problem of the following form:

$$\min_{w,b} \gamma||w||^2 + \sum_{i=1}^{L} \ell(f(x_i), y_i) \tag{1}$$

where the family of functions are

$$f(x) = w \cdot x + b \tag{2}$$

and $\{(x_i, y_i), \ldots, (x_L, y_L)\} \subset \mathbb{R}^d \times \{\pm 1\}$ are the labeled training examples, and the loss function $\ell(\cdot, \cdot)$ is the so-called hinge loss:

$$\ell(f(x), y) = \max(0, 1 - yf(x)). \tag{3}$$

To implement Transductive SVMs it is (almost) sufficient to take the SVM optimization problem (1) and add an extra term for the unlabeled examples:

$$\min_{w,b} \gamma||w||^2 + \sum_{i=1}^{L} \ell(f(x_i), y_i) + \lambda \sum_{i=1}^{U} \ell^*(f(x_i^*)) \tag{4}$$

where the U unlabeled examples use the so-called symmetric hinge loss function

$$\ell^*(f(x^*)) = \max(0, 1 - |f(x^*)|) \tag{5}$$

which, intuitively speaking, pushes the unlabeled examples far from the margin: the absolute value is necessary in equation (5) because one does not know which side of the hyperplane those examples should lie on, unlike the labeled examples, so effectively the classifier trains on its own predictions. This notion of *self-learning* (Chapelle et al., 2006) can cause disastrous consequences in some cases: especially when the dimensionality $d \gg L$ one might be able to classify all unlabeled examples as belonging to one class whilst still classifying the labeled data correctly, giving a low value of the objective function, but nonsense results. This is solved by introducing a so-called balancing constraint which attempts to keep some of the unlabeled examples in each class.

Many researchers seem to be believe that the TSVM objective function is a good choice for semi-supervised

learning. However, finding a solution to the non-convex problem is far from easy, and thus several implementations have been attempted thus far. We will now describe some of those specific implementations, and their key differences.

S^{3}VM The authors of (Bennet & Demiriz, 1998) proposed to use mixed integer programming to find the labeling with the lowest objective function. The optimization appears intractable for large datasets, as "the solver failed due to excessive branching" in those cases. Only the linear case was considered, and no balancing constraint was used.

SVMLight-TSVM In (Joachims, 1999) a heuristic algorithm was proposed that at first fixes the labels of the unlabeled examples and then iteratively switches those labels to improve the TSVM objective function, solving a convex SVM objective function at each step. The nonlinear case is implemented by solving in the dual, resulting in a kernel model of the form:

$$f(x) = \sum_{i=1}^{L} \alpha_i y_i K(x_i, x) + \sum_{i=1}^{U} \alpha_i^* K(x_i^*, x) + b \quad (6)$$

A balancing constraint enforces that the fraction of positive and negatives assigned to the unlabeled data should be the same fraction as found in the labeled data. According to the proof of convergence, the algorithm at worst case could look at all 2^U labelings, but this is rather unlikely. The algorithm can deal with a few thousand examples in the nonlinear case in practice, but is faster in the linear case.

VS^{3}VM In (Fung & Mangasarian, 2001) a concave-convex minimization approach was proposed that solves successive convex problems, usually requiring only 5-7 linear programs, where they chose the L_1 norm of w as a regularizer instead of the L_2 norm. They studied the linear case, with no balancing constraint. This method will scale like the linear solver used in each iteration.

∇TSVM More recently, the authors of (Chapelle & Zien, 2005) proposed to optimize TSVM by gradient descent in the primal. For the nonlinear case, Kernel PCA has to be performed so that optimization in the primal is possible. This algorithm is faster than SVMLight-TSVM at least for small datasets (Collobert et al., 2006), but still has cubic complexity $O((U+L)^3)$. This method also requires one to store the entire kernel matrix of $(U+L)^2$ elements in memory, which clearly becomes infeasible for large datasets. The authors introduced a balancing constraint that is amenable to gradient descent:

$$\frac{1}{U}\sum_{i=1}^{U} f(x_i^*) \;=\; \frac{1}{L}\sum_{i=1}^{L} y_i \,. \quad (7)$$

CCCP-TSVM The authors of (Collobert et al., 2006) proposed to apply the Concave-Convex procedure for non-convex problems to TSVMs, which can be seen as a nonlinear extension of VS^{3}VMs. It uses the same balancing constraint as ∇TSVM. This implementation is over 100 times faster than SVMLight-TSVM and 50 times faster than ∇TSVM (for $L+U=2000$), and appears to scale better as well. It has empirically quadratic complexity because it relies on the sparsity of the SVM solution for improved speed and memory requirements. However, it still takes around 40 hours on a modern machine to solve a problem with 60,000 unlabeled examples in the nonlinear case.

Large Scale Linear TSVMs The authors of (Sindhwani & Keerthi, 2006) recently proposed a large scale TSVM method for the linear case. They focused on text problems with large sparse feature vectors and train the model (2) directly in the primal. In particular, they use a label switching heuristic like SVMLight-TSVM, but switch multiple labels at once.

In the nonlinear case things are not so easy. One is restricted in the quest to reduce training time by the prediction speed of the model (6) . Moreover, computation grows as the training data grows (Steinwart & Scovel, 2005). Even if one tries tricks to keep a fixed number of basis functions these methods are still slow compared to multi-layer models (Burges, 1996).

2.2. Manifold-based regularization

A separate direction of research in semi-supervised learning is manifold-learning based regularization. The main idea in these approaches is to find a representation of the data which collapses points lying in the same manifold so that a classification algorithm can easily predict that they share the same class label.

These methods can be split into two categories: those which treat this as a two-stage problem: (i) learn an embedding and (ii) train a classifier in this new space, and those which try to do everything in a single step.

To train a two-stage classifier, in the first stage one employs any manifold-learning algorithm such as Isomap (Tenenbaum et al., 2000), Laplacian Eigenmaps (Belkin & Niyogi, 2003) or spectral clustering (Ng et al., 2002). The authors of (Chapelle et al., 2003) use such methods to build a kernel for SVMs

and call these kernels "cluster kernels". The "graph"-SVM method proposed in (Chapelle & Zien, 2005) also builds a kernel for SVM. In this method one embeds in a space where distances are the shortest paths on the graph weighted with the original distance measure, similar to the Isomap algorithm. Thus, points connected by regions of high density are close to each other in the new space.

To learn a single stage classifier, one has to introduce a regularizing term in the objective function which directly encodes behavior such as that described in the previous paragraph. The Laplacian Eigenmaps embedding algorithm in particular employs an objective function that is easily encoded in a classifier:

$$\sum_{ij} W_{ij}||f(x_i) - f(x_j)||^2 \tag{8}$$

Such a regularizer has been used both to generalize a Parzen-windows (Duda & Hart, 1973) type classifier resulting in a method called label propagation (Zhu & Ghahramani, 2002), and in SVMs. The SVM method is called Laplacian SVMs (LapSVM) (Sindhwani et al., 2005) and minimizes:

$$\min_{w,b} \sum_{i=1}^{L} \ell(f(x_i), y_i) + \gamma||w||^2 + \lambda \sum_{i,j=1}^{U} W_{ij}||f(x_i^*) - f(x_j^*)||^2 \tag{9}$$

We speculate here that forcing the Euclidean distance to be small if two points are assumed to be the same label might be a little stringent as for prediction it is only the sign of $f(x^*)$ that is important. Moreover, we also note that the lack of balancing constraint might mean in high dimensions that all the unlabeled examples can collapse to a single prediction.

In contrast, the LDS method (Chapelle & Zien, 2005) proposes to use both TSVM and manifold regularizers at once in a two-stage method. First, the Isomap-like embedding method of "graph"-SVM is used whereby data is clustered. Then, in the new embedding space, ∇TSVM is applied. The authors found that using both regularizers at once was better than using one type of regularizer alone.

In summary, we have discussed several algorithms which use two main types of regularizer: a clustering or an embedding that takes into account *structure* in the unlabeled data. Indeed TSVM is a kind of large margin clustering as has been exploited in (Xu et al., 2005) and is strongly related to classical techniques like competitive learning (Duda & Hart, 1973). In (Chapelle & Zien, 2005) the authors speculate that manifold-based regularization has a stabilizing effect on TSVM optimization. Without such neighborhood-based regularization TSVMs only compare unlabeled examples to the existing model, and not to each other. Using both approaches as in LDS is thus a smart idea, however it suffers from two problems: (i) the two-stage approach seems *ad-hoc* and (ii) the method is slow.

In the next Section we propose a new approach which remedies these problems.

3. Proposed Approach

We propose the following algorithm, named Manifold Transduction: minimize

$$\frac{1}{L}\sum_{i=1}^{L} \ell(f(x_i), y_i) + \frac{\lambda}{U^2} \sum_{i,j=1}^{U} W_{ij}\ \ell\big(f(x_i^*), y^*(\{i,j\})\big) \tag{10}$$

where

$$y^*(N) = \text{sign}(\sum_{k \in N} f(x_k^*)) \tag{11}$$

where the edge weights W_{ij} define pairwise similarity relationships between unlabeled examples x^*.

This objective, like TSVMs objective, is non-convex and there is no simple optimization scheme for solving it even for linear models such as kernel machines. Because of this fact, and the scalability problems with nonlinear kernel methods, we propose several novel algorithmic choices in its implementation:

(i) We minimize this function in the primal by stochastic gradient descent. This makes *online* semi-supervised learning possible for the first time.

(ii) In the nonlinear case we employ a multi-layer architecture to define $f(x)$. This makes both training and testing far faster than competing kernel methods such as TSVM.

(iii) We also make a specific recommendation for the implementation of an *online* balancing constraint.

We will now study this algorithm, and explain the reason for these choices in detail.

3.1. Objective function

In (10) we propose a new loss function for *unlabeled examples*:

$$\ell^*(f(x_i^*)) = \ell\Big(f(x_i^*), y^*(N)\Big) \tag{12}$$

where N is a set of examples that one believes share the same label, e.g. a set of neighboring examples. The

function y^* predicts the label of that set by taking the mean prediction.

For both labeled and unlabeled training data we use the hinge loss (3) as in SVMs.

In equation (10) we consider pairs of examples, weighted by the graph W_{ij}. If $W_{ii} = 1$ and $W_{ij} = 0$ for $i \neq j$ then we recover the TSVM loss function:

$$\ell^*(f(x_i^*)) = \ell\Big(f(x_i^*), \text{sign}(f(x_i^*))\Big) \qquad (13)$$

because we do not take neighborhood information into account.

Setting $W_{ij} = 1$ if x_i^* is among the k-nearest neighbors of x_j^*, and zero otherwise, our algorithm becomes a natural generalization of TSVM that regularizes using neighborhood information. This is a similar regularizer to the neighborhood-based manifold regularizers of Section 2.2 but based on *clustering* rather than *embedding*.

We make the assumption that if two examples are neighbors then they have the same *class label*, whereas manifold-based regularization assumes they are close in an *embedding space*. Our constraint is not as strict, but captures the prior we wish to encode. For example, if one class of data has more variance than the other, then the regularization of (9) might focus on that class, and ignore the other.

Extensions of our algorithm are also possible. First, in the multi-class case where $f(x^*)$ outputs a c-dimensional vector, we can define $y^*(N) = \text{argmax} \sum_{k \in N} f(x_k^*)$. Further, if the set N contains more than two examples then our algorithm takes into account a neighborhood in analogy to k-nearest neighbor. This is not easily possible with the approach of (9) which is limited to pairs.

3.2. Model: Multi-Layer Architecture

As already discussed, the issue that makes all the previously described algorithms computationally expensive in the nonlinear case is their choice of the kernel expansion (6). Instead we propose to use a multi-layer model of the form:

$$f(x) = \sum_{i=1}^{d} w_i^0 \; h_i(x) + b$$

where typically one chooses hidden units

$$h_i(x) = S\left(\sum_j w_j^i \; x_j + b^i\right)$$

Algorithm 1 Online Manifold Transduction

Input: labeled data (x_i, y_i) and unlabeled data x_i^*
repeat
  Pick a random labeled example (x_i, y_i)
  Make a gradient step to optimize $\ell(f(x_i), y_i)$
  Pick a random unlabeled example x_i^*
  Pick a random neighbor x_j^* of x_i^*
  Predict label $y^* = y^*(\{i, j\})$
  if fraction of recent assignments to class $y^* < p_{est}(y^*)$ (see Section 3.4) **then**
    Make a gradient step for $\ell(f(x_i^*), y^*)$
  end if
until stopping criteria is met.

where S is a non-linear squashing function. We use the Hard Tanh function:

$$S(x) = \begin{cases} 1 & \text{if } x \geq 1 \\ -1 & \text{if } x \leq -1 \\ x & \text{otherwise.} \end{cases}$$

In the multi-class case we define one output $f_i(x)$ for each class, but each function f_i shares the same hidden units h_j, as is often done in neural network models.

The flexibility of using multi-layer architectures also allows us to encode prior knowledge into our model. For example, convolutional neural networks (CNNs) (LeCun et al., 1998) have several layers of image patch based feature maps applied across the input image. Such networks have been shown to perform very well in digit, face and 3D object detection tasks.

3.3. Optimization: Stochastic Gradient

We optimize our objective *online*, in the primal, using stochastic gradient descent. Recent experimental comparisons show this approach often outperforms sophisticated optimizer schemes (Bottou, 2007). To simplify the hyperparameters we fix $\lambda = 1$ in our experiments, yielding the method described in Algorithm 1. If the model is multi-layered then we use backpropagation (see, e.g. (Duda & Hart, 1973)) during the gradient step. A typical stopping criteria is to use a validation set or to measure the objective function value.

3.4. Balancing Constraint

To implement a balancing constraint while learning *online* we keep a cache of (arbitrarily) the last $25c$ predictions $f(x_i^*)$ where c is the number of classes. This is dependent on c because if c is large the cache must also be large or the estimates will be too poor. We then try to make the next prediction *balanced* assuming we

have a fixed estimate $p_{est}(y)$ of the probability of each class, which without further information, can be estimated from the labeled data: $p_{trn}(y=i) = \frac{|\{i:y_i=i\}|}{L}$. We consider two alternatives:

1. **∇bal** Adding the term (7) to the objective function multiplied by a scaling factor as in ∇TSVMs. The disadvantage of such an approach is that the scaling factor is a further hyperparameter.
2. **ignore–bal** Count how many examples in the cache have been attributed to each class. If the next unlabeled example x^* is given a label y^* by the model that already has too many examples assigned to it, then we simply do not make a gradient step for this example.

We note that the quality of p_{trn} depends on the ratio of labeled examples L to the number of classes c, not the input dimensionality d. Thus it may be a good estimate in many real datasets. However, because in some of the small datasets used in (Chapelle & Zien, 2005) it is a poor estimate we consider improving this estimate by taking into account that we have access to unlabeled data. We suggest the following simple method p_{knn}: label the k nearest neighbors of each labeled example with its label. If k is large enough some labeled points will label the same examples, and so when we count the number of points assigned to each class, we achieve a smoothed version of p_{trn}.

4. Experiments

4.1. Small Scale Datasets

We first report results on three small-scale datasets, summarized in Table 1. We follow the methodology in (Chapelle & Zien, 2005; Collobert et al., 2006) and report the best mean test error for a *fixed* set of hyperparameters over 10 splits of the data. For our method, we test standard transduction (our regularizer with no neighborhood information), called TNN (Transductive Neural Network), and our method *with* neighborhood information, called ManTNN (Manifold Transduction Neural Network). We also compute a baseline Neural Network (NN).

For NN, TNN and ManTNN we fixed 50000 iterations of Algorithm 1 and for ManTNN we chose 10 nearest neighbors for all datasets. We also choose not to minimize $\ell(f(x_i^*), y^*)$ for the first $10L$ iterations so that the classifier first finds a good model with labeled data alone before using the unlabeled data. We thus have two free parameters: the choice of hidden units {0,50,100,150,200} and the choices of learning rate { 0.5, 0.1, 0.05, 0.01, 0.005, 0.001, 0.0005 }.

Table 1. Datasets used in the experiments. The first three are small-scale datasets using the same experimental setup as found in (Chapelle & Zien, 2005). Mnist1h and Mnist1k use the same experimental setup as in (Collobert et al., 2006). Mnist1k+Invar uses shifted versions of digits to make an unlabeled set of 630,000 examples.

data set	classes	dims	points	labeled

TNN	6.34	6.11	16.06
ManTNN	5.66	5.34	11.90

Balancing constraint comparison We first compare the balancing constraint methods ∇bal and ignore-bal and three different strategies for computing the class distribution p_{trn}, p_{knn} and p_{tst} as described in Section 3.4. p_{trn} measures the training set distribution, p_{knn} estimates the unlabeled set distribution (which is what we are really interested in) by using a k-nn like method, and p_{tst} is the true distribution of the unlabeled data, which is inaccessible in a real situation. A comparison on two of the datasets is given in Figure 2 (results are similar for "text").

We could not get ∇bal to work well in an online situation whereas the simple ignore-bal heuristic gives good results. Due to the small dataset size the difference in test error between using p_{tst} and p_{trn} is actually quite large. Using p_{knn} seems to be a better estimate than p_{trn}. We therefore adopt ignore-bal and the p_{knn} method in the following experiments.

Comparison with other methods We compare TNN and ManTNN to several TSVM implementations as well as label propagation, graph, LapSVM and LDS on the small scale datasets. The results given in Table 3 show that both TNN and ManTNN are competitive with existing approaches, and ManTNN, which includes the manifold-based transductive regularizer, outperforms TNN, which uses transduction alone.

4.2. Large Scale Dataset: MNIST

We then compared our method to SVMs and TSVMs on a "semi-supervised version" of the MNIST digit database, following (Collobert et al., 2006), using either 100 or 1000 labeled examples and 70000 unlabeled examples, and a validation set of 1000 examples for choosing parameters. Error rates are measured on the MNIST test set.

We used a two-layer neural network as before (baseline NN, TNN, ManTNN), choosing from the same set of hidden units and learning rates. We use the validation set as a stopping criteria for Algorithm 1.

We also applied convolutional networks (CNNs), and transductive versions of them, to this task. We chose an architecture similar to (LeCun et al., 1998). There are 6 layers. The first is six 3x3 spatial convolutions (outputting 26x26x6 features to the next layer). The second is six spatial 2x2 spatial subsamplings (outputting 13x13x6 features). The third is sixteen 4x4 spatial convolutions (outputting 10x10x16 features). The fourth is sixteen 2x2 spatial subsamplings (giving 5x5x16 features). The fifth is fifty 5x5 spatial convolutions (giving 1x1x50 features). This is followed by a standard fully connected layer with n hidden units (chosen as in the two-layer net), followed by a linear layer yielding the final 10 outputs (class predictions). CNNs encode prior knowledge about spatial features within the image, which should give improved accuracy over a standard NN.

Table 4. Results on Large-Scale Datasets: MNIST with 100 or 1000 labels and 70,000 unlabeled examples. Test Error is reported for Transductive (T-) and Manifold Transduction (ManT-) versions of Neural Networks (NN) and convolutional networks (CNN), and compared to SVMs and TSVMs. *ManTCNN (p_{tst})* uses the test distribution as the balancing constraint, which if this information were available, would give improved performance.

	Mnist1h	Mnist1k
SVM	23.44	7.77
CCCP-TSVM	16.81	5.38
NN	25.81	10.70
TNN	18.02	6.66
ManTNN	7.30	2.88
CNN	22.98	6.45
TCNN	13.01	3.50
ManTCNN	6.65	2.15
ManTCNN (p_{tst})	*1.96*	*1.87*

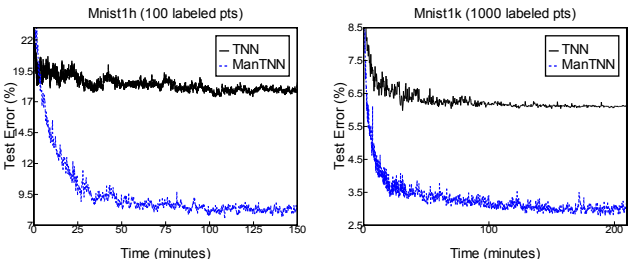

Figure 1. Test error versus training times for the TNN and ManTNN algorithms on Mnist (100 or 1000 labeled examples, 70000 unlabeled examples). These results compare favourably with the time to train the fastest TSVM algorithm (Collobert et al., 2006) which took 41.9 hours on the same machine.

The results are given in Table 4. The baseline NN performs slightly worse than SVM, but CNNs perform slightly better. Applying transduction, TNN is slightly worse than TSVMs, but TCNN is slightly better. Manifold Transduction outperforms all these methods, with ManTNN and ManTCNN performing almost as well as each other. The last row in the table shows ManTCNN trained with the true balancing constraint (knowing the test distribution). It appears that for only 100 labeled examples knowing this distribution could make results even better, although with 1000 labeled examples this is less important.

Training time for TNNs and ManTNNs are given in Figure 1. The results are shown for the best choice of hidden units and learning rate as chosen on the validation set. TNNs take around one hour to reach convergence, and ManTNNs (omitting the time to compute neighbors for ManTNN) take slightly longer. These times should be compared to the fastest TSVM implementation, CCCP-TSVMs, which took 41.9 hours on the same machine. Our code is not particularly optimized and is written in a scripting language with a C++ back-end. On MNIST, a nonlinear TNN with 200 hidden units can process 1 million unlabeled examples in an *online* fashion in 12.5 minutes.

Mnist1k+Invar We also performed experiments on MNIST1k with a larger unlabeled set of 630,000 examples by translating the original set by at most one pixel in each direction. TNN achieves a test error of 5.23% on the original test set, when choosing the training iteration that gives the minimum validation error, and ManTNN achieves a test error of 2.43%. Both methods outperform their counterparts trained with less unlabeled data using MNIST1k. Training time took 4.47 hours and 3.96 hours respectively for the two algorithms, including the computation time for generating the invariances.

5. Conclusions

In this article we introduced a large scale *nonlinear* method that elegantly combines the two main regularization principles for discriminative semi-supervised learning: transduction and neighborhood-based (manifold-based) regularization. Our future work will be to apply this approach to real large-scale nonlinear problems e.g. applications in vision and natural language processing.

Abstract

Policy gradient approaches are a powerful instrument for learning how to interact with the environment. Existing approaches have focused on propositional and continuous domains only. Without extensive feature engineering, it is difficult – if not impossible – to apply them within structured domains, in which e.g. there is a varying number of objects and relations among them. In this paper, we describe a non-parametric policy gradient approach – called NPPG – that overcomes this limitation. The key idea is to apply Friedmann's gradient boosting: policies are represented as a weighted sum of regression models grown in an stage-wise optimization. Employing off-the-shelf regression learners, NPPG can deal with propositional, continuous, and relational domains in a unified way. Our experimental results show that it can even improve on established results.

1. Introduction

Acting optimally under uncertainty is a central problem of artificial intelligence. If an agents learns to act solely on the basis of the rewards associated with actions taken, this is called reinforcement learning (Sutton & Barto, 1998). More precisely, the agent's learning task is to find a policy for action selection that maximizes its reward over the long run.

The dominant reinforcement learning (RL) approach for the last decade has been the value-function approach. An agent uses the reward it occasionally receives to estimate a value-function indicating the expected value of being in a state or of taking an action in a state. The policy is represented only implicitly, for instance as the policy that selects in each state the action with highest estimated value. As Sutton et al. (2000) point out, the value function approach, however, has several limitations. First, it seeks to find deterministic policies, whereas in real world applications the optimal policy is often stochastic, selecting different actions with specific probabilities. Second, a small change in the value-function parameter can push the value of one action over that of another, causing a discontinuous change in the policy, the states visited, and overall performance. Such discontinuous changes have been identified as a key obstacle to establishing convergence assurances for algorithms following the value-function approach (Bertsekas & Tsitsiklis, 1996). Finally, value-functions can often be much more complex to represent than the corresponding policy as they encode information about both the size and distance to the appropriate rewards. Therefore, it is not surprising that so called policy gradient methods have been developed that attempt to avoid learning a value function explicitly (Williams, 1992; Baxter et al., 2001; Konda & Tsitsiklis, 2003). Given a space of parameterized policies, they compute the gradient of the expected reward with respect to the policy's parameters, move the parameters into the direction of the gradient, and repeat this until they reach a local optimum. This direct approximation of the policy overcomes the limitations of the value function approach stated above. For instance, Sutton et al. (2000) show convergence even when using function approximation.

Current policy gradient methods have focused on propositional and continuous domains assuming the environment of the learning agent to be representable as a vector-space. Nowadays, the role of structure and relations in the data, however, becomes more and

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

more important (Getoor & Taskar, 2007): information about one object can help the agent to reach conclusions about other objects. Such domains are hard to represent meaningfully using a fixed set of features. Therefore, relational RL approaches have been developed (Džeroski et al., 2001), which seek to avoid explicit state and action enumeration as – in principle – traditionally done in RL through a symbolic representation of states and actions. Existing relational RL approaches, however, have focused on value functions and, hence, suffer from the same problems as their propositional counterparts as listed above.

In this paper, we present the first model-free policy gradient approach that deals with relational and propositional domains. Specifically, we present a non-parametric approach to policy gradients, called NPPG. Triggered by the observation that finding many rough rules of thumb of how to change the way to act can be a lot easier than finding a single, highly accurate policy, we apply Friedmann's (2001) gradient boosting. That is, we represent policies as weighted sums of regression models grown in a stage-wise optimization. Such a functional gradient approach has recently been used to efficiently train conditional random fields for labeling (relational) sequences using boosting (Dietterich et al., 2004; Gutmann & Kersting, 2006) and for policy search in continuous domains (Bagnell & Schneider, 2003). In contrast to the supervised learning setting of the sequence labeling task, feedback on the performance is received only at the end of an action sequence in the policy search setting. The benefits of a boosting approach to functional policy gradients are twofold. First, interactions among states and actions are introduced only as needed, so that the potentially infinite search space is not explicitly considered. Second, existing off-the-shelf regression learners can be used to deal with propositional and relational domains in a unified way. To the best of the authors' knowledge, this is the first time that such a unified treatment is established. As our experimental results show, NPPG can even significantly improve upon established results in relational domains.

We proceed as follows. We will start off by reviewing policy gradients and their mathematical background. Afterwards, we will develop NPPG in Section 3. In Section 4, we will present our experimental results. Before concluding, we will touch upon related work.

2. Policy Gradients

Policy gradient algorithms find a locally optimal policy starting from an arbitrary initial policy using a gradient ascent search through an explicit policy space. Consider the standard RL framework (Sutton & Barto, 1998), where an agent interacts with a Markov Decision Process (MDP). The MDP is defined by a number of states $s \in \mathcal{S}$, a number of actions $a \in \mathcal{A}$, state-transition probabilities $\delta(s,a,s') : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \to [0,1]$ that represent the probability that taking action a in state s will result in a transition to state s' and a reward function $r(s,a) : \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$. When the reward function is nondeterministic, we will use the expected rewards $R(s,a) = E_{s,a}[r(s,a)]$, where $E_{s,a}$ denotes the expectation over all states s and actions a. The state, action, and reward at time t are denoted as $s_t \in \mathcal{S}$, $a_t \in \mathcal{A}$ and $r_t (or\ R_t) \in \mathbb{R}$.

The agent selects which action to execute in a state following a policy function $\pi(s,a) : \mathcal{S} \times \mathcal{A} \to [0,1]$. Current policy gradient approaches assume that the policy function π is parameterized by a (weight) vector $\theta \in \mathbb{R}^n$ and that this policy function is differentiable with respect to its parameters, i.e., that $\frac{\partial \pi(s,a,\theta)}{\partial \theta}$ exists. A common choice is a Gibbs distribution based on a linear combination of features:

$$\pi(s,a) = e^{\Psi(s,a)} / \left(\sum\nolimits_b e^{\Psi(s,b)} \right) , \qquad (1)$$

where the potential function $\Psi(s,a) = \theta^T \phi_{sa}$ with ϕ_{sa} the feature vector describing state s and action a. This representation guarantees that the policy specifies a probability distribution independent of the exact form of the function Ψ. Choosing a parameterization, creates an explicit policy space $\mathbb{R}^n$ with n equal to size of the parameter vector θ. This space can be traversed by an appropriate search algorithm.

Policy gradients are computed w.r.t. a function ρ that expresses the value of a policy in an environment, $\rho(\pi) = \sum_{s \in \mathcal{S}} d^\pi(s) \sum_{a \in \mathcal{A}} \pi(s,a) \cdot Q^\pi(s,a)$, where Q^π is the usual (possibly discounted) state-action value function, e.g., $Q^\pi(s,a) = E_\pi \left[\sum_{i=0}^{\infty} \gamma^i R_{t+i} | s_t = s, a_t = a \right]$, and $d^\pi(s)$ is the (possibly discounted) stationary distribution of states under policy π. We assume a fully ergodic environment so that $d^\pi(s)$ exists and is independent of any starting state s_0 for all policies.

A property of ρ for both average reward reinforcement learning and episodic tasks with a fixed starting state s_0 is that (Sutton et al., 2000, Theorem 1)

$$\frac{\partial \rho}{\partial \theta} = \sum\nolimits_s d^\pi(s) \sum\nolimits_a \frac{\partial \pi(s,a)}{\partial \theta} \cdot Q^\pi(s,a) . \qquad (2)$$

Important to note is that this gradient does not include the term $\frac{\partial d^\pi(s)}{\partial \theta}$. Eq. (2) allows the computation of an approximate policy gradient through exploration. By sampling states s through exploration of the environment following policy π, the distribution $d^\pi(s)$ is

automatically represented in the generated sample of encountered states. The sum $\sum_a \frac{\partial \pi(s,a)}{\partial \theta} Q^\pi(s,a)$ then becomes an unbiased estimate of $\frac{\partial \rho}{\partial \theta}$ and can be used in a gradient ascent algorithm.

Of course, the value Q^π is unknown and must be estimated for each visited state-action pair either by using a Monte Carlo approach or by building an explicit representation of Q, although in this latter case care must be taken when choosing the parameterization of the Q-function (Sutton et al., 2000).

3. Non-Parametric Policy Gradients

A drawback of a fixed, finite parameterization of a policy such as in Eq. (1) is that it assumes each feature makes an independent contribution to the policy. Of course it is possible to define more features to capture combinations of the basic features, but this leads to a combinatorial explosion in the number of features, and hence, in the dimensionality of the optimization problem. Moreover, in continuous and in relational environments it is not clear at all which features to choose as there are infinitely many possibilities.

To overcome these problems, we introduce a different policy gradient approach based on Friedmann's (2001) gradient boosting. In our case, the potential function Ψ in the Gibbs distribution[1] of Eq. (1) is represented as a weighted sum of regression models grown in an stage-wise optimization. Each regression model can be viewed as defining several new feature combinations. The resulting policy is still a linear combination of features, but the features can be quite complex. Formally, gradient boosting is based on the idea of functional gradient ascent, which we will now describe.

3.1. Functional Gradient Ascent

Traditional gradient ascent estimates the parameters θ of a policy iteratively as follows. Starting with some initial parameters θ_0, the parameters θ_m in the next iteration are set to the current parameters plus the gradient of ρ w.r.t. to θ, i.e., $\theta_m = \theta_0 + \delta_1 + \ldots + \delta_m$ where $\delta_m = \eta_m \cdot \partial\rho/\partial\theta_{m-1}$ is the gradient multiplied by a constant η_m, which is obtained by doing a line search along the gradient. Functional gradient ascent is a more general approach, see e.g. (Friedman, 2001; Dietterich et al., 2004). Instead of assuming a linear parameterization for Ψ, it just assumes that Ψ will be represented by a linear combination of functions. Specifically, one starts with some initial function Ψ_0, e.g. based on the zero potential, and iteratively adds corrections $\Psi_m = \Psi_0 + \Delta_1 + \ldots + \Delta_m$. In contrast to the standard gradient approach, Δ_m here denotes the so-called functional gradient, i.e., $\Delta_m = \eta_m \cdot E_{s,a}\left[\partial\rho/\partial\Psi_{m-1}\right]$. Interestingly, this functional gradient coincides with what traditional policy gradient approach estimate, namely (2), as the following theorem says.

Theorem 3.1 (Functional Policy Gradient) *For any MDP, in either the average-reward or start-state formulation,*

$$E_{s,a}\left[\frac{\partial \rho}{\partial \Psi}\right] = \sum\nolimits_{s,a} d^\pi(s) \cdot \frac{\partial \pi(s,a)}{\partial \Psi} \cdot Q(s,a)\,. \quad (3)$$

This is a straightforward adaptation of Theorem 1 in (Sutton et al., 2000) and is also quite intuitive: the functional policy gradient indicates how we would like the policy to change in all states and actions in order to increase the performance measure ρ.

Unfortunately, we do not know the distribution $d^\pi(s)$ of how often we visit each state s under policy π. This is, however, easy to approximate from the empirical distribution of states visited when following π:

$$E_{s,a}\left[\frac{\partial \rho}{\partial \Psi}\right] \approx E_{s\sim\pi}\left[\sum\nolimits_a \underbrace{\frac{\partial \pi(s,a)}{\partial \Psi} \cdot Q(s,a)}_{=:f_m(s,a)}\right]\,, \quad (4)$$

where the state s is sampled according to π, denoted as $s \sim \pi$. We now have a set of traning examples from the distribution $d^\pi(s)$, so we can compute the value $f_m(s,a)$ of the functional gradient at each of the training data points for all[2] actions a applicable in s. We can then use these point-wise functional gradients to define a set of training examples $\{(s,a), f_m(s,a)\}$ and then train a function $f_m : \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$ so that it minimizes the squared error over the training examples. Although the fitted function f_m is not exactly the same as the desired functional gradient in Eq. (3), it will point in the same general direction assuming there are enough training examples. So, taking a step $\Delta_m = \eta_m \cdot f_m$ will approximate the true functional policy gradient ascent.

[1] Other distributions are possible but are subject to future research. For instance, it would be interesting to investigate modeling joint actions of multiple agents in relatioanl domains a long the lines of Guestrin et al. (2002).

[2] Here, an update is made for all actions possible in each state encountered irrespective of which action was actually taken. Alternatively, we can only make an update for the one action actually taken (Baxter et al., 2001). To compensate for the fact that some actions are selected more frequently than others, we divide by the probability of choosing the action, i.e., we use $f_m(s,a)/\pi(s,a)$ as functional gradient training examples and do not run over all actions.

As an example, we will now derive the point-wise functional gradient of a policy parameterized as a Gibbs distribution (1). For the sake of readability, we denote $\Psi(s,a)$ as Ψ_a and $\Psi(s,b)$ as Ψ_b.

Proposition 3.1 *The point-wise functional gradient of ρ with respect to a policy parameterized as a Gibbs distribution* (1) *equals to $Q(s,a) \cdot \frac{\partial \pi(s,a)}{\partial \Psi}$ with*

$$\frac{\partial \pi(s,a)}{\partial \Psi(s',a')} = \begin{cases} \pi(s,a)(1-\pi(s,a)) & \text{if } s = s' \wedge a = a', \\ -\pi(s,a)\pi(s,a') & \text{if } s = s' \wedge a \neq a' \\ 0 & \text{otherwise,} \end{cases}$$

To see this, consider the first case; the other cases can be derived in a similar way. Due to the Gibbs distribution, we can write $(\partial \pi(s,a))/(\partial \Psi(s,a)) =$

$$\frac{\partial}{\partial \Psi_a} \frac{e^{\Psi_a}}{\sum_b e^{\Psi_b}} = \frac{e^{\Psi_a} \cdot \sum_b e^{\Psi_b} - e^{\Psi_a} \cdot \sum_b \partial e^{\Psi_b}/\partial \Psi_a}{\left[\sum_b e^{\Psi_b}\right]^2} .$$

Assuming $(\partial \Psi_b)/(\partial \Psi_a) = 0$, i.e., Ψ_a and Ψ_b are independent, it holds $\sum_b \partial e^{\Psi_b}/\partial \Psi_a = e^{\Psi_a}$ and we can rewrite the state-action gradient as

$$= e^{\Psi_a} \frac{\left(\sum_b e^{\Psi_b} - e^{\Psi_a} \cdot \frac{\sum_b e^{\Psi_b}}{\sum_b e^{\Psi_b}}\right)}{\left[\sum_b e^{\Psi_b}\right]^2} = e^{\Psi_a} \frac{\left(1 - \frac{e^{\Psi_a}}{\sum_b e^{\Psi_b}}\right)}{\sum_b e^{\Psi_b}}$$

which simplifies – due to the definition of $\pi(s,a)$ – to

$$\frac{\partial \pi(s,a)}{\partial \Psi(s,a)} = \pi(s,a)(1-\pi(s,a)) .$$

The key point is the assumption $(\partial \Psi_b)/(\partial \Psi_a) = 0$. This actually means that we model Ψ with k functions f_k, one for each action a, i.e., $\Psi(s,a) = f_a(s)$. In turn, we estimate k regression models f_m^a. In the experiments, however, learning a single regression model f_m did not decrease performance so that we stick here to the conceptually easier variant of learning a single regression model f_m.

We call policy gradient methods that follow the outlined functional gradient approach *non-parametric policy gradients*, or NPPG for short. They are non-parametric because the number of parameters can grow with the number of episodes.

3.2. Gradient Tree Boosting

NPPG as summarized in Alg. 1 describes actually a family of approaches. In the following, we will develop a particular instance, called TreeNPPG, which uses regression tree learners to estimate f_m in line 6.

In TreeNPPG, the policy is represented by sums of regression *trees*. Each regression tree can be viewed as defining several new feature combinations, one corresponding to each path in the tree from the root to a leaf. The resulting policies still have the form of a linear combination of features, but the features can be quite complex. The trees are grown using a regression tree learner such as CART (Breiman et al., 1984), which in principle runs as follows. It starts with the empty tree and repeatedly searches for the best test for a node according to some splitting criterion such as weighted variance. Next, the examples $\mathcal{R}$ in the node are split into $\mathcal{R}_s$ (success) and $\mathcal{R}_f$ (failure) according to the test. For each split, the procedure is recursively applied, obtaining subtrees for the respective splits. As splitting criterion, we use the weighted variance on $\mathcal{R}_s$ and $\mathcal{R}_f$. We stop splitting if the variance in one node is small enough or a depth limit was reached. In leaves, the average regression value is predicted.

We propose to use regression tree learners because a rich variety of variants exists that can deal with finite, continuous and even relational data. Depending on the type of the problem domain at hand, one can instantiate the TreeNPPG algorithm by choosing the appropriate regression tree learner. We will give several examples in the following experimental section.

Algorithm 1: Non-Parametric Policy Gradient

1 Let Ψ_0 be the zero potential (the empty tree)
2 **for** $m = 1$ *to* N **do**
3 Choose a starting state s
4 Generate episodes $\mathcal{E}_m$ starting in s following the policy π_{m-1} with $\pi_{m-1}(s,a) = e^{\Psi_{m-1}(s,a)} / \left(\sum_b e^{\Psi_{m-1}(s,b)}\right)$
5 Generate functional gradient examples $\mathcal{R}_m = \{(s_i, a_{ij}), f_m(s_i, a_{ij})\}$ based on $\mathcal{E}_m$
6 Induce regression model f_m based on $\mathcal{R}_m$
7 Set potential to $\Psi_m = \Psi_{m-1} + \Delta_m$ where $\Delta_m = \eta_m \cdot f_m$ with local step size η_m
8 **return** *final potential* $\Psi = \Psi_0 + \Delta_1 + \ldots + \Delta_m$

4. Experimental Evaluation

Our intention is to investigate how well NPPG works. To this aim, we implemented it and investigated the following questions:

(Q1) Does TreeNPPG work and, if so, are there cases where it yields better results than current state-of-the-art methods? **(Q2)** Is TreeNPPG applicable across finite, continuous, and relational domains?

In the following, we will describe the experiments carried out to investigate the questions and their results.

(Q1) Blocks World: A Relational Domain

As a complex domain for empirical evaluation of TreeNPPG , we consider the well-known *blocks world* (Slaney & Thiébaux, 2001). To be able to compare the performance of TreeNPPG to other relational RL (RRL) systems, we adopt the same experimental environment as used for RRL by e.g. Driessens and Džeroski (2005). We learn in a world with 10 blocks and try to accomplish the $on(A, B)$ goal. This goal is parameterized and appropriate values for A and B are chosen at same the time as a starting state is generated. Thus, the reinforcement learn learns a single policy that stacks any two blocks. Although this is a relatively simple goal in a planning context, both RRL and our TreeNPPG algorithm use a model free approach and only learn from interactions with the environment. For the given setup this means that there are approximately 55.7 million reachable states[3] of which 1.44 million are goal states. The minimal number of steps to the goal is 3.9 on average. The percentage of states for other minimal solution sizes are given in Fig. 2. The agent only receives a reward of 1 if it reaches the goal in the minimal number of steps. The probability of receiving a reward using a random strategy is approximately 1.3%. To counter this difficulty of reaching any reward, we adopted the active guidance approach as proposed by Driessens and Dzeroski (2004), presenting the RL agent with 10% of expert traces during exploration in all experiments.

We apply TreeNPPG to this relational domain by simply employing the relational regression tree learner Tilde (Blockeel & De Raedt, 1998). Rather than using attribute-value or threshold tests in node of the tree, Tilde employs logical queries. Furthermore, a placeholder for domain elements (such as blocks) can occur in different nodes meaning that all occurrences denote the same domain element. Indeed, this slightly complicates the induction process, for example when generating the possible tests to be placed in a node. To this aim, it employs a classical *refinement operator* under θ-subsumption. The operator basically adds a literal, unifies variables, and grounds variables. When a node is to be splitted, the set of all refinements are computed and evaluated according to the chosen heuristic. Except for the representational differences, Tilde uses the same approach to tree-building as the generic tree learner. Because single episodes are too short and thus generate too few examples for Tilde to learn meaningful trees, we postpone calling Tilde until an episode brings the cumulated number of examples over 100. As a language bias for Tilde we employ the same language bias as used in published RRL experiments, including predicates such as *clear*, *on*, *above* and *compheight*[4]. Each learned model Δ_m, updates the potential function Ψ using a step-size $\eta_m = 1$. We count on the self-correcting property of tree boosting to correct over- or under-stepping the target on the next iteration.

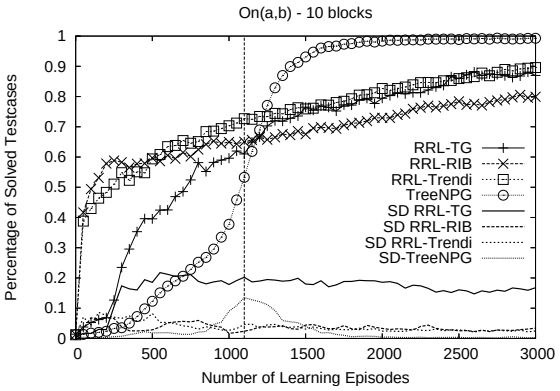

Figure 1. Comparison of the learning curves for Non-Parametric Policy Gradient and various RRL implementations on the on(A,B) task in a world with 10 blocks.

We ran experiments using three versions of the RRL system, i.e, TG (Driessens et al., 2001), RIB (Driessens & Ramon, 2003), and Trendi (Driessens & Džeroski, 2005), which represent the current state-of-the-art of RRL systems, and our TreeNPPG algorithm. After every 50 learning episodes, we fixed the strategy learned by RRL and tested the performance on 1000 randomly generated starting states. For TreeNPPG fixing the strategy is not required as it uses the learned strategy for exploration directly. Fig. 1 shows the resulting learning curves averaged over 10 test-runs as well as the standard deviations of these curves. As shown, TreeNPPG outperforms all tested versions of the RRL system. After approximately 2000 learning episodes, TreeNPPG solves 99% of all presented testcases in the minimal number of steps. With less than 4 steps per learning episode on average, this means that TreeNPPG generalizes the knowledge it collected by visiting less than 8000 states to solve 99% of 54.3 million states. Around this time, TreeNPPG has generated a list of 500 trees on average. One observation that can not be made directly on the shown graph is the stability of the TreeNPPG algorithm. Where the performance of the RRL system using TG

[3]We do not consider states in which the goal has already been satisfied as starting states. Therefore, a number of states where the goal is satisfied are not reachable, i.e., the states where $on(A, B)$ is satisfied and there are extra blocks on top of A.

[4]For a full overview and the semantics of these predicates, we refer to (Driessens & Džeroski, 2005).

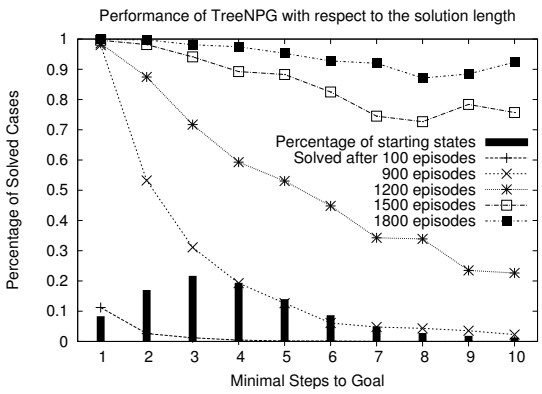

Figure 2. Detailed view of the learning performance of TreeNPPG showing the percentage of solved test-cases with respect to the minimal solution size for varying amounts of learning experience. The graph also shows the percentage of test-cases for each solution length.

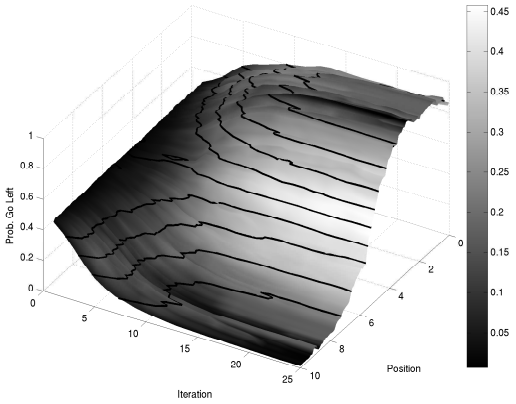

Figure 3. Learning performance of TreeNPPG on the continuous *corridor* task. Shown is how the probability of going *left* at all corridor positions evolves with the number of iterations. The shading indicates the standard deviation over the 30 runs of the experiment.

for regression can vary substantially between experiments, TreeNPPG follows an extremely similar path in each iteration of the experiment. The only variation between experiments is the exact time-frame of the phase transition in the results, as shown by the peak in TreeNPPG's standard deviation curve. Fig. 2 shows the results in more detail, plotting the percentage of solved test-cases with respect to the minimal solution length. As one can see, TreeNPPG gradually learns to solve problems with growing solution sizes. The graph also shows the percentage of test-cases for each solution size.

To summarize, the results clearly show that question **Q1** can be answered affirmatively.

(Q2) Corridor World: A Continuous Domain

To qualitatively test whether TreeNPPG is also applicable in continuous domains, we considered a simple *continuous corridor* domain. The task is to navigate a robot from any position $pos_0 \in [0, 10]$ in a one-dimensional corridor $[0, 10]$ to one of the exists at both ends (0 and 10). At each time $t = 0, 1, 2, \ldots$, the robot can go either one step to the *left* ($a = -1$) or one step to the *right* ($a = 1$); the outcome, however, is uncertain with $pos_{t+1} = pos_t + a + \mathcal{N}(1, 1)$. The robot is given a reward after each step equal to -1 if $pos \in (0, 10)$ and equal to 20 otherwise, i.e., it reaches one of the exists.

Fig. 3 shows how the stochastic policy evolves with the number of iterations, i.e., calls to the tree learner. These results are averaged over 30 reruns. In each run, we selected a random starting position pos_0 uniformly in $(0, 10)$, gathered learning examples from 30 episodes in each iteration, and used a step size $\eta_m = 0.7$. As one can see, the robot gradually learns to go *left* in the left section of the corridor and *right* in the right section. Quite intuitively, the uncertainty is highest in the middle part of the corridor.

We also ran experiments in a grid-world version of this problem. We do not report on the successful results here because finite domains are a special case of the relational and continuous cases. To summarize, question **Q2** can also be answered affirmatively.

5. Related Work

Within reinforcement learning (RL), there are two main classes of solution methods: value-function methods seek to estimate the value of states and actions whereas policy-based methods search for a good policy within some class of policies.

Within policy-based methods, policy gradients have received increased attention, see e.g. (Williams, 1992; Baxter et al., 2001; Guestrin et al., 2002; Konda & Tsitsiklis, 2003; Munos, 2006) as a non-exhausting list. Most closely related to NPPG is the work of Bagnell and Schneider (2003), see also (Bagnell, 2004). They proposed a functional gradient policy algorithms in reproducing kernel hilbert spaces for continuous domains. So far, however, this line of work has not considered (relationally) structured domains and the connection to gradient boosting was not employed.

Within value function approaches, the situation is slightly different. NPPG can be viewed as automatically generating a "variable" propositionalization or discretization of the domain at hand. In this sense, it is akin to tree-based state discretization RL ap-

proaches such as (Chapman & Kaelbling, 1991; McCallum, 1996; Uther & Veloso, 1998) and related approaches. Within this line of research, there have been some boosting methods proposed. Ernst et al. (2005) showed how to estimate Q functions with ensemble methods based on regression trees. Riedmiller (2005) keeps all regression examples and re-weights them according to some heuristic. Both neither consider policy gradients nor relational domains.

Recently, there have been some exciting new developments in combining the rich relational representations of classical knowledge representation with RL. While traditional RL requires (in principle) explicit state and action enumeration, these symbolic approaches seek to avoid explicit state and action enumeration through a symbolic representation of states and actions. Most work in this context, however, has focused on value function approaches. Basically, a number of relational regression algorithms have been developed for use in this RL system that employ relational regression trees (Driessens et al., 2001), relational instance based regression (Driessens & Ramon, 2003), graph kernels and Gaussian processes (Gärtner et al., 2003) and relational model-trees (Driessens & Džeroski, 2005). Finally, there is an increasing number of dynamic programming approaches for solving relational MDPs (Kersting et al., 2004; Sanner & Boutilier, 2005; Wang et al., 2007). In contrast to NPPG, they assume a model of the domain. It would be interesting, however, to combine NPPG with these approaches along the line of (Wang & Dietterich, 2003). A parametric step into this direction has been already taken by Aberdeen (2006).

6. Conclusions

We have introduced the framework of non-parametric policy gradient (NPPG) methods. It seeks to leverage the policy selection problem by approaching it from a gradient boosting perspective. NPPG is fast and straightforward to implement, combines the expressive power of relational RL with the benefits of policy gradient methods, and can deal with finite, continuous, and relational domains in a unified way. Moreover, the experimental results show a significant improvement over established results; for the first time, a (model-free) relational RL approach learns to solve $on(A, B)$ in a world with 10 blocks.

NPPG suggests several interesting directions for future research such as using more advanced regression models, developing actor-critic versions of NPPG estimating a value function in parallel to reduce the variance of the gradient estimates, and exploiting NPPG's ability to learn in hybrid domains with both discrete and continuous variables within real-world domains such as as robotics and network routing. Most interesting, however, is to address the more general problem of learning how to interact with (relationally) structured environments in the presence observation noise. NPPG is naturally applicable in this case and, hence, paves the way towards (model-free) solutions of what can be called relational POMDPs. This is a topic of high current interest since it combines the expressive representations of classical AI with the decision-theoretic emphasis of modern AI.

ICA and ISA Using Schweizer-Wolff Measure of Dependence

Sergey Kirshner SERGEY@CS.UALBERTA.CA
Barnabás Póczos POCZOS@CS.UALBERTA.CA
AICML, Department of Computing Science, University of Alberta, Edmonton, Alberta, Canada T6G 2E8

Abstract

We propose a new algorithm for independent component and independent subspace analysis problems. This algorithm uses a contrast based on the Schweizer-Wolff measure of pairwise dependence (Schweizer & Wolff, 1981), a non-parametric measure computed on pairwise ranks of the variables. Our algorithm frequently outperforms state of the art ICA methods in the normal setting, is significantly more robust to outliers in the mixed signals, and performs well even in the presence of noise. Our method can also be used to solve independent subspace analysis (ISA) problems by grouping signals recovered by ICA methods. We provide an extensive empirical evaluation using simulated, sound, and image data.

1. Introduction

Independent component analysis (ICA) (Comon, 1994) deals with a problem of a blind source separation under the assumptions that the sources are independent and that they are linearly mixed. ICA has been used in the context of blind source separation and deconvolution, feature extraction, denoising, and successfully applied to many domains including finances, neurobiology, and processing of fMRI, EEG, and MEG data. For a review on ICA, see Hyvärinen et al. (2001).

Independent subspace analysis (ISA) (also called multi-dimensional ICA and group ICA) is a generalization of ICA that assumes that certain sources depend on each other, but the dependent groups of sources are still independent of each other, i.e., the independent groups are multidimensional. The ISA task has been the subject of extensive research (e.g., Cardoso, 1998; Theis, 2005; Bach & Jordan, 2003; Hyvärinen & Köster, 2006; Póczos & Lőrincz, 2005) and applied, for instance, to EEG-fMRI data.

Our contribution, SWICA, is a new ICA algorithm based on Schweizer-Wolff (SW) non-parametric dependence measure. SWICA has the following properties:

- SWICA performs comparably to other state of the art ICA methods, outperforming them in a large number of test cases.
- SWICA is extremely robust to outliers as it uses *rank* values of the signals rather than their actual values.
- SWICA suffers less from the presence of noise than other algorithms.
- SW measure can be used as the cost function to solve ISA problems by grouping sources recovered by ICA methods.
- SWICA is simple to implement, and the Matlab/C++ code is available for public use.
- On a negative side, SWICA is slower than other methods, limiting its use to sources of moderate dimensions, and it requires more samples to demix sources with near-Gaussian distributions.

The paper is organized as follows. An overview of the ICA and ISA problems and methods is presented in Section 2. Section 3 motivates and describes Schweizer-Wolf dependence measure. Section 4 describes a 2-source version of SWICA, extends it to a d-source problem, describes an application to ISA, and mentions possible approaches for accelerating SWICA. Section 5 provides a thorough empirical evaluation of SWICA to other ICA algorithms under different settings and data types. The paper is concluded with a summary in Section 6.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

2. ICA and ISA

We consider the following problem. Assume we have d independent 1-dimensional sources (random variables) denoted by $S^1, \ldots, S^d$. We assume each source emits N i.i.d. samples denoted by $\left(s_1^i, \ldots, s_N^i\right)$. Let $\mathbf{S} = \left\{s_i^j\right\} \in \mathbb{R}^{d \times N}$ be a matrix of these samples. We assume that these sources are hidden, and that only a matrix $\mathbf{X}$ of mixed samples can be observed:

$$\mathbf{X} = \mathbf{AS}$$

where $\mathbf{A} \in \mathbb{R}^{d \times d}$. (We further assume that $\mathbf{A}$ has full rank d.) The task is to recover the sample matrix $\mathbf{S}$ of the hidden sources by finding a demixing matrix $\mathbf{W}$

$$\mathbf{Y} \quad = \quad \mathbf{WX} = (\mathbf{WA})\,\mathbf{S},$$

and the estimated sources $Y^1, \ldots, Y^d$ are mutually independent. The solution can be recovered only up to a scale and a permutation of the components; thus we assume that the data has been pre-whitened, and it is sufficient to search for an *orthogonal* matrix $\mathbf{W}$ (e.g., Hyvärinen et al., 2001). Additionally, since jointly Gaussian sources are not identifiable under linear transformations, we assume that no more than one source is normally distributed.

There are many approaches to solving the ICA problem, differing both in the objective function designed to measure the independence between the unmixed sources (sometimes referred to as a contrast function) and the optimization methods for that function. Most commonly used objective function is the mutual information (MI)

$$J(\mathbf{W}) = I\left(Y^1, \ldots, Y^d\right) = \sum_{i=1}^{d} h\left(Y^i\right) - h\left(Y^1, \ldots, Y^d\right) \tag{1}$$

where h is the differential entropy. Alternatively, one can minimize the sum $\sum_{i=1}^{d} h\left(Y^i\right)$ of the univariate entropies as the joint entropy is constant (e.g., Hyvärinen et al., 2001). Neither of these quantities can be evaluated directly, so approximations are used instead. Among effective methods falling in the former category is KernelICA (Bach & Jordan, 2002); RADICAL (Learned-Miller & Fisher, 2003) and FastICA (Hyvärinen, 1999) approximate the sum of the univariate entropies. There are other possible cost functions including maximum likelihood, moment-based methods, and correlation-based methods.

While ICA problems has been well-studied in the above formulation, there are a number of variations of it that are subject of active research. One such formulation is a noisy version of ICA

$$\mathbf{X} = \mathbf{AS} + \boldsymbol{\epsilon} \tag{2}$$

where multivariate noise $\boldsymbol{\epsilon}$ is often assumed normally distributed. Another related problem occurs when the mixed samples $\mathbf{X}$ are corrupted by a presence of outliers. There are many other possibilities that go beyond the scope of this paper.

Of a special note is a generalization of ICA where some of the sources are *dependent*, independent subspace analysis (ISA). For this case, the mutual information and Shannon entropies from Equation 1 would involve multivariate random vectors instead of scalars. Resulting multidimensional entropies are exponentially more difficult to estimate than their scalar counterparts, making ISA problem more difficult than ICA. However, Cardoso (1998) conjectured that the ISA problem can be solved by first preprocessing the mixtures $\mathbf{X}$ by an ICA algorithm and then grouping the estimated components with highest dependence. While the extent of this conjecture is still on open issue, it has been rigorously proven for some distribution types (Szabó et al., 2007). Even without a proof for the general case, a number of algorithms apply this heuristics with success (Cardoso, 1998; Theis, 2007; Bach & Jordan, 2003). There are ISA methods not relying on Cardoso's conjecture (e.g., Hyvärinen & Köster, 2006) although they are susceptible to getting trapped in local minima.

3. Non-parametric Rank-Based Approach

Most of the ICA algorithms use an approximation to mutual information (MI) as their objective functions, and the quality of the solution thus depends on how accurate is the corresponding approximation. The problem with using MI is that without a parametric assumption on the functional form of the joint distribution, MI cannot be evaluated exactly, and numerical estimation can be both inaccurate and computationally expensive. In this section, we explore other measures of pairwise association as possible ICA contrasts. To note, most commonly used measure of correlation, Pearson's linear correlation coefficient, cannot be used as it is invariant under rotations (once the data has been centered and whitened)

Instead, we are focusing on measures of dependence of the *ranks*. Ranks have a number of desirable properties – they are invariant under monotonic transformations of the individual variables, insensitive to outliers,

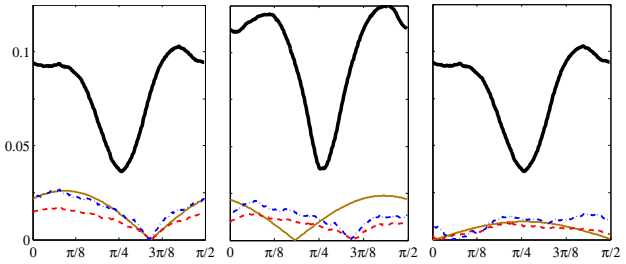

Figure 1. Absolute values of sample versions for Pearson's ρ_p (solid thin, brown), Kendall's τ (dashed, red), Spearman's ρ (dash-dotted, blue), and Schweizer-Wolff σ (solid thick, black) as a function of rotation angle $\left[0, \frac{\pi}{2}\right]$. Data was obtained by rotating by $\frac{\pi}{4}$ 1000 samples from a uniform distribution on $\mathbf{I}^2$ (left), with added outliers (center), and with added noise (right).

and not very sensitive to small amounts of noise. We found that a dependence measure defined on copulas (e.g., Nelsen, 2006), probability distributions on continuous ranks, has the right properties to be used as a contrast for ICA demixing.

3.1. Ranks and Copulas

Let a pair of random variables $(X, Y) \in \mathbb{R}^2$ be distributed according to a bivariate probability distribution P. Assume we are given N samples of (X, Y), $\mathcal{D} = \{(x_1, y_1), \ldots, (x_N, y_N)\}$. Let the rank $r_x(x)$ be the number of x_i, $i = 1, \ldots, N$ such that $x > x_i$, and let $r_y(y)$ be defined similarly.

Many non-linear dependence measures are based on ranks. Among most commonly used are Kendall's τ and Spearman's ρ rank correlation coefficients. Kendall's τ measures the difference between proportions of concordant pairs ((x_i, y_i) and (x_j, y_j) such that $(x_i - x_j)(y_i - y_j) > 0$) and discordant pairs. Spearman's ρ measures a linear correlation between ranks of $r_x(x)$ and $r_y(y)$. Both τ and ρ have a range of $[-1, 1]$ and are equal to 0 (in the limit) if the X and Y are independent. However, the converse is not true, and both τ and ρ can be 0 even if X and Y are not independent. While they are robust to outliers, neither ρ nor τ make for a good ICA contrast as they provide a noisy estimate for dependence from moderately-sized data sets when the dependence is weak (See Figure 1 for an illustration).

Rank correlations can be extended from samples to distributions with the help of *copulas*, distributions over continuous multivariate ranks. We will devise an effective robust contrast for ICA using a measure of dependence for copulas which is closely related to Spearman's ρ.

Let $\mathbf{I}$ denote a unit interval $[0, 1]$. A bivariate *copula* C is probability function (cdf) defined on a unit square, $C : \mathbf{I}^2 \to \mathbf{I}$ such that its univariate marginals are uniform, i.e., $C(u, 1) = u$, $C(1, v) = v$, $\forall u, v, \in \mathbf{I}$.[1] Let $U = P_x(X)$ and $V = P_y(Y)$ denote the corresponding cdfs for previously defined random variables X and Y. Variables $X = P_x^{-1}(U)$ and $Y = P_y^{-1}(V)$ can be defined in terms of the inverse of marginal cdfs. Then, for $(u, v) \in \mathbf{I}^2$, define C as

$$C(u, v) = P\left(P_x^{-1}(u), P_y^{-1}(v)\right).$$

It is easy to verify that C is a copula. Sklar's theorem (Sklar, 1959) states that such copula exists for any distribution P, and that it is unique on the range of values of the marginal distributions. A copula can be thought of as binding univariate marginals P_x and P_y to make a distribution P.

Copulas can also be viewed as a canonical form of multivariate distributions as they preserve multivariate dependence properties of the corresponding families of distributions. For example, the mutual information of the joint distribution is equal to the negentropy of its copula restricted to the region on which the copula *density* function (denoted in this paper by $c(u, v)$) is defined:

$$\begin{aligned} c(u, v) &= \frac{\partial^2 C(u, v)}{\partial u \partial v} = \frac{p(x, y)}{p_x(x)\, p_y(y)}; \\ I(X, Y) &= \int_{\mathbf{I}^2} c(u, v) \ln c(u, v)\, du dv. \end{aligned}$$

Such negentropy is minimized when $C(u, v) = \Pi(u, v) = uv$. Copula Π is referred to as the *product* copula and is equivalent to variables U and V (and the original variables X and Y) being mutually independent. This copula will play a central part in definition of contrasts in the next subsection.

Copulas can also be viewed as a joint distribution over univariate *ranks*, and therefore, preserve all of the rank statistics of the corresponding multivariate distributions; rank based statistics can be expressed in terms of the copula alone. For example, Spearman's ρ has a convenient functional form in terms of the corresponding copulas (e.g., Nelsen, 2006):

$$\rho = 12 \int_{\mathbf{I}^2} (C(u, v) - \Pi(u, v))\, du dv. \qquad (3)$$

[1] While we restrict our attention to bivariate copulas, many of the definitions and properties described in this section can be extended to a d-variate case.

As the true distribution P and its copula C are not known, the rank statistics can be estimated from the available samples using an *empirical copula* (Deheuvels, 1979). For a data set $\{(x_1, y_1), \ldots, (x_N, y_N)\}$, an empirical copula C_N is given by

$$C_N\left(\frac{i}{N}, \frac{j}{N}\right) = \frac{\#\text{ of } (x_k, y_k) \text{ s.t. } x_k \leq x_i \text{ and } y_k \leq y_j}{N}. \quad (4)$$

Well-known sample versions of several non-linear dependence measures can be obtained using an empirical copula (e.g., Nelsen, 2006). For example, sample version r of Spearman's ρ appears to be a grid integration evaluation of its expression in terms of a copula (Equation 3):

$$r = \frac{12}{N^2 - 1} \sum_{i=1}^{N} \sum_{j=1}^{N} \left(C_N\left(\frac{i}{N}, \frac{j}{N}\right) - \frac{i}{N} \times \frac{j}{N} \right). \quad (5)$$

3.2. Schweizer-Wolff σ and κ

Part of the problem with Kendall's τ and Spearman's ρ as a contrast for ICA is a property that their value may be 0 even though the corresponding variables X and Y are not independent. Instead, we suggest using Schweizer-Wolff σ, a measure of dependence between two continuous random variables (Schweizer & Wolff, 1981):

$$\sigma = 12 \int_{\mathbf{I}^2} |C(u, v) - uv| \, \mathrm{d}u\mathrm{d}v. \quad (6)$$

σ can be viewed as an L_1 norm between a copula for the distribution and a product copula. It has a range of $[0, 1]$, with an important property that $\sigma = 0$ if and only if the corresponding variables are mutually independent, i.e., $C = \Pi$. The latter property suggests an ICA algorithm for a pair of variables: pick a rotation angle such that the corresponding demixed data set has its σ minimized. A sample version of σ is similar to that of ρ (Equation 5):

$$s = \frac{12}{N^2 - 1} \sum_{i=1}^{N} \sum_{j=1}^{N} \left| C_N\left(\frac{i}{N}, \frac{j}{N}\right) - \frac{i}{N} \times \frac{j}{N} \right|. \quad (7)$$

We note that other measures of dependence can be potentially used as an ICA contrast. We also experimented with an L_∞ version of σ, $\kappa = 4 \sup_{\mathbf{I}^2} |C(u, v) - uv|$, a dependence measure similar to Kolmorogov-Smirnov univariate statistic (Schweizer & Wolff, 1981), with results similar to σ.

4. SWICA: A New Algorithm for ICA and ISA

In this section, we present a new algorithm for ICA and ISA demixing. The algorithm uses Schweizer-Wolff σ estimates as a contrast in demixing pairs of variables; we named this algorithm Schweizer-Wolff contrast for ICA, or SWICA for short.

4.1. 2-dimensional Case

First, we tackle the case of a two-dimensional signal $\mathbf{S}$ mixed with a 2×2 matrix $\mathbf{A}$. We, further assume $\mathbf{A}$ is orthogonal (otherwise achievable by whitening). The problem is then reduced to finding a demixing rotation matrix $\mathbf{W} = \begin{bmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{bmatrix}$.

For the objective function, we use s (Equation 7) computed on $2 \times N$ matrix $\mathbf{Y} = \mathbf{WX}$ of rotated samples. Given an angle θ, $s(\boldsymbol{Y}(\theta))$ can be computed by first sorting each of the rows of $\mathbf{Y}(\theta)$ and computing row ranks for each entry of $\mathbf{Y}(\theta)$, then computing an empirical copula C_N (Equation 4) for ranks of $\mathbf{Y}$, and finally computing $s(\mathbf{Y}(\theta))$ (Equation 7). The solution is then found by finding angle θ minimizing $s(\mathbf{Y}(\theta))$. Similar to RADICAL (Learned-Miller & Fisher, 2003), we find such solution by searching over K values of θ in the interval $\left[0, \frac{\pi}{2}\right)$. This algorithm is outlined in Figure 2.

4.2. d-dimensional Case

A d-dimensional linear transformation described by a $d \times d$ orthogonal matrix $\mathbf{W}$ is equivalent to a composition of 2-dimensional rotations (called *Jacobi* or *Givens* rotations) (e.g., Comon, 1994). The transformation matrix itself can be written as a product of corresponding rotation matrices, $\mathbf{W} = \mathbf{W}_L \times \ldots \times \mathbf{W}_1$ where each matrix $\mathbf{W}_l$, $l = 1, \ldots, L$ is a rotation matrix (by angle θ_l) for some pair of dimensions (i, j). Thus a d-dimensional ICA problem can be solved by solving 2-dimensional ICA problems in succession. Given a current demixing matrix $\mathbf{W}_c = \mathbf{W}_l \times \ldots \times \mathbf{W}_1$ and a current version of the signal $\mathbf{X}_c = \mathbf{W}_c\mathbf{X}$, we find an angle θ corresponding to $\mathrm{SWICA}\left(\mathbf{X}_c^{(i,j)}, K\right)$. Taking an approach similar to RADICAL, we perform a fixed number of successive sweeps through all possible pairs of dimensions (i, j).

We should note that while d-dimensional SWICA is not guaranteed to converge, it converges in practice a vast majority of the time. A likely explanation is that each 2-dimensional optimization finds a transfor-

Algorithm SWICA($\mathbf{X}, K$)
Inputs: $\mathbf{X}$, a $2 \times N$ matrix where rows are mixed signals (centered and whitened), K equispaced evaluation angles in the $[0, \pi/2)$ interval

For each of K angles θ in the interval $[0, \pi/2)$ ($\theta = \frac{\pi k}{2K}, k = 0, \ldots, K-1$.)

- Compute rotation matrix

$$\mathbf{W}(\theta) = \begin{bmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{bmatrix}$$

- Compute rotated signals $\mathbf{Y}(\theta) = \mathbf{W}(\theta)\mathbf{X}$.
- Compute $s(\mathbf{Y}(\theta))$, a sample estimate of σ (Equation 7)

Find best angle $\theta_m = \arg\min_\theta s(\mathbf{Y}(\theta))$

Output: Rotation matrix $\mathbf{W} = \mathbf{W}(\theta_m)$, demixed signal $\mathbf{Y} = \mathbf{Y}(\theta_m)$, and estimated dependence measure $s = s(\boldsymbol{Y}(\theta_m))$

Figure 2. Outline of SWICA algorithm (2-d case).

mation that reduces the sum of entropies for the corresponding dimensions, reducing the overall sum of entropies. In addition to this, Learned-Miller and Fisher (2003) suggest that the minimization of the overall sum of entropies in this fashion (by changing only two terms in the sum) may make it easier to escape local minima.

4.3. Complexity Analysis and Acceleration Tricks

2-dimensional SWICA requires a search over K angles. For each angle, we first sort the data to compute the ranks of each data point ($\mathcal{O}(N \log N)$), and then use these ranks to compute s by computing the empirical copula and summing over the $N \times N$ grid (Equation 7), requiring $\mathcal{O}(N^2)$ additions. Therefore, running time complexity of 2-d SWICA is $\mathcal{O}(KN^2)$. Each sweep of a d-dimensional ICA problem solves a 2-dimensional ICA problem for each pair of variables, $\mathcal{O}(d^2)$ of them; S sweeps would have $\mathcal{O}(Sd^2KN^2)$ complexity. In our experiments, we employed $K = 180, S = 1$ for $d = 2$, and $K = 90, S = d$ for $d > 2$.

The most expensive computation in SWICA is $\mathcal{O}(N^2)$ needed to compute $s(\mathbf{Y}(\theta))$. Reducing this complexity, either by approximation, or perhaps, by an efficient rearrangement of the sum, is left to future research. We used several other tricks to speed up the computation. One, for large N ($N > 2500$) we estimated s using only N_s^2 ($N_s = \lfloor \frac{N}{\lceil \frac{N}{2500} \rceil} \rfloor$) terms in the sum corresponding to equispaced gridpoints on $\mathbf{I}^2$. Two, when searching for θ minimizing $s(\mathbf{Y}(\theta))$, it is unnecessary to sum over all N^2 terms when evaluating a candidate θ if a partial sum already results in a value of $s(\mathbf{Y}(\theta))$ larger than the current best. This optimization translates into a 2-fold speed increase in practice. Three, it is unnecessary to complete all S sweeps if the algorithm already converged. One possible measure of convergence is the Amari error (Equation 8) measured for the cumulative rotation matrix for the most recent sweep.

4.4. Using Schweizer-Wolff σ for ISA

Following Cardoso's conjecture, ISA problems can be solved by first finding a solution to an ICA problem, and then by grouping resulting sources that are *not* independent (Cardoso, 1998). We propose employing Schweizer-Wolff σ to measure dependence of sources for an ICA solution as it provides a computationally effective alternative to mutual information, commonly used measure of source dependence. Note that ICA solution, the first step, can be obtained using any approach, e.g., FastICA due to its computational speed for large d. One commonly used trick for grouping the variables is to use a non-linear transformation of the variables to "amplify" their dependence as independent variables remain independent under such transformations.[2]

5. Experiments

For the experimental evaluation of SWICA, we considered several settings. For the evaluation of the quality of demixing solution matrix $\mathbf{W}$, we computed the Amari error (Amari et al., 1996) for the resulting transformation matrix $\mathbf{B} = \mathbf{WA}$. Amari error $r(\mathbf{B})$ measures how different matrix $\mathbf{B}$ is from a permutation matrix, and is defined as

$$\alpha \sum_{i=1}^{d} \left(\frac{\sum_{j=1}^{d} |b_{ij}|}{\max_j |b_{ij}|} - 1 \right) + \alpha \sum_{j=1}^{d} \left(\frac{\sum_{i=1}^{d} |b_{ij}|}{\max_i |b_{ij}|} - 1 \right). \tag{8}$$

where $\alpha = 1/(2d(d-1))$. $r(\mathbf{B}) \in [0, 1]$, and $r(\mathbf{B}) = 0$ if and only if $\mathbf{B}$ is a permutation matrix. We compared SWICA to FastICA (Hyvärinen, 1999), KernelICA-KGV (Bach & Jordan, 2002), RADICAL (Learned-Miller & Fisher, 2003), and JADE (Cardoso, 1999).

[2]Such transformations are at the core of the KernelICA and JADE ICA algorithms.

For the simulated data experiments, we used 18 different one-dimensional densities to simulate sources. These test-bed densities (and some of the experiments below) were proposed by Bach and Jordan (2002) to test KernelICA and by Learned-Miller and Fisher (2003) to evaluate RADICAL; we omit the description of these densities due to lack of space as they can be looked up in the above papers.

Table 1 summarizes the medians of the Amari errors for 2-dimensional problems where both sources had the same distribution. Samples from these sources were then transformed by a random rotation, and then demixed using competing ICA algorithms. SWICA outperforms its competitors in 8 out of 18 cases, and performs comparably in several other cases. However, it performs poorly when the joint distribution for the sources is close to a Gaussian (e.g., (d) t-distribution with 5 degrees of freedom). One possible explanation for why SWICA performs worse than its competitors for these cases is that by using ranks instead of the actual values, SWICA is discarding some of the information that may be essential to separating such sources. However, given larger number of samples, SWICA is able to separate near-Gaussian sources (data not shown due to space constraints). SWICA also outperformed other methods when sources were not restricted to come from the same distribution (Table 2) and proved effective for multi-dimensional problems ($d = 4, 8, 16$).

Figure 3 summarizes the performance of ICA algorithms in the presence of outliers for the d-source case ($d = 2, 4, 8$). Distributions for the sources were chosen at random from the 18 distributions from the experiment in Table 1. The sources were mixed using a random rotation matrix. The mixed sources were then corrupted by adding $+5$ or -5 to a single component for a small number of samples. SWICA significantly outperforms the rest of the algorithms as the contrast used by SWICA is insensitive to minor changes in the sample ranks introduced by a small number of outliers. For $d = 2$, we tested SWICA further by significantly increasing the number of outliers; the performance was virtually unaffected when the proportion of the outliers was below 20%. SWICA is also less sensitive to noise than other ICA methods (Figure 4).

We further tested SWICA on sound and image data. We mixed $N = 1000$ samples from 8 sound pieces of an ICA benchmark[3] by a random orthogonal 8×8 matrix. Then we added 20 outliers to this mixture in the same way as in the previously described outlier experiment and demixed them using ICA algorithms. Figure 5 shows that SWICA outperforms other methods on this task. For the image experiment, we used 4 natural images[4] of size 128×256. The pixel intensities we normalized in the [0, 255] interval. Each image was considered as a realization of a stochastic variable with 32768 sample points. We mixed these 4 images by a 4×4 random orthogonal mixing matrix, resulting in a mixture matrix of size 4×32768. Then we added large $+2000$ or -2000 outliers to 3% randomly selected points of these mixture, and then selected at random 2000 samples from the 32768 vectors. We estimated the demixing matrix $\mathbf{W}$ using only these 2000 points,

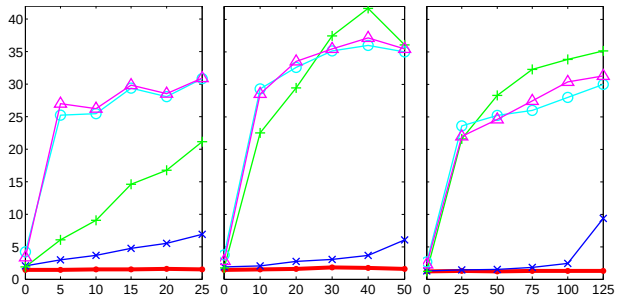

Figure 3. Amari errors (multiplied by 100) for 2-d (left), 4-d (center), and 8-dimensional (right) ICA problem in the presence of outliers. The plot shows the median values over $R = 1000, 100, 100$ replicas of $N = 1000, 2000, 5000$ samples for $d = 2, 4, 8$, respectively. Legend: Swica – red dots (thick), RADICAL – blue x's, KernelICA – green pluses, FastICA – cyan circles, JADE – magenta triangles. The x-axis shows the number of outliers.

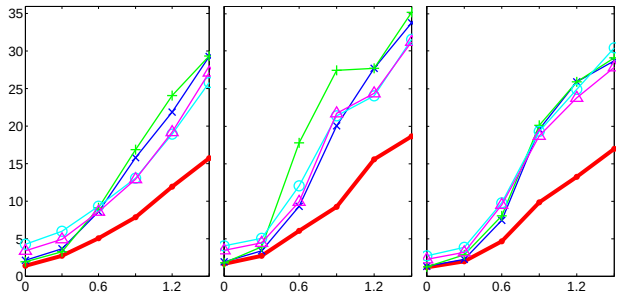

Figure 4. Amari errors (multiplied by 100) for 2-d (left), 4-d (center), and 8-dimensional (right) ICA problems in the presence of independent Gaussian noise applied to mixed sources. The plot shows the median values of $R = 1000, 100, 100$ replicas of $N = 1000, 2000, 5000$ samples for $d = 2, 4, 8$, respectively. The abscissa shows the variance of the Gaussian noise, $\sigma^2 = (0, 0.3, 0.6, 0.9, 1.2, 1.5)$. The legend is the same as in Figure 3.

and then recovered the hidden sources for all 32768 samples using this matrix. SWICA significantly outperformed other methods. Figure 7 shows an example of the demixing achieved by different ICA algorithms.

Finally, we applied Schweizer-Wolff σ in an ISA setting. We used 6 3-dimensional sources where each variable was sampled from a geometric shape (Figure 6a), resulting in 18 univariate hidden sources. These sources ($N = 1000$ samples) were then mixed with a random 18×18 orthogonal matrix (Figure 6b). Applying Cardoso's conjecture, we first processed the mixed sources using FastICA, and then clustered the recovered sources using σ computed on their absolute values (a non-linear transformation) (Figure 6c). The hidden subspaces were recovered with high precision as indicated by the Hinton diagram of **WA** (Figure 6d).

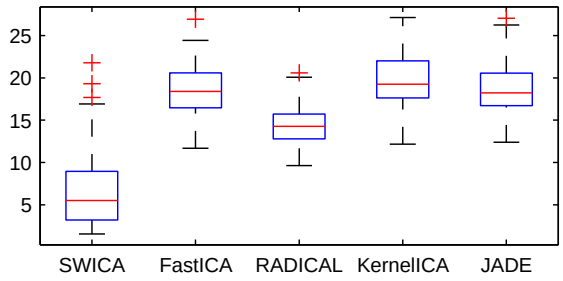

Figure 5. Box plot of Amari errors (multiplied by 100) for the mixed sounds with outliers. Plot was computed over $R = 100$ replicas.

6. Conclusion

We proposed a new ICA and ISA method, SWICA, based on a non-parametric rank-based estimate of the dependence between pairs of variables. Our method frequently outperforms other state of the art ICA algorithms, is very robust to outliers, and only moderately sensitive to noise. On the other hand, it is somewhat slower than other ICA methods, and requires more samples to separate near-Gaussian sources. In the future, we plan to investigate possible accelerations to the algorithm, and statistical characteristics of the source distributions that affect the contrast.

Abstract

The need to meaningfully combine sets of rankings often comes up when one deals with ranked data. Although a number of heuristic and supervised learning approaches to rank aggregation exist, they require domain knowledge or supervised ranked data, both of which are expensive to acquire. In order to address these limitations, we propose a mathematical and algorithmic framework for learning to aggregate (partial) rankings without supervision. We instantiate the framework for the cases of combining permutations and combining top-k lists, and propose a novel metric for the latter. Experiments in both scenarios demonstrate the effectiveness of the proposed formalism.

1. Introduction

Consider the scenario where each member of a panel of judges independently generates a (partial) ranking over a set of items while attempting to reproduce a true underlying ranking according to their level of expertise. This setting motivates a fundamental machine learning and information retrieval (IR) problem - the necessity to meaningfully aggregate preference rankings into a joint ranking. The IR community refers to this as *data fusion*, where a joint ranking is derived from the outputs of multiple retrieval systems. For example, in *meta-search* the aim is to aggregate Web search query results from several engines into a more accurate ranking. In many natural language processing applications, such as *machine translation*, there has been an increased interest in combining the results of multiple systems built on different principles in an effort to improve performance (Rosti et al., 2007).

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

One impediment to solving *rank aggregation* tasks is the high cost associated with acquiring full or partial preference information, making supervised approaches of limited utility. For data fusion, efforts to overcome this difficulty include applying domain specific heuristics (Shaw & Fox, 1994) or collecting such preference information indirectly (e.g. using clickthrough data (Joachims, 2002)). In order to address this limitation, we propose a general *unsupervised learning* framework for (partial) rank aggregation.

Analyzing ranked data is an extensively studied problem in statistics, information retrieval, and machine learning literature. (Mallows, 1957) introduced a distance-based model for fully ranked data and investigated its use with Kendall's and Spearman's metrics. The model was later generalized to other distance functions and for use with partially ranked data (Critchlow, 1985). (Lebanon & Lafferty, 2002) proposed a multi-parameter extension, where multiple modal rankings (e.g. expert opinions) are available and use their formalism for supervised ensemble learning; they also analyzed their model for partially ranked data (Lebanon & Lafferty, 2003).

The first key contribution of our work is the derivation of an EM-based algorithm for learning the parameters of the extended Mallows model without supervision. We instantiate the model with appropriate distance functions for two important scenarios: combining permutations and combining top-k lists. In the context of defining distances between rankings, various metrics have been proposed and analyzed (Critchlow, 1985; Estivill-Castro et al., 1993). Distances over top-k lists, i.e. rankings over the k most preferable objects, receive particular attention in the IR community (Fagin et al., 2003). (Fligner & Verducci, 1986) show that a class of distance functions between full rankings, such as Kendall's and Cayley's metrics, decompose into a sum of independent components allowing for efficient parameter estimation of the standard Mallows model.

A second key contribution of our work is the derivation

of a novel decomposable distance function for top-k lists. We show it to be a generalization of the Kendall metric and demonstrate that it can be decomposed, enabling us to estimate the parameters of the extended Mallows model efficiently.

Among recent work, (Busse et al., 2007) propose a method for clustering heterogeneous rank data based on the standard Mallows model. More directly related, many heuristics as well as a number of supervised learning approaches (Liu et al., 2007) exist for rank aggregation, although few *learn* to combine rankings without any supervision. (Klementiev et al., 2007) frame unsupervised rank aggregation as an optimization problem specifically for top-k lists, which relies on user-tuned parameters, a form of implicit supervision, whereas we describe a general unsupervised framework that can be instantiated to top-k lists in addition to other settings.

The remainder of the paper is organized as follows: section 2 formalizes distance-based ranking models and introduces relevant notation. Section 3 derives our EM-based algorithm for learning model parameters and specifies the requirements for efficient learning and inference. Section 4 instantiates the framework for two common scenarios: permutations (full rankings) and top-k lists. Section 5 experimentally demonstrates the model's effectiveness in both cases. Finally, section 6 concludes the work and gives ideas for future directions.

2. Distance-Based Ranking Models

2.1. Notation and Definitions

Let $\{x_1, \ldots, x_n\}$ be a set of objects to be ranked, i.e. assigned rank-positions $1, \ldots, n$, by a judge. We denote the resulting permutation $\pi = (\pi(1), \ldots, \pi(n))$, where $\pi(i)$ is the rank assigned to object x_i. Correspondingly, we use $\pi^{-1}(j)$ to denote the index of the object assigned to rank j.

Let $\mathcal{S}_n$ be the set of all $n!$ permutations over n items, and let $d : \mathcal{S}_n \times \mathcal{S}_n \to \mathbb{R}$ be a distance function between two permutations. We will require $d(\cdot, \cdot)$ to be a *right-invariant metric* (Diaconis & Graham, 1977): in addition to the usual properties of a metric, we will also require that the value of $d(\cdot, \cdot)$ does not depend on how the set of objects is indexed. In other words, $d(\pi, \sigma) = d(\pi\tau, \sigma\tau)\ \forall \pi, \sigma, \tau \in \mathcal{S}_n$, where $\pi\tau$ is defined by $\pi\tau(i) = \pi(\tau(i))$.

In particular, note that $d(\pi, \sigma) = d(\pi\pi^{-1}, \sigma\pi^{-1}) = d(e, \sigma\pi^{-1})$, where $e = (1, \ldots, n)$ is the identity permutation. That is, the value of d does not change if we re-index the objects such that one of the permutations becomes e and the other $\nu = \sigma\pi^{-1}$. Borrowing the notation from (Fligner & Verducci, 1986) we abbreviate $d(e, \nu)$ as $D(\nu)$. In a later section, when we define ν as a random variable, we may treat $D(\nu) = D$ as a random variable as well: whether it is a distance function or a r.v. will be clear from the context.

2.2. Mallows Models

While a large body of work on ranking models exists in statistics literature, of particular interest to us are the distance based conditional models first introduced in (Mallows, 1957). Let us give a brief review of the formalism and elucidate some of the its properties relevant to our work. The model generates a judge's rankings according to:

$$p(\pi|\theta, \sigma) = \frac{1}{Z(\theta, \sigma)} \exp(\theta\ d(\pi, \sigma)) \tag{1}$$

where $Z(\theta, \sigma) = \sum_{\pi \in \mathcal{S}_n} \exp(\theta\ d(\pi, \sigma))$ is a normalizing constant. The parameters of the model are $\theta \in \mathbb{R}$, $\theta \leq 0$ and $\sigma \in \mathcal{S}_n$, referred to as the dispersion and the location parameters, respectively. The distribution's single mode is the modal ranking σ; the probability of ranking π decreases exponentially with distance from σ. When $\theta = 0$, the distribution is uniform, and it becomes more concentrated at σ as θ decreases.

One property of (1) is that the normalizing constant $Z(\theta, \sigma)$ does not depend on σ due to the right invariance of the distance function:

$$Z(\theta, \sigma) = Z(\theta) \tag{2}$$

Let us denote the moment generating function of D under (1) as $M_{D,\theta}(t)$, and as $M_{D,0}(t)$ under the uniform distribution ($\theta = 0$). Since (1) is an exponential family,

$$M_{D,\theta}(t) = \frac{M_{D,0}(t + \theta)}{M_{D,0}(\theta)}$$

Therefore,

$$\begin{aligned} E_\theta(D) &= \frac{1}{M_{D,0}(\theta)} \frac{dM_{D,0}(t+\theta)}{dt}\bigg|_{t=0} \\ &= \frac{d \ln(M_{D,0}(t))}{dt}\bigg|_{t=\theta} \end{aligned} \tag{3}$$

(Fligner & Verducci, 1986) note that if a distance function can be expressed as $D(\pi) = \sum_{i=1}^{m} V_i(\pi)$, where

$V_i(\pi)$ are independent (with π uniformly distributed) with m.-g.f. $M_i(t)$, then $M_{D,0}(t) = \prod_{i=1}^{m} M_i(t)$. Consequently, (3) gives:

$$E_\theta(D) = \frac{d}{dt} \sum_{i=1}^{m} \ln M_i(t) \Big|_{t=\theta} \quad (4)$$

We will call such distance functions *decomposable* and will later use (4) in section 4 in order to estimate θ efficiently.

2.3. Extended Mallows Models

(Lebanon & Lafferty, 2002) propose a natural generalization of the Mallows model to the following conditional model:

$$p(\pi|\boldsymbol{\theta}, \boldsymbol{\sigma}) = \frac{1}{Z(\boldsymbol{\theta}, \boldsymbol{\sigma})} p(\pi) \exp\left(\sum_{i=1}^{K} \theta_i \; d(\pi, \sigma_i) \right) \quad (5)$$

where $\boldsymbol{\sigma} = (\sigma_1, \ldots, \sigma_K) \in \mathcal{S}_n^K$, $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_K) \in \mathbb{R}^K$, $\boldsymbol{\theta} \leq \mathbf{0}$, $p(\pi)$ is a prior, and normalizing constant $Z(\boldsymbol{\theta}, \boldsymbol{\sigma}) = \sum_{\pi \in \mathcal{S}_n} p(\pi) \exp(\sum_{i=1}^{K} \theta_i \; d(\pi, \sigma_i))$.

The rankings σ_i may be thought of as votes of K individual judges, e.g. rankings returned by multiple search engines for a particular query in the meta-search setting. The free parameters θ_i represent the degree of expertise of the individual judges: the closer the value of θ_i to zero, the less the vote of the i-th judge affects the assignment of probability.

Under the right-invariance assumption on d, we can use property (2) to derive the following generative story underlying the extended Mallows model:

$$p(\pi, \boldsymbol{\sigma}|\boldsymbol{\theta}) = p(\pi) \prod_{i=1}^{K} p(\sigma_i|\theta_i, \pi) \quad (6)$$

That is, π is first drawn from prior $p(\pi)$. $\boldsymbol{\sigma}$ is then made up by drawing $\sigma_1 \ldots \sigma_K$ *independently* from K Mallows models $p(\sigma_i|\theta_i, \pi)$ with the *same* location parameter π.

It is straightforward to generalize both Mallows models (Critchlow, 1985), and the extended Mallows models to *partial rankings* by constructing appropriate distance functions. We will assume this more general setting in the following section.

3. Learning and Inference

In this section, we derive the general formulation of Expectation Maximization algorithm for parameter estimation of the extended Mallows models (5), and suggest a class of distance functions for which learning can be done efficiently. We then describe an inference procedure for the model.

3.1. EM Background and Notation

Let us start with a brief overview of Expectation-Maximization (Dempster et al., 1977) mostly to introduce some notation. EM is a general method of finding maximum likelihood estimate of parameters of models which depend on unobserved variables. The EM procedure iterates between:

E step: estimate the expected value of complete data log-likelihood with respect to unknown data $\mathcal{Y}$, observed data $\mathcal{X}$, and current parameter estimates θ':

$$T(\theta, \theta') \quad = \quad E[\log p(\mathcal{X}, \mathcal{Y}|\theta)|\mathcal{X}, \theta']$$

M step: choose parameters that maximize the expectation computed in the E step:

$$\theta' \leftarrow \operatorname*{argmax}_{\theta} T(\theta, \theta')$$

In our setting, the $K > 2$ experts generate votes $\boldsymbol{\sigma}$ corresponding to the unobserved true ranking π. We will see multiple instances of $\boldsymbol{\sigma}$ so the observed data we get are ranking vectors $\mathcal{X} = \{\boldsymbol{\sigma}^{(j)}\}_{j=1}^{Q}$ with the corresponding true (unobserved) rankings $\mathcal{Y} = \{\pi^{(j)}\}_{j=1}^{Q}$.

In the meta-search example, $\sigma_i^{(j)}$ is the ranking of the i-th (of the total of K) search engine for the j-th (of the total of Q) query. The (unknown) true ranking corresponding to the j-th query is denoted as $\pi^{(j)}$.

3.2. EM Derivation

We now use the generative story (6) to derive the following propositions (proofs omitted due to space constraints):

Proposition 1. *The expected value of the complete data log-likelihood under* (5) *is:*

$$T(\boldsymbol{\theta}, \boldsymbol{\theta'}) = \sum_{(\pi^{(1)}, \ldots, \pi^{(Q)}) \in \mathcal{S}_n^Q} \mathcal{L}_{\boldsymbol{\theta}} \; \mathcal{U}_{\boldsymbol{\theta'}} \quad (7)$$

where the complete data log-likelihood $\mathcal{L}_{\boldsymbol{\theta}}$ *is:*

$$\mathcal{L}_{\boldsymbol{\theta}} = \sum_{j=1}^{Q} \log p(\pi^{(j)}) - Q\sum_{i=1}^{K} \log Z(\theta_i) + \sum_{j=1}^{Q}\sum_{i=1}^{K} \theta_i \; d(\pi^{(j)}, \sigma_i^{(j)})$$

and the marginal distribution of the unobserved data $\mathcal{U}_{\boldsymbol{\theta'}}$ *is:*

$$\mathcal{U}_{\boldsymbol{\theta'}} = \prod_{j=1}^{Q} p\left(\pi^{(j)} | \boldsymbol{\theta'}, \boldsymbol{\sigma}^{(j)}\right)$$

Proposition 2. *$T(\boldsymbol{\theta}, \boldsymbol{\theta'})$ is maximized by $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_K)$ such that:*

$$E_{\theta_i}(D) = \sum_{\substack{(\pi^{(1)},\ldots,\pi^{(Q)}) \\ \in \mathcal{S}_n^Q}} \left(\frac{1}{Q}\sum_{q=1}^{Q} d(\pi^{(q)}, \sigma_i^{(q)})\right) \mathcal{U}_{\boldsymbol{\theta'}} \quad (8)$$

That is, on each iteration of EM, we need to evaluate the right-hand side (RHS) of (8) and solve the LHS for θ_i for each of the K components.

3.3. Model Learning and Inference

At first, both evaluating the RHS of (8) and solving the LHS for θ_i seem quite expensive ($> n!$). While true in general, we can make the learning tractable for a certain type of distance functions.

In particular, if a distance function can be decomposed into a sum of independent components under the uniform distribution of π (see section 2.2), property (4) may enable us to make the estimation of the LHS efficient. In Section 4, we show two examples of such distance functions (for permutations and top-k lists).

In order to estimate the RHS, we use the Metropolis algorithm (Hastings, 1970) to sample from (5). The chain proceeds as follows: denoting the most recent value sampled as π_t, two indices $i, j \in \{1, \ldots, n\}$ are chosen at random and the objects $\pi_t^{-1}(i)$ and $\pi_t^{-1}(j)$ are transposed forming π'_t. If $a = p(\pi'_t|\boldsymbol{\theta}, \boldsymbol{\sigma})/p(\pi_t|\boldsymbol{\theta}, \boldsymbol{\sigma}) \geq 1$ the chain moves to π'_t. If $a < 1$, the chain moves to π'_t with probability a; otherwise, it stays at π_t. (Diaconis & Saloff-Coste, 1998) show quick convergence for Mallows model with Cayley's distance. While no convergence results are known for the extended Mallows model with arbitrary distance, we found experimentally that the MC chain converges rapidly with the two distance functions used in this work ($10n$ steps in experiments of Section 5).

As the chain proceeds, we update the distance value with the incremental change due to a single transposition, instead of recomputing it from scratch, resulting in substantial savings in computation.

Alternatively, we also found (Section 5.1) that a combination of rankings σ_i weighted by $\exp(-\theta_i)$ provides a reasonable and quick estimate for evaluating the RHS.

Sampling or the suggested alternative RHS estimation used during training is also used for model inference.

4. Model Application

Overcoming the remaining hurdle (the LHS estimation) in learning the model efficiently depends on the definition of a distance function. We now consider two particular types of (partial) rankings: permutations, and top-k lists. The latter is the case when each judge specifies a ranking over k most preferable objects out of n. For instance, a top-10 list may be associated with the 10 items on the first page of results returned by a web search engine. For both permutations and top-k lists, we show distance functions which satisfy the decomposability property (Section 2.2), which, in turn, allows us to estimate the LHS of (8) efficiently.

4.1. Combining Permutations

Kendall's tau distance (Kendall, 1938) between permutations π and σ is a right-invariant metric defined as the minimum number of pairwise adjacent transpositions needed to turn one permutation into the other. Assuming that one of the permutations, say σ, is the identity permutation e (we can always turn one of the permutations into e by re-indexing the objects without changing the value of the distance, see Section 2.1), it can be written as:

$$D_K(\pi) = \sum_{i=1}^{n-1} V_i(\pi)$$

where[1] $V_i(\pi) = \sum_{j>i} I(\pi^{-1}(i) - \pi^{-1}(j))$. V_i are independent and uniform over integers $[0, n-i]$ (Feller, 1968) with m.-g.f. $M_i(t) = \frac{1}{n-i+1}\sum_{k=0}^{n-i} e^{tk}$. Following (Fligner & Verducci, 1986), equation (4) gives:

$$E_\theta(D_K) = \frac{ne^\theta}{1-e^\theta} - \sum_{j=1}^{n} \frac{je^{\theta j}}{1-e^{\theta j}} \quad (9)$$

$E_\theta(D_K)$ is monotone decreasing, so line search for θ will converge quickly.

[1] $I(x) = 1$ if $x > 0$, and 0 otherwise.

4.2. Combining Top-k Lists

We now propose an extension of the Kendall's tau distance to top-k lists, i.e. the case where π and σ indicate preferences over different (possibly, overlapping) subsets of $k \leq n$ objects.

Let us denote by F_π and F_σ the elements in π and σ respectively, noting that $|F_\pi| = |F_\sigma| = k$. We define $Z = F_\pi \cap F_\sigma$, $|Z| = z$, $P = F_\pi \setminus F_\sigma$, and $S = F_\sigma \setminus F_\pi$ (note that $|P| = |S| = k - z = r$). We treat π and σ as rankings, which for us will mean that the smallest index will indicate the top, i.e. contain the most preferred object. For notational convenience, let us now define the *augmented ranking* $\tilde{\pi}$ as π augmented with the elements of S assigned the same index $(k+1)$, one past the bottom of the ranking as shown on Figure 1 ($\tilde{\sigma}$ is defined similarly). We will slightly abuse our notation and denote $\tilde{\pi}^{-1}(k+1)$ to be the set of elements in position $(k+1)$.

Kendall's tau distance D_K is naturally extended from permutations to augmented rankings.

Definition 1. *Distance $\tilde{D}_K(\tilde{\pi}, \tilde{\sigma})$ between augmented rankings $\tilde{\pi}$ and $\tilde{\sigma}$ is the minimum number of adjacent transpositions needed to turn $\tilde{\pi}$ into $\tilde{\sigma}$.*

It can be shown that $\tilde{D}_K(\tilde{\pi}, \tilde{\sigma})$ is a right-invariant metric, thus we will again simplify the notation denoting it as $\tilde{D}_K(\tilde{\pi})$. This distance can be decomposed as:

$$\tilde{D}_K(\tilde{\pi}) = \sum_{\substack{i=1 \\ \tilde{\pi}^{-1}(i) \in Z}}^{k} \tilde{V}_i(\tilde{\pi}) + \sum_{\substack{i=1 \\ \tilde{\pi}^{-1}(i) \notin Z}}^{k} \tilde{U}_i(\tilde{\pi}) + \frac{r(r+1)}{2}$$

where

$$\begin{aligned} \tilde{V}_i(\tilde{\pi}) &= \sum_{\substack{j=i \\ \tilde{\pi}^{-1}(j) \in Z}}^{k} I(\tilde{\pi}^{-1}(i) - \tilde{\pi}^{-1}(j)) + \\ &\quad \sum_{j \in \tilde{\pi}^{-1}(k+1)} I(\tilde{\pi}^{-1}(i) - j) \\ \tilde{U}_i(\tilde{\pi}) &= \sum_{\substack{j=i \\ \tilde{\pi}^{-1}(j) \in Z}}^{k} 1 \end{aligned}$$

Decomposing $\tilde{D}_K(\tilde{\pi})$, the second term is the minimum number of adjacent transpositions necessary to bring the r elements not in Z (grey boxes on Figure 1) to the bottom of the ranking. The third term is the minimum number of adjacent transpositions needed to switch them with the elements in $\tilde{\pi}^{-1}(k+1)$, which would then appear in the correct order in the bottom r positions. Finally, the first term is the adjacent transpositions necessary to put the k elements now in the list in the natural order.

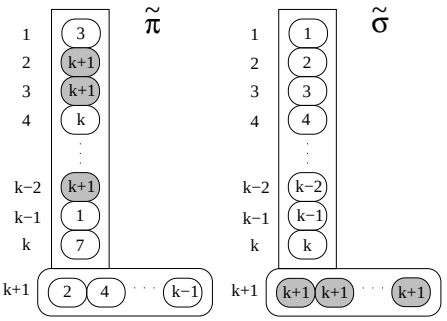

Figure 1. An example of augmented permutations $\tilde{\pi}$ (left) and identity augmented permutation $\tilde{\sigma}$ (right, in natural order). Grey boxes are objects in π but not in σ. $\tilde{D}_K(\tilde{\pi})$ is the minimum number of adjacent transpositions needed to turn $\tilde{\pi}$ into $\tilde{\sigma}$: namely, bring all grey boxes into the position $k+1$ and put the remaining k objects in their natural order.

It can be shown that the random variable summands comprising $\tilde{D}_K(\tilde{\pi})$ are independent when $\tilde{\pi}$ is uniformly distributed. Furthermore, $\tilde{V}_i$ and $\tilde{U}_j$ are uniform over integers $[0, k-i]$ and $[0, z]$, with moment generating functions $\frac{1}{k-i+1}\sum_{j=0}^{k-i} e^{tj}$ and $\frac{1}{z+1}\sum_{j=0}^{z} e^{tj}$, respectively. Assuming $z > 0$, and $r > 0$ equation (4) gives:

$$E_\theta(\tilde{D}_K) = \frac{ke^\theta}{1-e^\theta} - \sum_{j=r+1}^{k} \frac{je^{j\theta}}{1-e^{j\theta}} + \frac{r(r+1)}{2} - r(z+1)\frac{e^{\theta(z+1)}}{1-e^{\theta(z+1)}} \qquad (10)$$

If $r = 0$ (i.e. the augmented rankings are over the same objects), both the distance and the expected value reduce to the Kendall distance results. Also, if $z = 0$ (i.e. the augmented rankings have no objects in common), $\tilde{D}_K = E_\theta(\tilde{D}_K) = k(k+1)/2$, which is the smallest number of adjacent transpositions needed to move the $r = k$ objects in $\tilde{\pi}^{-1}(k+1)$ into the top k positions.

$E_\theta(\tilde{D}_K)$ is decreasing monotonically, so we can again use line search to find the value of θ. Notice that the expected value depends on the value of z (the number of common elements between the two permutations). We will compute the average value of z as we estimate the RHS of (8) and use it to solve the LHS for θ.

5. Experimental Evaluation

We demonstrate the effectiveness of our approach for permutations and top-k lists considered in Section 4.

5.1. Permutations

We first consider the scenario of aggregating permutations. For this set of experiments, the votes of $K = 10$ individual experts were produced by sampling standard Mallows models (1), with the same location parameter $\sigma^* = e$ (an identity permutation over $n = 30$ objects), and concentration parameters $\theta^*_{1,2} = -1.0$, $\theta^*_{3,..,9} = -0.05$, and $\theta^*_{10} = 0$ (the latter generating all permutations uniformly randomly). The models were sampled 10 times, resulting in $Q = 10$ lists of permutations (one for each "query"), which constituted the training data.

In addition to the sampling procedure described in Section 3.3 to estimate the RHS of (8), we also tried the following weighted Borda count approximation. For each "query" q, we took the K votes and mixed them into a single permutation $\hat{\sigma}_q$ as follows: a score for each of the n objects is computed as a weighted combination of ranks assigned to that object by individual judges. The aggregate permutation $\hat{\sigma}_q$ is obtained by sorting the objects according to their resulting scores. The weights are computed using the current values of the model parameters as $\exp(-\theta_i)$. The rationale is that the smaller the absolute value of θ_i, the lower the relative quality of the ranker, and the less it should contribute to the aggregate vote. Finally, the RHS for the i-th component is computed as the distance from its vote to $\hat{\sigma}_q$ averaged over all Q queries.

We also tried using the true permutation σ^* in place of $\hat{\sigma}_q$ to see how well the learning procedure can do.

At the end of each EM iteration, we sampled the current model (5), and computed the Kendall's tau distance between the generated permutation to the true σ^*. Figure 2 shows the model performance when sampling and the proposed approximation are used to estimate the RHS. Although the convergence is much faster with the approximation, the model trained with the sampling method achieves better performance approaching the case when the true permutation is known.

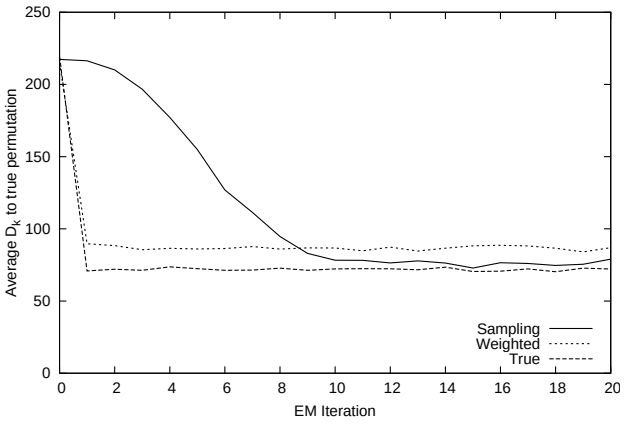

Figure 2. Permutations: learning performance of the model (averaged over 5 runs) when RHS is estimated using sampling (Sampling), the proposed weighted Borda count approximation (Weighted), or the true permutation (True). Although the convergence is much faster with the approximation, model trained with the sampling method achieves better performance.

5.2. Top-k lists

In order to estimate the model's performance in the top-k list combination scenario, we performed data fusion experiments using the data from the ad-hoc retrieval shared task of the TREC-3 conference (Harman, 1994). Our goal here is to examine the behavior of our approach as we introduce poor judges into the constituent ranker pool. In this shared task, 40 participants submitted top-1000 ranking over a large document collection for each of the 50 queries. For our experiments, we used top-100 ($k = 100$) rankings from $K = 38$ of the participants (two of the participants generated shorter rankings for some of the queries and were not used) for all $Q = 50$ queries. We replaced a specific number $K_r \in [0, K]$ of the participants with random rankers (drawing permutations of k documents from the set of documents returned by all participants for a given query uniformly randomly). We then used our algorithm to combine top-k lists from K_r random rankers and $(K - K_r)$ participants chosen at random.

We measure performance using the precision in top-$\{10, 30\}$ documents as computed by *trec_eval*[2] from the TREC conference series. As a baseline, we use $CombMNZ_{rank}$ suggested in (Klementiev et al., 2007). It is a variant of a commonly used $CombMNZ$ (Shaw & Fox, 1994). Given a query q for each document x in the collection it computes a score $N_x \times \sum_{i=1}^{K}(k - r_i(x, q))$, where $r_i(x, q)$ is the rank of the document x in the ranking returned by participant i for the query q, and N_x is the number of participants which place x in their top-k rankings. The aggregate

[2]Available at http://trec.nist.gov/

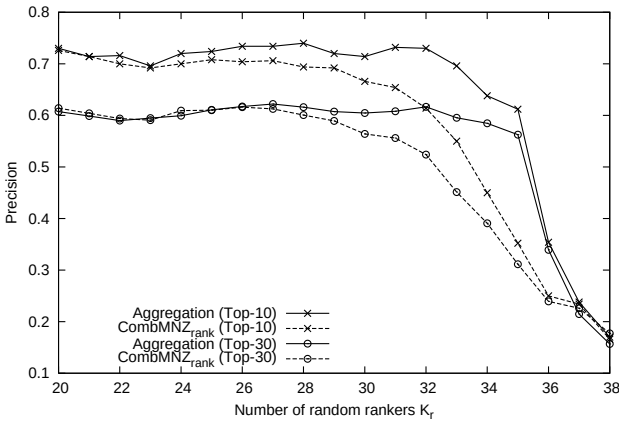

Figure 3. Top-k lists: precision of the aggregate ranker as a function of the number of random component rankers K_r in top 10 and top 30 documents. Our algorithm learns to discount the random components without supervision substantially improving over $CombMNZ_{rank}$.

ranking is obtained by sorting documents according to their scores. Intuitively, the more component rankers rank a document highly the higher it appears in the aggregate ranking.

Figure 3 shows that our algorithm learns to discount the random components *without supervision* substantially improving over the baseline as $K_r \to K$.

We also compared our results with the ULARA algorithm (Klementiev et al., 2007). These results were not included since we found ULARA to be too sensitive to user-defined parameters (an implicit form of supervision) with results varying between competitive with our model to comparable with $CombMNZ_{rank}$.

5.3. Model Dispersion Parameters

In order to demonstrate the relationship between the learned dispersion parameters of the model, $\boldsymbol{\theta}$, and the relative performance of the constituent rankers, we also conducted a meta-search experiment. First, we generated $Q = 50$ queries which result in an unambiguous most relevant document and submitted them to $K = 4$ commercial search engines. For each engine, we kept the 100 highest ranked documents (10 pages of 10 documents each) after removing duplicates, and unified URL formatting differences between engines. We measure performance with Mean Reciprocal Page Rank ($MRPR$), which we define as mean reciprocal rank of the page number on which the correct document appears.

Table 1 shows $MRPR$ of the four search engines and their corresponding model parameters. As expected, the results suggest a correlation between the magnitude of the dispersion parameters and the relative system performance, implying that their values may also be used for unsupervised search engine evaluation. Finally, our model achieves $MRPR = 0.92$ beating all of the constituent rankers.

Table 1. $MRPR$ of the four search engines and their corresponding model parameters; the results suggest a correlation between the magnitude of the dispersion parameters and the relative system performance.

	$S1$	$S2$	$S3$	$S4$
θ	-0.065	0.0	-0.066	-0.049
$MRPR$	0.86	0.43	0.82	0.78

6. Conclusions and Future Work

We propose a formal mathematical and algorithmic framework for aggregating (partial) rankings without supervision. We derive an EM-based algorithm for the extended Mallows model and show that it can be made efficient for the right-invariant decomposable distance functions. We instantiate the framework and experimentally demonstrate its effectiveness for the important cases of combining permutations and combining top-k lists. In the latter case, we introduce the notion of augmented permutation and a novel decomposable distance function for efficient learning.

A natural extension of the current work is to instantiate our framework for other types of partial rankings, as well as to cases where ranking data is not of the same type. The latter is of practical significance since often preference information available is expressed differently by different judges (e.g. top-k rankings of different lengths).

Another direction for future work is to extend the rank aggregation model to accommodate position dependence. In IR, more importance is generally given to results appearing higher in the rankings. Within our framework one may be able to design a distance function reflecting this requirement. Additionally, the quality of votes produced by individual components may depend on the rank, e.g. in the top-k scenario some rankers may be better at choosing few most relevant objects, while others may tend to have more relevant objects in the k selected but may not rank them well relative to one another. This case may be modeled by adding a dependency on rank to the dispersion parameters of the model.

In addition, this framework appears promising for a number of applications. Besides the NLP problems mentioned before, such as learning to combine output from multiple machine translation systems, one interesting setting may be *domain adaptation*. Here, the task is to adapt a hypothesis trained with ample labeled data from one input distribution to a second distribution where minimal training data is available. When the hypothesis is a trained aggregate ranker, we expect the relative expertise of its components to change and can use our approach to reweigh them accordingly.

Acknowledgments

We would like to thank Ming-Wei Chang, Sariel Har-Peled, Vivek Srikumar, and the anonymous reviewers for their valuable suggestions. Abstract

We consider the problem of optimizing multi-label MRFs, which is in general NP-hard and ubiquitous in low-level computer vision. One approach for its solution is to formulate it as an integer linear programming and relax the integrality constraints. The approach we consider in this paper is to first convert the multi-label MRF into an equivalent binary-label MRF and then to relax it. The resulting relaxation can be efficiently solved using a maximum flow algorithm. Its solution provides us with a partially optimal labelling of the binary variables. This partial labelling is then easily transferred to the multi-label problem. We study the theoretical properties of the new relaxation and compare it with the standard one. Specifically, we compare tightness, and characterize a subclass of problems where the two relaxations coincide. We propose several combined algorithms based on the technique and demonstrate their performance on challenging computer vision problems.

1. Introduction

One of the major advances in computer vision in the past few years has been the development of efficient deterministic algorithms for solving discrete labeling problems. Labeling problems occur in many places from dense stereo and image segmentation (Boykov et al., 2001; Szeliski et al., 2006) to the use of pictorial structures for object recognition (Felzenszwalb & Huttenlocher, 2000). They can be shown to be equivalent to the problem of estimating the maximum a posterior (MAP) solution in graphical models such as Markov Random Fields (MRF) and Conditional Random Fields (CRF), which is also often referred to as *energy minimization*.

A number of powerful algorithms are present in the literature which deal with the problem. For certain subclasses of the problem, it is possible to compute the exact solution in polynomial time: MRFs of bounded tree-width, *e.g.* (Lauritzen, 1998); with convex pairwise potentials (Ishikawa, 2003); with submodular potentials of binary (Hammer, 1965; Kolmogorov & Zabih, 2004) or multi-label (Schlesinger & Flach, 2000; Kovtun, 2004) variables; with permuted submodular potentials (Schlesinger, 2007). However, the problem of minimizing a general energy function is NP-hard. Nevertheless it is just these sorts of general energies that occur in many vision problems and making progress towards their solution is of paramount importance.

Energy Minimization as a Linear Program General discrete energy minimization can be seen as an integer programming problem. Dropping integrality constraints leads to an attractive linear programming relaxation (LP-1). Unfortunately, linear programs arising from this scheme in vision applications are of very large scale, and are not practical to solve with general methods. A number of algorithms have been developed (Schlesinger, 1976; Koval & Schlesinger, 1976; Wainwright et al., 2003; Kolmogorov, 2006; Werner, 2007) which attempt to solve this relaxation by exploiting the special structure of the problem. However, their common drawback is that they may converge to a suboptimal point. Other developed methods for energy minimization include local search algorithms (Boykov et al., 2001), primal-dual method (Komodakis & Tziritas, 2005), subgradient methods (Schlesinger & Giginyak, 2007; Komodakis et al., 2007). Some local search algorithms provide

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

approximation ratio guarantee for (semi-)metric energies (Boykov et al., 2001; Komodakis & Tziritas, 2005). Finally, there are methods which output a partial assignment of labels with guaranteed optimality certificate for binary (Hammer et al., 1984; Boros et al., 1991; Boros et al., 2006; Rother et al., 2007) and multi-label (Kovtun, 2003; Kovtun, 2004) problems. Dead-end elimination is another related method for identifying non-optimal assignments based on local sufficient conditions, it was originally proposed (Desmet et al., 1992) for predicting and designing the structures of proteins. In this paper we develop a novel method for obtaining partial optimal solutions of functions of multi-label variables.

Our method works by first transforming the multi-label energy function to a function involving binary variables (Schlesinger & Flach, 2006). This binary energy is then minimized by applying the *roof dual* relaxation (Boros & Hammer, 2002; Hammer et al., 1984), which can be solved efficiently using a single graph cut. More importantly, solving the roof dual relaxation results in an assignment of a subset of the variables which is guaranteed to be valid for any optimal solution. This partially optimal solution can be used to constrain the state space of the original multi-label problem. As we show, this approach may be viewed as a different LP-relaxation of the multi-label energy minimization problem (LP-2).

Comparing LP-1 with LP-2 We present a number of theoretical results studying properties of LP-2 and relating LP-2 with LP-1. Our first result is that LP-1 is a tighter relaxation of the energy minimization problem compared to LP-2. We show in the paper that solutions of LP-1 necessarily satisfy the constraints derived by LP-2, so additional guarantees for methods based on LP-1 may follow. We also identify a subclass of problems for which LP-2 is as tight as LP-1. Thus, for problems of this subclass LP-1 can be solved exactly and efficiently using combinatorial methods.

It was recently demonstrated that the roof dual relaxation performs well for a number of computer vision applications (Kolmogorov & Rother, 2007; Rother et al., 2007) which are naturally formulated as a binary energy minimization. However, it turns out that when multi-label problems are formulated as binary energy minimization the roof dual relaxation leaves many variables unassigned. We therefore use recently proposed enhancements of the roof dual technique called "probing" (Boros et al., 2006; Rother et al., 2007) which can often help resolve these ambiguities. Our last contribution is providing an alternative formulation of LP-2: we prove that it is equivalent to computing a decomposition of the energy into submodular and supermodular parts so that the sum of the lower bounds for each part is maximized. Precise details of this theoretical result are given in (Shekhovtsov et al., 2008, section 10).

Although this is primarily a theoretical paper, we have performed a number of experiments with various energy models arising in vision applications, including image restoration, object-based segmentation, and image stitching. Our experiments show that the proposed method outperforms the competing method of (Kovtun, 2003) by labelling many more random variables. We also demonstrate that it may help solving difficult problems by reducing their state space and applying other methods to the reduced problem.

2. Energy Minimization

Let $\mathcal{L} = \{1 \dots K\}$ be a set of labels. Let $G = (\mathcal{V}, \mathcal{E})$ be a graph, where the set of edges $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is antisymmetric and antireflexive, *i.e.* $(s,t) \in \mathcal{E} \Rightarrow (t,s) \notin \mathcal{E}$. We denote an ordered pair $(s,t) \in \mathcal{E}$ simply by st. Let each graph node $s \in \mathcal{V}$ be assigned a label $x_s \in \mathcal{L}$ and let a *labeling* (or *configuration*) be defined as $\mathrm{x} = \boldsymbol{\{} x_s \,|\, s \in \mathcal{V} \boldsymbol{\}}$[1]. Let $\boldsymbol{\{}\theta_s(i) \in \mathbb{R} \,|\, i \in \mathcal{L},\, s \in \mathcal{V}\boldsymbol{\}}$ be *univariate* potentials and $\boldsymbol{\{}\theta_{st}(i,j) \in \mathbb{R} \,|\, i,j \in \mathcal{L},\, st \in \mathcal{E}\boldsymbol{\}}$ be *pairwise* potentials of a random field. Let in addition θ_{const} be a *constant* term, and let a concatenated vector of potentials, including the constant term, be denoted as $\theta = (\theta, \theta_{\text{const}}) \in \Omega = \mathbb{R}^{\mathcal{I} \cup \{\text{const}\}}$, where set of indices

$$\mathcal{I} = \{(s,i) \,|\, s \in \mathcal{V},\, i \in \mathcal{L}\} \cup \{(st, ij) \,|\; st \in \mathcal{E},\, i,j \in \mathcal{L}\} \tag{1}$$

corresponds to all univariate and pairwise terms. Notation $\theta_{\mathcal{I}}$ will thus refer to all components of θ but the constant term. The *energy* of a configuration x of the random field is defined as:

$$E(\mathrm{x}|\theta) = \sum_{s \in \mathcal{V}} \theta_s(x_s) + \sum_{st \in \mathcal{E}} \theta_{st}(x_s, x_t) + \theta_{\text{const}}. \tag{2}$$

2.1. LP-relaxation

We will study two different relaxations of minimization of (2). Both relaxations can be written using the same formulation but will differ in the graph, number of labels and potential vector involved.

Energy function (2) can be conveniently written using a scalar product in Ω as $E(\mathrm{x}|\theta) = \langle \mu(\mathrm{x}), \theta \rangle$, where $\mu(\mathrm{x}) \in \{0,1\}^{\mathcal{I} \cup \{\text{const}\}}$ is defined by $\mu(\mathrm{x})_s(i) = \delta_{\{x_s = i\}}$, $\mu(\mathrm{x})_{st}(i,j) = \delta_{\{x_s = i\}}\delta_{\{x_t = j\}}$ and $\mu(\mathrm{x})_{\text{const}} = 1$. In this notation minimization of E is expressed as:

$$\min_{\mathrm{x} \in \mathcal{L}^{\mathcal{V}}} \langle \mu(\mathrm{x}), \theta \rangle. \tag{3}$$

[1] Notation $\boldsymbol{\{} x_s | s \in S \boldsymbol{\}}$ (bold brackets), where S is a finite set, will stand for the concatenated vector of variables x_s, rather than the set of their values.

The LP-relaxation of (3) reviewed in, *e.g.*, (Werner, 2007) is constructed as follows. For each variable x_s, a set of relaxed variables $\mu_s(i) \in [0,1]$, $i \in \mathcal{L}$ is introduced. These variables are required to satisfy the *normalization* constraints

$$\sum_{i\in\mathcal{L}} \mu_s(i) = 1, \quad \forall s \in \mathcal{V}. \tag{4}$$

Further, for each pair (x_s, x_t), $st \in \mathcal{E}$ the relaxed variables $\mu_{st}(i,j) \in [0,1]$, $i,j \in \mathcal{L}$ are introduced which must satisfy the *marginalization* constraints:

$$\begin{aligned} \sum_{j'\in\mathcal{L}} \mu_{st}(i,j') &= \mu_s(i), \quad \forall st \in \mathcal{E}, \forall i \in \mathcal{L}, \\ \sum_{i'\in\mathcal{L}} \mu_{st}(i',j) &= \mu_t(j), \quad \forall st \in \mathcal{E}, \forall j \in \mathcal{L}. \end{aligned} \tag{5}$$

The concatenated vector $\mu \in \Omega$ satisfying these constraints will be called a *relaxed* labeling. Indeed, a vector μ with all integral components uniquely represents a labeling x. When the integrality constraints are dropped we get the following relaxation of (3):

$$\min_{\mu\in\Lambda_{G,\mathcal{L}}} \langle \mu, \theta \rangle, \tag{6}$$

where $\Lambda_{G,\mathcal{L}} = \left\{ \mu \in \Omega_+ \,|\, A\mu_{\mathcal{I}} = \mathbf{0},\ B\mu_{\mathcal{I}} = \mathbf{1},\ \mu_{\text{const}} = 1 \right\}$ is called the *local* (Wainwright et al., 2003) polytope of graph G. Here set Ω_+ denotes vectors from Ω with all nonnegative components, equalities $A\mu_{\mathcal{I}} = \mathbf{0}$ express marginalization constraints (5), and equalities $B\mu_{\mathcal{I}} = \mathbf{1}$ express normalization constraints (4).

2.2. Binary Energy Minimization

Energy minimization problems with 2 labels ($|\mathcal{L}| = 2$) are conveniently described in terms of *binary* (or Boolean) variables, *i.e.* with set of labels being $\mathbb{B} = \{0,1\}$. For clarity we will denote binary configurations by z. Univariate and pairwise terms of (2) can be written as:

$$\begin{aligned} &\theta_s(z_s) = \theta_s(1)z_s + \theta_s(0)(1-z_s), \\ &\theta_{st}(z_s,z_t) = \theta_{st}(1,1)z_sz_t + \theta_{st}(0,1)(1-z_s)z_t \\ &+\theta_{st}(1,0)z_s(1-z_t) + \theta_{st}(0,0)(1-z_s)(1-z_t). \end{aligned} \tag{7}$$

Expanding brackets in (7) it is clear that (2) can be transformed to the form:

$$E(\mathrm{z}|\eta) = \sum_s \eta_s z_s + \sum_{st} \eta_{st} z_s z_t + \eta_{\text{const}}, \tag{8}$$

which is a quadratic function of binary variables. Functions of the form $\mathbb{B}^{\mathcal{V}} \mapsto \mathbb{R}$ are called *pseudo-Boolean* (Boros & Hammer, 2002) and minimization (or maximization) of (8) is called quadratic Pseudo-boolean optimization.

Calculating coefficients η from θ is equivalent to choosing the reparametrization $\hat{\theta} \equiv \theta$ with non-zero elements being only $\hat{\theta}_s(1)$, $\hat{\theta}_{st}(1,1)$ and $\hat{\theta}_{\text{const}}$.

It is easy to see that pseudo-Boolean optimization, energy minimization with 2 labels and the MIN-CUT problem are all equivalent problems, and can be simply converted one into another. It is also known that polynomially solvable MIN-CUT problems (those having weights of all edges in the graph non-negative) correspond to quadratic pseudo-Boolean problems with all weights η_{st} being non-positive, which is equivalent to the condition of submodularity of $E(\cdot|\eta)$.

2.3. LP-relaxation of Binary Problems

As shown in (Hammer et al., 1984), the LP relaxation (6) for the case of binary variables has special properties, which in general do not hold in the multi-label case. First, there exists a *half-integral* optimal relaxed labeling μ^*, i.e. all components are 0, $\frac{1}{2}$ or 1. Second, if μ^* is integral for some node s (i.e. $\mu^*_s(\alpha) = 0$), then there exists a global minimum z of the original function in which $z_s = \alpha$. In other words, by solving the LP relaxation we can obtain constraints on the global minima of the binary energy. These constraints can be expressed as

$$\mathrm{z}^{\min} \le \mathrm{z} \le \mathrm{z}^{\max}, \tag{9}$$

where $\mathrm{z}^{\min}, \mathrm{z}^{\max} \in \mathbb{B}^{\mathcal{V}}$ and inequalities are componentwise. For instance, $0 \le z_s \le 1$ implies no constraints on z_s, while $0 \le z_s \le 0$ implies that z_s is constrained to be 0.

If (9) holds for all optimal solutions z, then the pair $(\mathrm{z}^{\min}, \mathrm{z}^{\max})$ is said to define *strong* persistency; if (9) holds for some optimal solution z then $(\mathrm{z}^{\min}, \mathrm{z}^{\max})$ defines *weak* persistency (Boros & Hammer, 2002). It is important to note that the LP relaxation can be solved very efficiently by computing minimum cut/maximum flow in an appropriately constructed graph. The technique in (Boros et al., 1991) is perhaps the most efficient; we will refer to it as the Qudratic Pseudo-Boolean Optimization (QPBO) method[2]. It yields a pair $(\mathrm{z}^{\min}, \mathrm{z}^{\max})$ defining strong persistency.

Recently, two techniques were introduced which extend the QPBO method. The first one is *Probing* (Boros et al., 2006), or *QPBO-P*. It fixes a certain node s to a particular label α, runs QPBO thus obtaining some information about global minimizers of the energy. This information is incorporated into the energy (e.g. if we learn that $z_s = z_t$ for all optimal solutions then we contract nodes s and t), and the "probing" is performed for other nodes until convergence. An efficient implementation of QPBO-P was described in (Rother et al., 2007). The second method

[2]Following (Rother et al., 2007) we use the abbreviation QPBO to denote the max-flow algorithm for computing the roof-dual (Boros et al., 1991) rather then the optimization problem itself.

is *Improve*, or *QPBO-I* (Rother et al., 2007). It takes an input labeling z and tries to improve its energy by fixing a subset of nodes to labels specified by z and running QPBO. These operations guarantee not to increase the energy, and in practice do often decrease it.

3. Solving Multi-label Problems

We now address the problem of minimizing energy functions involving multi-label variables.

3.1. Converting Multi-label Problems Into Binary Ones

As was discussed in Sec. 2.2, there are simple transitions between energy minimization with two labels, MIN-CUT problem and the quadratic pseudo-Boolean optimization. Thus, it is not essentially important to which of those forms a multi-label problem will be reduced. The construction (Ishikawa, 2003; Kovtun, 2004; Schlesinger & Flach, 2006) adopted to our notation of binary energies is as follows.

We start the transformation procedure by obtaining a reparametrization $\hat{\theta} \equiv \theta$ which satisfies the following:

$$\begin{aligned} \hat{\theta}_{st}(1,j) = \hat{\theta}_{st}(i,1) &= 0 \quad st \in \mathcal{E},\ i,j \in \mathcal{L} \\ \hat{\theta}_{s}(1) &= 0 \quad s \in \mathcal{V}. \end{aligned} \tag{10}$$

This reparametrization is easy to construct. For example, to achieve $\hat{\theta}_{st}(i,1) = 0$ one needs to subtract the value $\gamma_c(i) = \theta_{st}(i,1)$ from $\theta_{st}(i,j)$ and add it to $\theta_s(i)$, which does not change the energy, and so on, see (Shekhovtsov et al., 2008) for details. Note that in the case of two labels, this reparametrization $\hat{\theta}$ immediately provides coefficients for writing a binary energy in the form (8).

Let the tuple $(\mathcal{L}, G, \theta)$ define a multi-label energy minimization problem. Let $\tilde{\mathcal{L}}$ to refer to the set of the last $K-1$ labels of $\mathcal{L}$, i.e. $\tilde{\mathcal{L}} = \{2 \dots K\}$. The components of the equivalent binary energy minimization problem are given as follows (Fig 1):

- Graph $N = (V, A)$, where $V = \mathcal{V} \times \tilde{\mathcal{L}}$ and $A = A_{\mathcal{E}} \cup A_{\mathcal{V}}$. $A_{\mathcal{E}} = \big\{((s,i),(t,j)) \,|\, st \in \mathcal{E},\ i,j \in \tilde{\mathcal{L}}\big\}$. $A_{\mathcal{V}} = \big\{((s,i),(s,i-1)) \,|\, s \in \mathcal{V},\ i = 3 \dots K\big\}$.
- Binary configuration $\mathrm{z} \in \mathbb{B}^V$. For a configuration $\mathrm{x} \in \mathcal{L}^{\mathcal{V}}$ the corresponding binary configuration z(x) is defined by

$$\mathrm{z}(\mathrm{x})_{(s,i)} = \delta_{\{i \le x_s\}}, \quad (s,i) \in V. \tag{11}$$

- For a binary configuration z, the corresponding multi-label configuration x (denoted as x(z)) is found as:

$$x_s = 1 + \sum_{i \in \tilde{\mathcal{L}}} z_{(s,i)}. \tag{12}$$

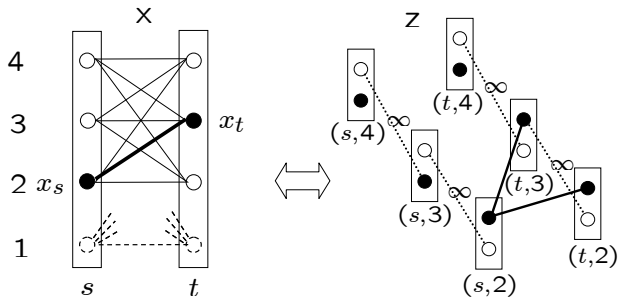

Figure 1. Converting multi-label problems into binary ones. Left: an interaction pair $st \in \mathcal{E}$ of the multi-label energy function; a labeling x is shown by black circles; lowest labels are dashed since all weights in $\hat{\theta}$ associated with them are 0. Right: binary variables $z_{(s,i)}, z_{(t,j)}$ used for encoding the multi-label problem; labeling z(x) is shown by black. Note that if the link $(x_s = 2, x_t = 3)$ is active (left) then two links $[(s,2),(t,2)]$ and $[(s,2),(t,3)]$ are active (right) .

- Binary energy function

$$E(\mathrm{z}|\eta) = H(\mathrm{z}) + \sum_{u \in V} \eta_u z_u + \sum_{uv \in A_{\mathcal{E}}} \eta_{uv} z_u z_v + \eta_{\text{const}}, \tag{13}$$

where weights η are set such that

$$E(\mathrm{z}(\mathrm{x})|\eta) = E(\mathrm{x}|\hat{\theta}) = E(\mathrm{x}|\theta),\ \forall \mathrm{x} \in \mathcal{L}^{\mathcal{V}}. \tag{14}$$

In particular pairwise terms η_{uv} are assigned as

$$\eta_{(s,i),(t,j)} = D_{ij}\hat{\theta}_{st} \quad st \in \mathcal{E},\ i,j \in \tilde{\mathcal{L}}, \tag{15}$$

where $D_{ij}\theta_{st} = \theta_{st}(i,j) + \theta_{st}(i-1,j-1) - \theta_{st}(i,j-1) - \theta_{st}(i-1,j)$. Hard constraints H are as follows:

$$H(\mathrm{z}) = \sum_{uv \in A_{\mathcal{V}}} h(z_u, z_v), \tag{16}$$

where $h(z_{(s,i)}, z_{(s,i-1)}) = 0$ if $z_{(s,i)} \le z_{(s,i-1)}$ and ∞ otherwise (see Fig. 1). Hard constraints ensure that any z with finite energy is in the form (11).

It is already known that the above defined transformation can be used together with st-mincut algorithms to efficiently and exactly solve lattice-submodular multi-label problems. In this paper, we broaden its applicability by showing how it can be used in conjunction with roof-duality to obtain partial optimal solutions for general problems. An important aspect of the transformation is that (11) depends on the ordering of $\mathcal{L}$. This will lead to certain limitations in the sequel. An interesting question raised by reviewers is whether it is possible to use a different reduction to binary variables which does not depend on the order. This does not look straightforward. For example, a rather natural reduction suggested by reviewers is to use binary indicator variables $z_{(s,i)} = \delta_{\{x_s = i\}}$

and enforce constraint $\sum_i z_{(s,i)} \leq 1$ via $K(K-1)/2$ hard pairwise terms and constraints $\sum_i z_{(s,i)} \geq 1$ by adding sufficiently large negative value to all unary terms. Unfortunately, the LP relaxation of the resulting binary problem can be shown to be degenerate (see (Shekhovtsov et al., 2008)).

3.2. Multi-label QPBO

Let (G, K, θ) define a multi-label energy minimization problem, and $(N, \mathbb{B}, \eta)$ define the corresponding binary energy minimization problem. The LP-relaxation of the multi-label problem is defined as:

$$\min_{\mu \in \Lambda_{G,\mathcal{L}}} \langle \mu, \theta \rangle \qquad \text{(LP-1)}$$

while that of the binary problem defined as:

$$\min_{\nu \in \Lambda_{N,\mathbb{B}}} \langle \nu, \eta \rangle. \qquad \text{(LP-2)}$$

We attempt minimization of $E(\mathrm{x}|\theta)$ by applying QPBO and its extensions -P, -I (Boros et al., 2006; Rother et al., 2007) to the binary energy $E(\cdot|\eta)$. We call the new methods *multi-label* QPBO (-P,-I), or short MQPBO (-P,-I). As the original QPBO methods efficiently solves LP-2, it is important to see how LP-2 is related to the original problem $\min_{\mathrm{x}} E(\mathrm{x}|\theta)$ and to its relaxation LP-1. The following results apply.

Statement 1. Let $(\mathrm{z}^{\min}, \mathrm{z}^{\max})$ define strong persistency for $E(\cdot|\eta)$ such that $E(\mathrm{z}^{\min}) < \infty$ and $E(\mathrm{z}^{\max}) < \infty$. Then any optimal configuration $\mathrm{x} \in \operatorname{argmin}_{\mathcal{L}^{\mathcal{V}}} E(\cdot|\theta)$ must satisfy

$$\mathrm{x}^{\min} \leq \mathrm{x} \leq \mathrm{x}^{\max}, \qquad (17)$$

where $\mathrm{x}^{\min} = \mathrm{x}(\mathrm{z}^{\min})$, $\mathrm{x}^{\max} = \mathrm{x}(\mathrm{z}^{\max})$.

The proof (Shekhovtsov et al., 2008) is simply by using the relation (12).

Thus for each variable s there is an interval of labels $[x_s^{\min}, x_s^{\max}]$ outside of which no label may be selected in an optimal solution. All labels outside the interval may therefore be safely discarded. As is seen, the ordering of $\mathcal{L}$ turns to be very important. While in many practical application there is a natural ordering defined, generally, constraints in the form of intervals derived from arbitrary ordering may be very weak.

A pairwise term θ_{st} is called submodular (resp. supermodular) if

$$D_{ij}\theta_{st} \leq 0 \text{ (resp. } \geq 0 \text{)}, \quad i, j = 2 \ldots K. \qquad (18)$$

Theorem 1. *If the term θ_{st} is either submodular or supermodular for each edge $st \in \mathcal{E}$, the relaxations LP-1 and LP-2 coincide, and there exist a mapping between their optimal solutions.*

Proof sketch. We have already used the mapping (11) to relate integral solutions of the two problems such that the energy is preserved. It is quite straightforward to extend it to an injective mapping Π of relaxed labelings μ to relaxed labelings ν, preserving the associated primal costs of LP-1 and LP-2. However, inverting this mapping is not always possible, so there might be a solution ν of LP-2, for which there is no corresponding solution μ of LP-1. Under conditions of the theorem a correction to a solution ν can be applied such that it remains optimal and has a preimage in the mapping Π feasible to LP-1. See details in (Shekhovtsov et al., 2008). □

Corollary 1. It is known that LP-2 can be solved using a network flow algorithm (Hammer et al., 1984). This implies that for a subclass of problems (defined by conditions of the above theorem) there exist **efficient** fully combinatorial algorithms to solve LP-1, which is an improvement over, *e.g.*, message passing algorithms such as TRW-S. But currently, we do not see applications for the case where a part of interactions is submodular and the other part is supermodular.

The next result shows that strong persistency constraints (17) can be also extended to relaxed labelings:

Theorem 2. *Let $\mathrm{x}^{\min} = \mathrm{x}(\mathrm{z}^{\min})$, $\mathrm{x}^{\max} = \mathrm{x}(\mathrm{z}^{\max})$ be the output of MQPBO, and let $\mu \in \Lambda_{G,\mathcal{L}}$ be an optimal solution of LP-1. Then $\mu_{s;i} = 0$ for labels i outside the interval $[x_s^{\min}, x_s^{\max}]$ for all $s \in \mathcal{V}$.*

Proof sketch. Assume μ violates constraints of the theorem. Let then $\nu = \Pi\mu$. For the binary problem it follows from the roof duality that a "truncated" solution, $\bar{\nu}$ may be constructed, which has non-zero weights $\bar{\nu}_u(a)$ only for labels $a \in \mathbb{B}$ such that $z_u^{\min} \leq a \leq z_u^{\max}$, $u \in V$ and such that the primal cost is decreased: $\langle \bar{\nu}, \eta \rangle < \langle \nu, \eta \rangle$. It can then be mapped back to a solution $\bar{\mu} = \Pi^{-1}\bar{\nu}$ of LP-1 of a strictly lower cost than μ. This contradicts to the optimality of μ. See details in (Shekhovtsov et al., 2008). □

The theorem shows that LP-1 never selects nodes which are rejected by LP-2, this may be useful in the analysis of the algorithms related to LP-1.

4. Enhanced Algorithms

In this section we discuss in more detail the "probing" and "improve" versions of MQPBO and show how they could be used in combination with other algorithms for minimization of multi-label energy functions.

MQPBO-P. This enhancement applies the probing technique (Boros et al., 2006; Rother et al., 2007) to binarized energy functions. It computes stronger constraints of the form (17) on the set of optimal config-

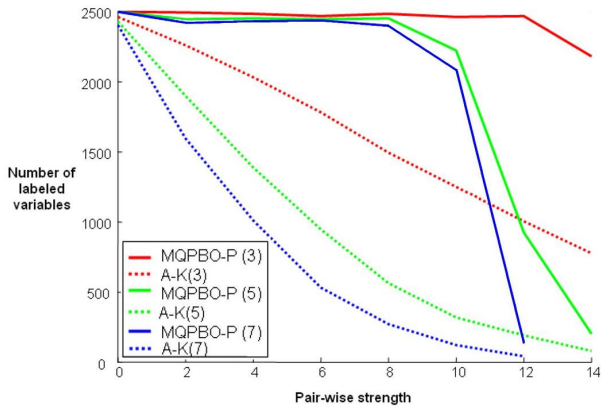

Figure 2. The number of labelled variables in the partially optimal solutions obtained by using MQPBO-P and the algorithm (Kovtun, 2003) (denoted by A-K). Results are shown for energy functions involving variables taking 3, 5 and 7 labels.

urations. Our results show that these constraints allow us to isolate the optimal labels for many random variables of the original energy function. In fact for certain energy functions we obtained the global minimum configuration. If latter is not the case then constraints (17) lead to a simplified minimization problem with a smaller or *restricted* solution space, which can be further approached by any other minimization algorithms.

As was mentioned above, MQPBO, and hence the probing extension, is not invariant to permutations of labels. While we are using a fixed ordering in all our experiments, the method could be potentially run under different orderings thus extracting multiple constraints.

MQPBO-P + X. Similar to QPBO+X (Rother et al., 2007), restriction of the energy function obtained by MQPBO(-P) is then minimized using any other minimization algorithm **X**. In our experiments we used max-product BP (Pearl, 1988), TRW-S (Kolmogorov, 2006) and α-expansion algorithm (Boykov et al., 2001).

MQPBO-I. By using QPBO-I (Rother et al., 2007) on the binarized problem any complete labelling of the multi-label MRF can be updated such that its energy never increases. This procedure can be seen as a local search algorithm.

5. Experimental Results

We now provide the results of using our method to minimize energy functions encountered in computer vision problems. To get a good understanding of the performance of our method we also tested it on synthetic energy functions.

	Pairwise Strength						
Truncation	λ=0	λ=2.4	λ=4.8	λ=7.2	λ=9.6	λ=12.0	λ=14.4
T = 6 (convex)	0	0	0	0	0	0	0
T = 5	0	0	0	0	0	0	0
T = 4	0	0	0	0	0	3	6
T = 3	0	3	4	14	22	26	30
T = 2	0	3	11	20	42	329	1971
T = 1 (Potts)	0	8	19	23	398	2336	2488

Figure 3. Effect of non-convexity: the number of unlabelled variables in the MQPBO-P solution for different values of pairwise strength λ and truncation T.

Synthetic Problems. The energy functions corresponding to the synthetic problems contained 50×50 multi-label variables which interacted under a 4-connected neighborhood. We used different numbers of labels and strengths of pairwise potentials in our experiments. Unary potentials $\theta_s(x_s)$ are sampled uniformly in $\{0,1\ldots100\}$. The pairwise potentials had the form of a linear truncated model $\theta_{st}(x_s,x_t) = \frac{\lambda}{T}\min(|x_s - x_t|, T)$, where T is the truncation and λ is the pairwise strength. Fig. 2 shows comparison of MQPBO-P to (Kovtun, 2003), truncation T is fixed to 1. It is seen that the proposed method labels more variables for a range of parameters. To study the effect of non-convexity, we varied truncation T and strength λ of the pairwise terms (Fig. 3). The number of labels in this case is fixed to 7. Our experiments show

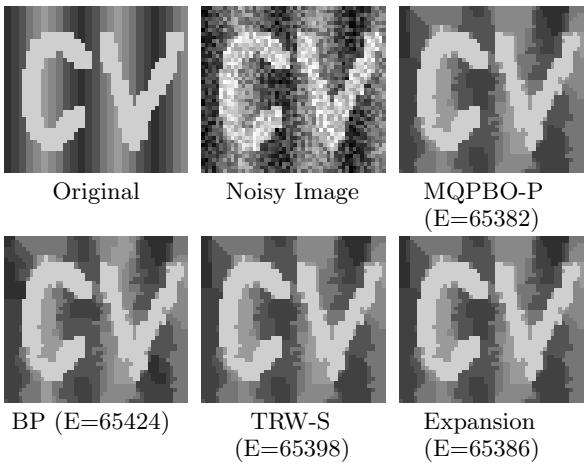

Figure 4. Image Denoising: results obtained by different energy minimization algorithms. The energy used for this experiment has $|\mathcal{L}_I| = 7$, $\gamma = 14$ and $T = 4$. Results are annotated with their respective energy costs. All algorithms were run untill convergence. Observe that MQPBO-P labels all variables and thus obtains the globally optimal solution for this energy.

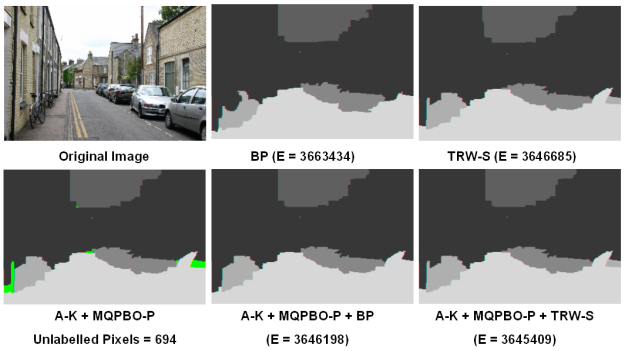

Figure 5. Object Segmentation and Recognition using (Shotton et al., 2006). The first row contains an image from the MSRC (Shotton et al., 2006) dataset and the results of running BP and TRW-S on the full energy. Different levels of gray denote different object classes such as "sky" and "road". The partially optimal solution obtained by running MQPBO-P and A-K (Kovtun, 2003) is shown in the bottom row, left image. Unlabeled pixels are shown in green. This solution is used to obtain a restricted energy. Running BP (bottom, middle) and TRW-S (bottom, right) on the restricted energy gives solutions with lower energy. Hence running A-K + MQPBO-P + "X" is better than running "X" alone. In all cases BP and TRW-S were run for 50 iterations.

that MQPBO-P finds the globally optimal solution of energy functions where the pairwise term is small in magnitude or is nearly *convex*. As expected, the number of variables labelled by the algorithm decrease with increase in the strength and non-convexity of the pairwise terms (Fig. 3).

Image Denoising. We now test the MQPBO-P algorithm on the problem of image denoising and restoration. There is a random variable for each pixel in the image. The label set for the problem is the set of intensities $\mathcal{L}_I$ the pixels can take. The unary cost for taking a particular label (intensity) is defined as $\theta_s(x_s) = |I_s - \phi(x_s)|$ where I_s is the intensity of the pixel s in the image, and the function ϕ maps the labels to their corresponding intensity levels. The pairwise terms of the energy are defined as: $\theta_{st}(x_s, x_t) = \gamma \min(|x_s - x_t|, T)$ where γ is a model parameter and T is the truncation used. Our experiments showed that the MQPBO-P algorithm performed quite well on the energy function and in some cases obtained the globally optimal solution which was not achieved by other energy minimization algorithms (see Fig. 4).

Object based Segmentation. We now show the results of using the MQPBO-P method for restricting the energy functions. Our results show that the restriction significantly reduces the number of variables and makes them amenable for minimization using other algorithms. We test the algorithm on the problem of object segmentation and recognition. We use the energy function formulated in (Shotton et al., 2006). The binarized energy function corresponding to this problem has around 10^7 variables and running MQPBO-P on it directly is quite time consuming. To reduce the size of the problem we first run the partial optimality algorithm described in (Kovtun, 2003), referred to as A-K. MQPBO-P is run on the restriction obtained using A-K. This combined procedure leaves 694 variables unlabelled. The results are shown in Fig. 5.

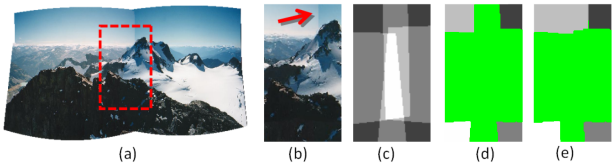

Figure 6. In this application we are stitching together four images (already rectified) to a panoramic image. Running alpha expansion gives result (a) and a zoom-in (dashed rectangle) is shown in (b). The red arrow indicates a visible cut. Image (c) shows the number of possible labels for this image area, where white means all four images overlap and very dark means only one image is possible for those pixels. When applying MQPBO and MQPBO-P to this image portion we obtain labelling (d) and (e) respectively, where green means unlabeled and the different gray scales represent different labels. We see that MQPBO-P is able to label more pixels than MQPBO. It is also worth noting that the visible cut in (b) is indeed the global minimum which can be seen from labelling (e).

Image Stitching. Finally, we investigated an application where MQPBO-P shows its limitations. For panoramic stitching the unary terms are either zero or infinity, depending on the presence or absence of an image, and consequently the pairwise terms dominate the energy. We use the panoramic stitching formulation from (Agarwala et al., 2004) where pairwise terms model the visibility of a transition, different for each pair of images. The results are discussed in fig 6.

6. Conclusions

This paper addressed the problem of minimizing non-submodular multi-label energy functions. These are used extensively in computer vision and are generally NP-hard to minimize. We present a method for obtaining partially optimal solutions of such energies derived from roof-dual based methods for binary energy functions. We give new theoretical insights in the underlying LP relaxation, being efficiently solved by the method. Although this work is mainly theoretical in nature we hope to inspire people to use these ideas to develop better optimization algorithms. We also believe that this approach is useful for other impor-

tant problems in computer vision such as MRF/CRF learning.

Abstract

We consider the task of learning to accurately follow a trajectory in a vehicle such as a car or helicopter. A number of dynamic programming algorithms such as Differential Dynamic Programming (DDP) and Policy Search by Dynamic Programming (PSDP), can efficiently compute non-stationary policies for these tasks — such policies in general are well-suited to trajectory following since they can easily generate different control actions at different times in order to follow the trajectory. However, a weakness of these algorithms is that their policies are *time-indexed*, in that they apply different policies depending on the current time. This is problematic since 1) the current time may not correspond well to where we are along the trajectory and 2) the uncertainty over states can prevent these algorithms from finding any good policies at all. In this paper we propose a method for *space-indexed* dynamic programming that overcomes both these difficulties. We begin by showing how a dynamical system can be rewritten in terms of a spatial index variable (i.e., how far along the trajectory we are) rather than as a function of time. We then use these space-indexed dynamical systems to derive space-indexed version of the DDP and PSDP algorithms. Finally, we show that these algorithms perform well on a variety of control tasks, both in simulation and on real systems.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

1. Introduction

We consider the task of learning to accurately follow a trajectory, for example in a car or helicopter. This is one of the most basic and fundamental problems in reinforcement learning and control. One class of approaches to this problem uses dynamic programming. These algorithms typically start at the last time-step T of a control task, and compute a simple (say, linear) controller for that time-step. Then, they use dynamic programming to compute controllers for time-steps $T-1$, $T-2$ and so on down to time-step 1. Some examples of algorithms in this family include (Jacobson & Mayne, 1970; Bagnell et al., 2004; Atkeson & Morimoto, 2003; Lagoudakis & Parr, 2003), and all of them output time-varying/non-stationary policies that choose the control action as a function of time. Given that following a trajectory requires one to choose very different control actions at different parts of the trajectory — for example, the controls while driving a car on a straight part of the trajectory are very different from the controls needed during a turn – these dynamic programming algorithms therefore initially seem well-suited for trajectory following.

However, a weakness in the naive dynamic programming approach is that the control policies are *time-indexed*. That is, these algorithms output a sequence of controllers $\pi_1, \pi_2, \ldots, \pi_T$ and execute controller π_t at time t. However, as time passes, the uncertainty over the state increases, and this can greatly degrade controller performance. For example, suppose we are driving a car around a track with both straight and curved portions, and suppose that the controller at time t assumed the car was on a curved portion. If, due to the natural stochasticity of the environment, the car was actually on a straight portion of the track at this time, the resulting controller would perform very poorly, and this problem increases over time. This

problem can be alleviated slightly be "re-indexing" the controllers by state during execution. That is, at time t we do not necessarily execute controller π_t, but instead we examine *all* the controllers $\pi_1, \ldots, \pi_T$, and execute the controller whose corresponding state is closest to the current state — several variations on this approach exist, and we will discuss them further in Section 5. However, there are two fundamental limitations of this general method. First, because we are executing a different policy from the one learned by dynamic programming, it is difficult to provide any of the performance guarantees that often accompany the purely time-indexed dynamic programming algorithms. Second, and more fundamentally, the uncertainty over states in the distant future often make it extremely difficult to learn *any* good policy using the time-indexed algorithms. This means that regardless of how we re-index the controllers during execution, we are unlikely to obtain good performance.

In this paper we propose a method for *space-indexed* dynamic programming that addresses both these concerns. More precisely, we will define a spatial index variable d that measures how far we have traveled along the target trajectory. Then, we will use policies π_d that depend on d — where we are along the trajectory — rather than the current time t. In order to learn such policies, we define the notion of a *space-indexed dynamical system*, and show how various dynamical systems can be rewritten such that their dynamics are indexed by d instead of by time t. This then allows us to extend various dynamic programming algorithms to produce space-indexed policies — in particular, we develop a space-indexed versions of the Differential Dynamic Programming (DDP) (Jacobson & Mayne, 1970) and Policy Search by Dynamic Programming (PSDP) algorithms (Bagnell et al., 2004). Finally, we successfully apply this method to several control tasks, both in simulation and in the real world.

The remainder of this paper is organized as follows. In Section 2 we show how to transform a standard (time-indexed) dynamical system into a space-indexed dynamical system. Using this transformation, in Section 3 we develop space-indexed versions of the DDP and PSDP algorithms. In Section 4 we present experimental results on several control tasks. Finally, in Sections 5 and 6 we discuss related work and conclude the paper.

2. Space-indexed Dynamical Systems

Standard dynamic programming algorithms are very efficient because they know in advance that the policies $\pi_1, \ldots, \pi_T$ will be executed in a certain sequence (and that each policy will be executed only once), and can thus solve for them in reverse order. The key difficulty of generalizing a dynamic programming algorithm to the space-indexed setting is that it is difficult to know in advance where in space (i.e., how far along the trajectory) the vehicle will be at each step, and thus which space-indexed policy will be executed when. For example, if the vehicle is currently at space-index d, then there is no guarantee that executing policy π_d for one time-step will put the vehicle in space-index $d+1$. But if π_d might be executed multiple times before switching to π_{d+1}, then in general its parameters cannot be solved for in closed form during the dynamic programming backup step, and require some complex policy search instead. In this section we discuss a method for addressing this problem. Specifically, we will rewrite the dynamics of a system so that the states and transitions are indexed by the spatial-index variable d rather than by the time t.

Suppose we are given a general non-linear dynamics model in the form of a (possibly stochastic) differential equation $\dot{s} = f(s, u)$, where $s \in \mathbb{R}^n$ denotes the state vector $u \in \mathbb{R}^m$ denotes the control input, and $\dot{s}$ denotes the derivative of the state vector with respect to time. While some classical control algorithms operate directly on this differential equation, a common technique in reinforcement learning and control is to create a discrete-time model of the system

$$s_{t+1} = F(s_t, u_t) + w_t$$

by numerical integration, where s_t and u_t denote the state and input at time t respectively, and w_t is a zero-mean IID noise term (typically taken to be Gaussian with some prespecified covariance, for example). A simple but very common method for achieving this discretization is by Euler integration. In this case the state evolves as

$$s_{t+\Delta t} = s_t + f(s_t, u_t)\Delta t + w_t$$

where Δt is the integration time constant (the variance of w_t will scale linearly with the time constant as well). Note that even though the system evolves in continuous time, by making the decision to model it as a discrete-time system, we have made a decision to explicitly represent the state only at certain *instants* in time ($t = \Delta t, t = 2\Delta t, \ldots$).

When transitioning to a space-indexed dynamical system, we instead will explicitly represent the state only when it is at certain *points* along the trajectory. We begin by representing the time-indexed state as $s_t = [x_t, \theta_t]^T$, where $x \in \mathbb{R}^p$ represents what we refer to as the *spatial portions* of the state (in this paper we typically consider the spatial portions of the state to be the 2D or 3D position). Now, assume we are

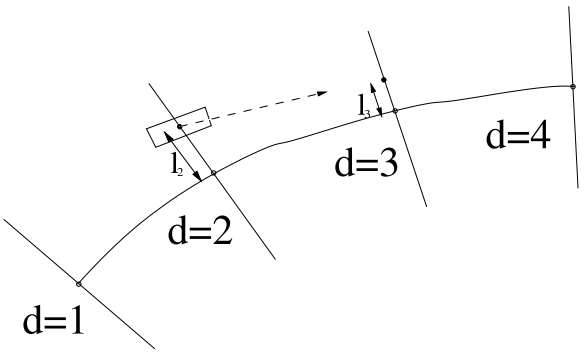

Figure 1. Figure illustrating space-indexed dynamics.

given a target trajectory in the space of x, such as the curved path shown in Figure 1. We choose a total of D discrete points along the trajectory, and designate the target state at these points as $x_1^\star, x_2^\star, \ldots, x_D^\star$. In the space-indexed dynamical system, we will explicitly represent the state only when the state lies on a hyperplane which is orthogonal to the target direction of travel and which passes through the one of the target points $x_d^\star$. More formally, we let $\dot{x}_d^\star$ be the instantaneous direction of motion (along the target trajectory) at point d. We will then explicitly represent the state only when $(x - x_d^\star)^T \dot{x}_d^\star = 0$. This situation is depicted in Figure 1.

Because we constrain the state in this manner, our space-indexed state will have a different set of variables as our time-indexed state. In particular, we represent the space-indexed state as $\tilde{s}_d = [t_d, \ell_d, \theta_d]^T$ where $t_d \in \mathbb{R}$ denotes the time of the system, $\ell_d \in \mathbb{R}^{p-1}$ denotes the lateral deviation from the target trajectory — for $x \in \mathbb{R}^p$ a point satisfying the constraint that $(x - x_d^\star)^T \dot{x}_d^\star = 0$ can be represented using $p-1$ dimensions and this gives the lateral deviation term — and θ_d denotes the non-spatial portions of the state as before. The time variable t_d is kept for completeness, but it can be ignored if the policies do not depend on time.

Now we can rewrite the dynamics so that they are indexed by space rather than time; this will give us an equation for computing $\tilde{s}_{d+1}$ from $\tilde{s}_d$. For simplicity, we develop an Euler integration-like method, but the technique could also be extended to higher-order numerical integration methods. Rather than simulating the system forward by a fixed time step, we *solve* for Δt such that the next state will lie exactly on the $d+1$ plane. Temporarily ignoring the noise term, we solve

$$(\dot{x}_{d+1}^\star)^T (x + \dot{x}\Delta t - x_{d+1}^\star) = 0$$

for Δt. Note that a positive solution for Δt may not always exist, but it typically does except in degenerate cases, when the vehicle starts moving perpendicular or backward with respect to the desired direction, and this is unlikely given any reasonable controller. When $\Delta t > 0$ does exist, we can compute $s_{t+\Delta t} = s_t + f(s_t, u_t)\Delta t$ and use this to find the next space-indexed state

$$\tilde{s}_{d+1} = [t_d + \Delta t, \ell_{d+1}, \theta_{t+\Delta t}]^T$$

where ℓ_{d+1} is $x_{t+\Delta t} - x_{d+1}^\star$ expressed in the $\mathbb{R}^{p-1}$ subspace defined by the plane through $x_{d+1}^\star$. This gives us our final space-indexed simulator in the form

$$\tilde{s}_{d+1} = \tilde{F}(\tilde{s}_d, u_d) + \tilde{w}_d \tag{1}$$

where $\tilde{w}_d$ is a noise term. Although the distribution of $\tilde{w}_d$ is in general quite complex, we can apply methods from stochastic calculus to efficiently draw samples from this distribution. However, in practice we find that a simpler approximate approach works just as well: we compute $s_{t+\Delta t}$ as above, assuming no noise, then add noise as in the time-indexed model. This will result in a point that may no longer lie exactly on the space-index plane, so lastly we form the line between the states s_t and $s_{t+\Delta t}$ and let $\tilde{s}_{d+1}$ be the point where this line intersects the $d+1$ plane.

3. Space-indexed Dynamic Programming

In this section we use the techniques presented in the previous section to develop space-indexed versions of the Differential Dynamic Programming (DDP) and Policy Search by Dynamic Programming (PSDP) algorithms. We begin by defining notation. Let S be the state space and A be the action space (so that in the context of the dynamical system above, $S = \mathbb{R}^n$ and $A = \mathbb{R}^m$). Since, as described above, there exists a one-to-one mapping from time-indexed states to space-indexed states, all the quantities below can be equivalently expressed in terms of the space-indexed state. A reward function is a mapping $R : S \to \mathbb{R}$ and a policy is a mapping $\pi : S \to A$. Given a non-stationary sequence of policies $(\pi_t, \ldots, \pi_T)$ we define the value function

$$V_{\pi_t, \ldots \pi_T}(s) = \tfrac{1}{T} E[\textstyle\sum_{i=t}^T R(s_i) | s_t = s; (\pi_t, \ldots, \pi_T)].$$

3.1. Space-indexed DDP

We first review (time-indexed) DDP briefly. DDP approximates the dynamics and cost function of a system along a specific sequence of states. Given an initial controller π_{init}, DDP simulates the system to generate a sequence of states $s_1, \ldots, s_T$. It then linearizes the dynamics around these points to obtain a time-varying linear dynamical system, and forms a second-order (quadratic) approximation to the reward function. This system can then be solved by the Linear

Quadratic Regulator (LQR) algorithm (Anderson & Moore, 1989), which results in a new controller and a new sequence of states. This process is repeated until convergence.

Space-indexed DDP proceeds in the same manner. Given some initial controller π_{init} and space-indexed dynamical system of the form (1)[1], we simulate the system forward for D space-indexes, resulting in a set of states $\tilde{s}_1, \ldots, \tilde{s}_D$. Using our dynamics model, we form the first order Taylor expansion of the dynamics at each point along the trajectory, which results in the (space-indexed) linearized dynamics:

$$\tilde{s}_{d+1} = A_d \tilde{s}_d + B_d u_d.$$

As in standard DDP, we form a quadratic approximation of the reward function $R_d(\tilde{s}) = -\tilde{s}^T Q_d \tilde{s}$, where Q_d is some (usually PSD) matrix. This reduces the problem to an LQR problem, which can be solved efficiently using a backward recursion.

3.2. Space-indexed PSDP

We now briefly review PSDP. As input, PSDP takes a time horizon T, a restricted policy class Π, and a sequence of baseline distributions over the states space $\mu_1, \ldots, \mu_T$, where we can informally think of μ_t as providing a distribution over which states would be visited at time t by a "good" policy. Given policies $\pi_{t+1}, \ldots, \pi_T$, PSDP computes (or approximates via Monte-Carlo sampling and parameter search)

$$\pi_t = \arg\max_{\pi \in \Pi} E_{s \sim \mu_t}[V_{\pi, \pi_{t+1} \ldots \pi_T}(s)]. \qquad (2)$$

By starting with $t = T$ and proceeding down to $t = 1$, the algorithm is able to generate a sequence of policies that can perform well on the desired task. The space-indexed version of PSDP proceeds exactly as above, replacing the time t with the space index d and using the space-indexed simulator to generate the Monte-Carlo samples.

Just as in the time-indexed version, the space-indexed version of PSDP comes with nontrivial performance guarantees, formalized by the theorem below. The theorem follows immediately from the equivalent theorem for the time-indexed version of PSDP, and from the fact that the space-indexed dynamics and reward function do not depend on time.

Theorem 3.1 [following (Bagnell et al., 2004)] *Suppose $\pi = (\pi_1, \ldots, \pi_D)$ is a policy returned by an ϵ-approximate version of state-indexed PSDP where on each step the algorithm obtains π_d such that*

$$E_{s \sim \mu_d}[V_{\pi_d, \pi_{d+1}, \ldots, \pi_D}(s)] \geq \arg\max_{\pi \in \Pi} E_{s \sim \mu_d}[V_{\pi, \pi_{d+1} \ldots \pi_D}(s)] - \epsilon$$

Then for all $\pi_{\text{ref}} \in \Pi^D$,

$$V_\pi(s_0) \geq V_{\pi_{\text{ref}}}(s_0) - D\epsilon - D d_{\text{var}}(\mu, \mu_{\pi_{\text{ref}}})$$

where μ is the baseline distribution over space-index states (without the time component) provided to SI-PSDP, d_{var} denotes the average variational distance, and $\mu_{\pi_{\text{ref}}}$ is the state distribution induced by π_{ref}.

This bound not only provides a performance guarantee for the space-indexed PSDP algorithm, it also helps to elucidate the advantage of space-indexing over time-indexing. The bound implies that to make PSDP and SI-PSDP perform as well as possible, it would be best to provide them with $\mu_{\pi^\star}$, the baseline distribution of the optimal controller, as the baseline distribution. But for time-indexed PSDP, the natural stochasticity of the environment can cause this distribution to be highly spread out over the state space, even for the optimal policy. Therefore, when performing the maximization (2), it is likely that *no* policy in the class will perform very well, since this would require a policy that could operate well over many different regions of the state space. Thus, regardless of whether or not we re-index the resulting controllers by state during execution, the time-indexed version of PSDP would fail to find a good policy. In contrast, if we are doing a good job following the trajectory, then we would expect that the distribution over states at each space-index would be much tighter, allowing the space-indexed PSDP to perform much better.

4. Experiments

4.1. Autonomous Driving

We begin by considering the problem of autonomously and accurately following a trajectory with a car, such as that shown in Figure 4. Our first set of experiments were carried out in a simulator of the vehicle, built following (Rossetter & Gerdes, 2002) (with model parameters such as the vehicle dimensions, total weight, etc). To follow the desired trajectory, we applied the space-indexed DDP algorithm described above.

Prior to the work presented in this paper, significant engineering effort went into a hand-designed trajectory following controller; this was an initial version of the controller described in (Hoffmann et al., 2007), which was a hand-optimized, linear, regulation controller that computes its actions as a function of state

[1] For the DDP algorithm, we ignore the noise term $\tilde{w}_d$ because by the principle of certainty equivalence, the optimal controller for LQR does not depend on the variance/magnitude of the noise (Anderson & Moore, 1989).

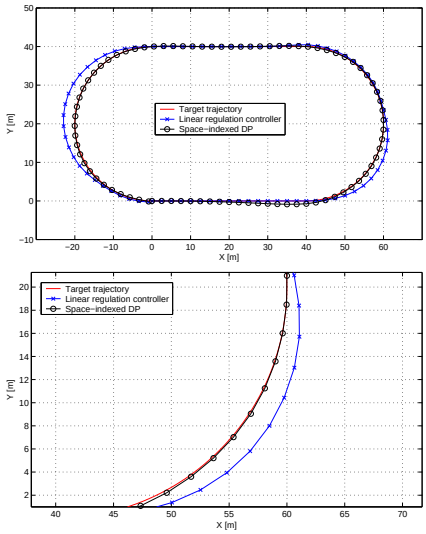

Figure 2. Comparison of the regulation controller and space-indexed controller. The figure below is a magnification of one of the turns.

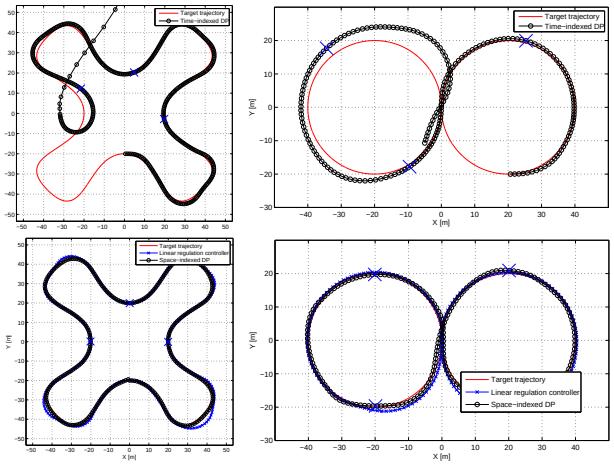

Figure 3. Two example trajectories where a time-indexed controller (above) performs significantly worse than the space-indexed controller (below).

features such as lateral error, orientation error, and so on. We used this controller to generate an initial trajectory for our space-indexed DDP algorithm; however, the results of space-indexed DDP were actually very insensitive to the choice of this initial controller.

Figure 2 shows the performance of the space-indexed DDP algorithm and the hand-tuned controller in simulation, when following an oval-like track at 30mph, along with a magnified view of the show the performance on one of the turns. We see that space-indexed DDP outperforms the hand-tuned controller; our controller has an RMS lateral error 0.26m, whereas the hand-tuned controller's RMS error is 1.18m.

Figure 3 shows a comparison between the performance of space-indexed and time-indexed dynamic programming. Due to the stochasticity of the simulator, the actual state s_t, for large t, is increasingly unlikely to be close to where the t-th step of the linearization occurred. Therefore the linearized approximation is less likely to be an accurate approximation of the "local" dynamics at time t. This is reflected in the figures: the time-indexed controllers initially perform well, but as time passes the controllers start to be executed at incorrect points along the trajectory, eventually leading the vehicle to veer off course. Using the space-indexed controller, however, the vehicle is able to accurately track the trajectory even for an arbitrarily long amount of time. For this relatively simple trajectory following task, re-indexing the time-indexed controllers by their spatial state, as described in the introduction, does perform well. However, as we will demonstrate in the next section, for more complex control tasks this is not the case.

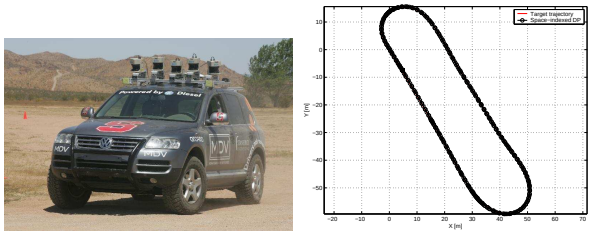

Figure 4. Picture of the vehicle used for experiments (left), and trajectory from a run on the actual car (right).

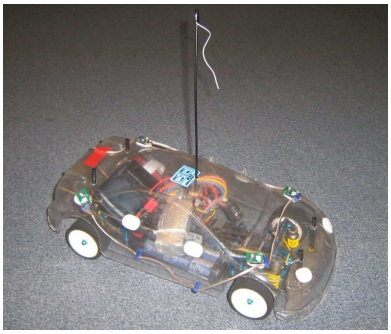

Figure 5. Autonomous RC car.

We also tested our method on the actual vehicle; the vehicle itself is described further in (Thrun & al., 2006). Figure 4 shown a typical result from an actual run on the vehicle moving at 10mph. The RMS error on the actual vehicle was about 0.17m, and the target and actual trajectories are indistinguishable in the figure.

4.2. Autonomous Driving with Obstacles

We next consider the more challenging control task of following a trajectory in the presence of obstacles. For this task we evaluated our methods on an RC car, shown in Figure 5. Since we want to learn a single controller that is capable of avoiding obsta-

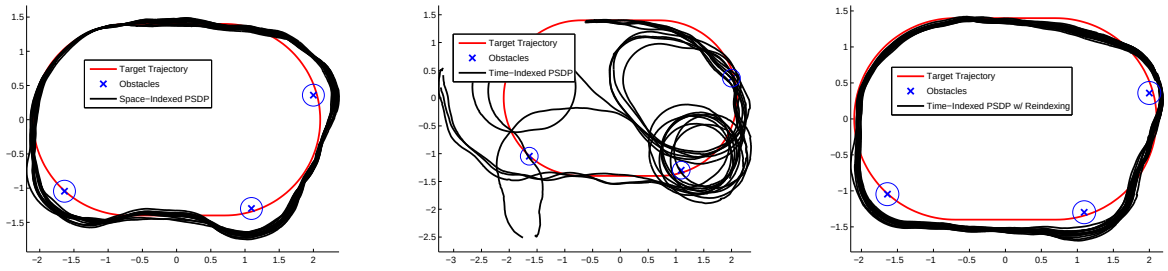

Figure 6. Trajectories taken by the real RC car on a course with obstacles, using space-indexed PSDP (left), time-indexed PSDP (middle), and time-indexed PSDP with re-indexing by space (right).

cles placed at arbitrary points along the trajectory, DDP is a poor algorithm (DDP learns a controller for a single fixed trajectory, but in this task we need to follow different trajectories depending on the location of the obstacles). Therefore, we apply the space-indexed version of PSDP to this task. Videos of the resulting controllers for this task are available at: `http://cs.stanford.edu/~kolter/icml08videos`.

In greater detail, we applied the space-indexed PSDP algorithm as follows. The native action space for the car domain is a two-dimensional input specifying the velocity and steering angle (between -28 degrees and 28 degrees), but for our task we kept the velocity fixed at 1.5 m/s and discretized the commanded steering angle into five equally spaced angles. To generate the initial distribution for PSDP, $\mu_1, \ldots, \mu_D$, we sampled 2000 different trials in a simulator of the car, using a PD controller. Then, for each space index from $D-1$ down to 1, we (approximately) solved the optimization problem (2) by first trying each possible action for each of the 2000 sampled states, then executing the learned controller for all subsequent space-indices to compute the resulting cost of the policy.[2] We then tried to learn the optimal action as a linear function of various state features; in particular, each controller was of the form: $u_{\text{steer}} = \arg\max_i w_i^T \phi(s)$ where $w_i \in \mathbb{R}^n$ is a weight vector learned by a multi-class SVM-like algorithm[3], and $\phi(s) \in \mathbb{R}^n$ is a feature vector. In our setting the features comprised of 1) the x and y location of the car, 2) the sine and cosine of the current car orientation, 3) 16 exponential RBF functions, spaced uniformly around the car, indicating the presence of an obstacle, and 4) a constant term. In addition to the space-indexed version, we also evaluated the performance of a pure time-indexed version, and a time-indexed version where we re-index the controllers as follows: at time t rather than execute the controller π_t, we examine all the controllers $\pi_1, \ldots, \pi_T$ and execute the controller $\pi_{t'}$ with minimum distance from the current state to the mean of the distribution $\mu_{t'}$.

Table 1. Average costs and collision counts for the simulated RC car with obstacles, averaged over 1000 runs.

Algorithm	Cost	Collisions
SI-PSDP	**56.17 ± 0.43**	**51**
TI-PSDP	58.39 ± 0.40	181
TI-PSDP w/ re-indexing	58.19 ± 0.37	212
Hand-tuned PD Controller	58.35 ± 0.34	231

Table 1 shows the average cost incurred and total number of collisions for the different controllers in 1000 simulated trials, where each trial had three randomly placed obstacles on the trajectory. As can be seen, the space-indexed version outperforms all the other variants of the algorithm as well as a hand-tuned PD controller that we previously spent a good deal of time trying to tune. The performance benefits of the space-indexed controller become even more pronounced on the real system. Figure 6 shows typical resulting trajectories from the space-indexed controller, the pure time-indexed controller, and the time-indexed controller with re-indexing. Due to the stochasticity of

[2] We used a cost function (i.e., negative reward), of

$$C(s_d) = \theta_1 \ell^2 + \theta_2 (1 - dist/\theta_3) \mathbf{1}\{dist < \theta_3\}$$

where $dist$ denotes the distance to the nearest obstacle, $\mathbf{1}$ is the indicator function, and $\theta_1, \ldots, \theta_3$ are parameters that trade off the relative cost of deviating from the trajectory and getting close to obstacles. For our experiments, we used $\theta_1 = 1000$, $\theta_2 = 500$ and $\theta_3 = 0.5$.

[3] Algorithmic details: the PSDP algorithm with discrete actions leads to a cost-sensitive, k-class learning problem with examples form $\{\phi(s^{(i)}) \in \mathbb{R}^n, c^{(i)} \in \mathbb{R}^k\}$, $i = 1, \ldots m$ where $\phi(s^{(i)})$ are the features, and $c_j^{(i)}$ represents the cost of classifying example i as belonging to class j. We approximately solve this problem with a support vector machine-like algorithm, which bears some similarly to previous work in cost-sensitive SVM earning (Geibel et al., 2004). The algorithm finds the solution to the optimization problem:

$$\begin{aligned} \min_{w,\xi \geq 0} \quad & \textstyle\sum_{j=1}^k \frac{1}{2}\|w_j\|^2 + C \sum_{i=1}^m \sum_{j,l=1}^k (c_j^{(i)} - c_l^{(i)})^+ \xi_{i,j,l} \\ \text{s.t.} \quad & (w_l - w_j)^T \phi(s^{(i)}) \geq 1 - \xi_{i,j,l} \quad \forall i, j, k. \end{aligned}$$

Figure 7. Tempest autonomous helicopter.

the real domain, the pure time-indexed approach performs very poorly. Re-indexing the controllers helps significantly, but the space-indexed version still performs substantially better (an incurred cost of 49.32 for space-indexed versus 59.74 for time-indexed with re-indexing, and the latter controller will nearly always hit at least one of the obstacles on the track). As seen in the figure, the space indexed version is able to track the trajectory well, while reliably avoiding obstacles.

4.3. Autonomous Helicopter Flight

We also apply these ideas to a simulated autonomous helicopter. This work used a stochastic simulator of the autonomous helicopter shown in Figure 7, and we considered the problem of making accurate, high-speed (5m/s) turns on this helicopter. We applied the space-indexed PSDP algorithm to this task due to the fact that the policy search setting allowed us to greatly restrict the class of control policies π_d under consideration (the space of all control policies for helicopter flight is very large, so we wanted to limit the risk of unexpected behavior). In particular, the "actions" of the controllers corresponded to picking a location of set point $x^\star$ which is then fed into a regulation controller, such as those described in (Bagnell & Schneider, 2001; Ng et al., 2004). Space constraints preclude a full description of the environment and algorithm, but the overall algorithm proceeds as in the previous section.

Figure 8 shows a typical result of applying the space-indexed PSDP algorithm to this task, along with the trajectory taken by a simple linear regulation controller. By varying the set point differently at different points along the trajectory, the space-indexed PSDP algorithm follows the trajectory much more accurately.

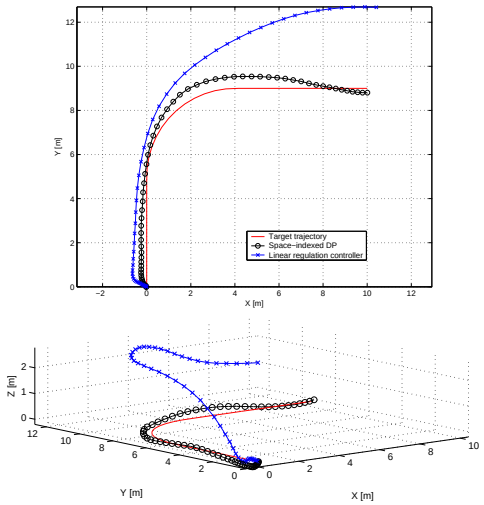

Figure 8. Comparison of the regulation controller and space-indexed controller in the helicopter simulation. The figure below shows the trajectories in three dimensions.

5. Related Work

The idea that a control policy should be dependent on the system's spatial state is by no means a new idea in the reinforcement learning and control literature. In the Markov Decision Process (MDP) formalism (Puterman, 1994), a policy is a mapping from states (which typically describe the *spatial* state of the system) to actions. In light of this observation, many classical dynamic programming algorithms such as value iteration or policy iteration can be viewed as performing dynamic programming on spatial states. However, in high-dimensional, continuous state spaces, the well-known "curse of dimensionality" renders a naive application of these algorithms intractable. Indeed, it is this reality that often motivates the jump to the trajectory following approach, where we want to find polices that perform well along the trajectory in particular.

There are also a number of methods for trajectory following. A common approach is to design a "regulation controller" that can keep the vehicle stable at a specified position $x^\star$. By smoothly moving $x^\star$ along the target trajectory, we can cause the vehicle to move along this path (Franklin et al., 1995; Dorf & Bishop, 2000). This approach works well when the regulation controller has very high bandwidth – i.e., if it can track $x^\star$ almost exactly as it varies — and is successful in application areas such as control of robot arms. But in more general settings in which the actual state x of the vehicle tends to lag well behind changes to $x^\star$, one often ends up manually and laboriously adjusting the regulation controller to try to obtain proper trajectory following performance. There are methods for compensating for this lag such as feedback linearization (Sastry, 1999), and there have also been many methods devised for trajectory following on specific systems (Egerstedt & Hu, 2000; Johnson & Calise, 2002). However, we know of no method for trajectory following in the general case of the nonholonomic, underaccuated vehicles that we consider.

The idea of partitioning the state space into regions, and using different controllers in the different regions, is a common practice in control, and often is referred to as gain-scheduling (Leith & Leithead, 2000). Taken

in the general sense, the algorithm we present in this paper can be viewed as a method for gain-scheduling, though more often the term is used for a particular application of this approach to the contexts of linear parameter varying systems. Such methods typically linearize the dynamical system around certain operating points, learn controllers at each point, and smoothly interpolate between controllers at various locations. However, the focus of this work is often to prove stability of such controllers using Lyapunov theory, and the overall approach is substantially different from what we consider here.

Model predictive control (MPC) (Garcia et al., 1989) (indirectly) addresses the issue of state uncertainty increasing over time, by explicitly computing new controllers at every time step in an online manner. However, MPC is generally orthogonal to the ideas we present here, since one could just as easily use a space-indexed dynamic programming method for the local controller in MPC. Furthermore, MPC can often times be computationally impractical to run real-time. An alternative approach is to use a local control method, such as DDP, in order to estimate the value function along several trajectories, and use these local estimates to build an approximate global model of the value function (Atkeson, 1994; Tassa et al., 2007). However, since these methods employ DDP, which is a time-indexed algorithm, they can potentially suffer the same problems as time-indexed methods in general.

6. Conclusions

In this paper we presented a space-indexed dynamic programming method for trajectory following. We showed how to convert standard time-indexed dynamical systems into equivalent space-indexed dynamical systems, and used this formulation to derive space-indexed versions of two well-known dynamic programming algorithms, DDP and PSDP. Finally, we successfully applied these methods to several control tasks, and demonstrated superior performance compared to their time-indexed counterparts.

Abstract

The central issue in representing graph-structured data instances in learning algorithms is designing features which are invariant to permuting the numbering of the vertices. We present a new system of invariant graph features which we call the skew spectrum of graphs. The skew spectrum is based on mapping the adjacency matrix of any (weigted, directed, unlabeled) graph to a function on the symmetric group and computing bispectral invariants. The reduced form of the skew spectrum is computable in $O(n^3)$ time, and experiments show that on several benchmark datasets it can outperform state of the art graph kernels.

1. Introduction

After real valued vectors and strings, the third most fundamental type of data instance in machine learning are graphs. In addition to application domains such as bioinformatics (Sharan & Ideker, 2006), chemoinformatics (Bonchev & Rouvray, 1991), social networks (Kumar et al., 2006), etc., where information is presented as a graph from the start, graphs are also used to capture the relationships between the different parts of segmented images in computer vision (Harchaoui & Bach, 2007), and to capture grammatical structure in language (Collins & Duffy, 2002). Graphs may be directed or undirected, weighted or unweighted, and their vertices may be labeled, partially labeled or unlabeled. In each of these cases, the challenge is to represent graphs in a way that preserves their structure, but is insensitive to spurious transformations, such as changing the (arbitrary) numbering of their vertices.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Given a graph $\mathcal{G}$, the two main lines of research that have emerged to address the above problem focus respectively on (a) designing an explicit feature mapping $\mathcal{G} \mapsto (q_1, q_2, \ldots, q_k)$; and (b) designing a kernel $k(\mathcal{G}_1, \mathcal{G}_2)$. Proponents of the first approach exploit global invariant properties of $\mathcal{G}$, such as the eigenvalues of its graph Laplacian, or local invariant properties, such as the number of occurrences in $\mathcal{G}$ of a library of small subgraphs. In contrast, proponents of the kernel approach use various intuitions about simultaneous random walks and diffusion on product graphs (Gärtner, 2003).

The new method that we present in this paper belongs in the first of the above two categories, but is distinguished from prior work (with the exception of (Shawe-Taylor, 1993)) by its algebraic character. In this regard, it is related to the recent line of papers (Kondor et al., 2007; Huang et al., 2008; Kondor, 2007a) introducing concepts from non-commutative harmonic analysis to machine learning. The mathematical foundations of our work are Kakarala's seminal results on the bispectra of functions on compact groups (Kakarala, 1993; Kakarala, 1992), and the recent discovery of a unitarily equivalent, but computationally more attractive set of invariants called the skew spectrum (Kondor, 2007b). We show how these general theories can be harnessed to construct graph invariants, and examine in detail their computational properties.

Experiments on standard datasets of chemical compounds show that the skew spectrum of graphs is competitive with the state of the art in graph features, and in some cases outperforms all other methods. A major advantage of the skew spectrum is that since it is an explicit feature mapping, it can be applied as a preprocessing step, and hence scales linearly with the number of examples. The computational complexity of computing the (reduced) skew spectrum of a single graph of n nodes scales with n^3. Uniquely amongst the graph invariants used in machine learning, the skew spectrum has a fixed number of scalar components (85

for the complete skew spectrum and 49 for its reduced version), resulting in a very compact representation. This does not stop the skew spectrum form remaining competitive both in speed and representational accuracy up to about $n = 300$.

For those technical details of the skew spectrum which could not be squeezed into this conference paper we refer the reader to the accompanying report (Kondor, 2008).

2. Graph Invariants

In this paper $\mathcal{G}$ will be a directed weighted graph of n vertices. We represent $\mathcal{G}$ by its adjacency matrix $A \in \mathbb{R}^{n\times n}$, where $[A]_{i,j} \in \mathbb{R}$ is the weight of the edge from vertex i to vertex j. Unweighted graphs are special cases satisfying $[A]_{i,j} \in \{0, 1\}$, while undirected graphs are special cases satisfying $A^\top = A$. We assume that A has no self-loops, i.e., $[A]_{i,i} = 0$ for $i = 1, 2, \ldots, n$.

Recall that a **permutation** of n objects is a bijective map $\pi\colon \{1, 2, \ldots, n\} \to \{1, 2, \ldots, n\}$. Permuting the labels on the vertices of $\mathcal{G}$ by π results in a new adjacency matrix A^π with entries

$$[A^\pi]_{\pi(i),\pi(j)} = [A]_{i,j}, \tag{1}$$

but A and A^π both represent the same graph $\mathcal{G}$. A function $q(A)$ is called a **graph invariant** if it is invariant to relabelings of this kind, i.e., if $q(A) = q(A^\pi)$ for any permutation π. Our objective is to construct a system $(q_1, q_2, \ldots, q_k)$ of graph invariants which capture as much information about $\mathcal{G}$ as possible, yet can be computed economically.

2.1. Reduction to Left-translation Invariance

Our approach is based on the fact that permutations form a **group**. This means that if for a pair of permutations σ_1 and σ_2, we define their product $\sigma_3 = \sigma_2\sigma_1$ by composition of maps, i.e., $\sigma_3(i) = \sigma_2(\sigma_1(i))$, then the following axioms are satisfied:

1. for any two permutations σ_1 and σ_2, the product $\sigma_2\sigma_1$ is also a permutation;
2. for any three permutations σ_1, σ_2 and σ_3, $\sigma_1(\sigma_2\sigma_3) = (\sigma_1\sigma_2)\sigma_3$;
3. The identity $e(i) = i$ is a permutation;
4. For any permutation σ, there is an inverse permutation σ^{-1} satisfying $\sigma\sigma^{-1} = \sigma^{-1}\sigma = e$.

The group of permutations of n objects is called the **symmetric group** over n letters and is denoted $\mathbb{S}_n$.

To find graph invariants we begin by mapping A to a function $f\colon \mathbb{S}_n \to \mathbb{R}$, defined as

$$f(\sigma) = A_{\sigma(n),\sigma(n-1)}. \tag{2}$$

Note that this is a very special type of function on $\mathbb{S}_n$ in that it is constant on each block of permutations

$$S_{i,j} = \{\, \sigma \in \mathbb{S}_n \mid \sigma(n) = i,\ \sigma(n-1) = j \,\}. \tag{3}$$

For $k < n$, identifying $\mathbb{S}_k$ with the subgroup of permutations permuting $1, 2, \ldots, k$ amongst themselves and leaving $k + 1, \ldots, n$ fixed, the above blocks, of which there are $n(n-1)$ in total, each have the form $\sigma\,\mathbb{S}_{n-2} = \{\, \sigma\tau \mid \tau \in \mathbb{S}_{n-2} \,\}$, and are called **left** $\mathbb{S}_{n-2}$–**cosets**.

Defining f as in (2) ensures that under relabeling it transforms in a transparent fashion. Specifically, if f' is the function corresponding to A^π, then

$$f'(\pi\sigma) = A^\pi_{(\pi\sigma)(n),(\pi\sigma)(n-1)} = A_{\sigma(n),\sigma(n-1)} = f(\sigma). \tag{4}$$

In general, a function $g\colon \mathbb{S}_n \to \mathbb{R}$ related to f by $g(\sigma) = f(\pi^{-1}\sigma)$ is called the **left-translate** of f by π, and is denoted f^π. Equation 4 tells us that $f' = f^\pi$, reducing the problem of constructing graph invariants to finding left-translation invariant features of functions on $\mathbb{S}_n$.

2.2. Invariant Matrices

Now consider the weighted sum of matrices

$$\widehat{f}_\rho = \sum_{\sigma\in\mathbb{S}_n} f(\sigma)\,\rho(\sigma), \tag{5}$$

where $\rho(\sigma)$ is a system of complex valued matrices satisfying

$$\rho(\sigma_2\,\sigma_1) = \rho(\sigma_2)\,\rho(\sigma_1) \qquad \sigma_1, \sigma_2 \in \mathbb{S}_n,$$

as well as the unitarity condition $\rho(\sigma^{-1}) = (\rho(\sigma))^{-1} = \rho(\sigma)^\dagger$. Such systems of matrices are called **unitary matrix representations** of $\mathbb{S}_n$. Changing variables from σ to $\sigma' = \pi^{-1}\sigma$ shows that

$$\begin{aligned}\widehat{f}^\pi_\rho = \sum_{\sigma\in\mathbb{S}_n} f(\pi^{-1}\sigma)\,\rho(\sigma) &= \sum_{\sigma'\in\mathbb{S}_n} f(\sigma')\,\rho(\pi\sigma') \\ &= \sum_{\sigma'\in\mathbb{S}_n} f(\sigma')\,\rho(\pi)\,\rho(\sigma') = \rho(\pi)\,\widehat{f}_\rho,\end{aligned}$$

which suggests that (5) is a good starting point for constructing left-translation invariants of f. For example, the matrix $\widehat{a}_\rho = \widehat{f}^\dagger_\rho \cdot \widehat{f}_\rho$ is invariant because

$$\begin{aligned}\widehat{a}^\pi_\rho = \widehat{f}^{\pi\,\dagger}_\rho \cdot \widehat{f}^\pi_\rho = (\rho(\pi)\widehat{f}_\rho)^\dagger(\rho(\pi)\widehat{f}_\rho) = \\ \widehat{f}^\dagger_\rho\,\rho(\pi)^\dagger\,\widehat{\rho}(\pi)\,\widehat{f}_\rho = \widehat{f}^\dagger_\rho \cdot \widehat{f}_\rho = \widehat{a}_\rho.\end{aligned} \tag{6}$$

The question we face is how to construct such invariants in a systematic way with minimum redundancy, yet maximum representational power.

3. Irreps and the Fourier Transform

It is easy to see that if $\rho_1 : \mathbb{S}_n \to \mathbb{C}^{d\times d}$ is a unitary representation of $\mathbb{S}_n$, and T is any $d \times d$ unitary matrix, then $\rho_2(\sigma) = T\,\rho_1(\sigma)\,T^\dagger$ is also a unitary representation. Such pairs of representations are said to be **equivalent**. Once we have computed (5) with $\rho = \rho_1$, computing it again with $\rho = \rho_2$ will not lead to additional invariants, since $\widehat{f}_{\rho_2} = T\widehat{f}_{\rho_1}T^\dagger$.

Another potential source of redundancy is reducibility. A representation ρ is said to be **reducible** if for some unitary T it splits in the form

$$\rho(\sigma) = T \left(\begin{array}{c|c} \rho_1(\sigma) & \\ \hline & \rho_2(\sigma) \end{array} \right) T^\dagger \qquad \sigma \in \mathbb{S}_n$$

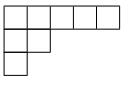
into a direct sum of smaller representations ρ_1 and ρ_2. Once again, $\widehat{f}_\rho$ does not supply any information on top of $\widehat{f}_{\rho_1}$ and $\widehat{f}_{\rho_2}$ because $\widehat{f}_\rho = T(\widehat{f}_{\rho_1} \oplus \widehat{f}_{\rho_2})T^\dagger$.

To avoid these redundancies we will use a *complete set of inequivalent irreducible unitary representations* (**irreps** for short). Such a set we denote by $\mathcal{R}$. The corresponding set of matrices

$$\widehat{f}_\rho = \sum_{\sigma\in\mathbb{S}_n} f(\sigma)\,\rho(\sigma), \qquad \rho \in \mathcal{R}, \tag{7}$$

is called the **Fourier transform** of f, and it provides the basis for generalizing harmonic analysis to non-commutative groups (Diaconis, 1988; Rockmore, 1997). Just as the classical Fourier transforms, $\mathcal{F}\colon f \to (\widehat{f}_\rho)_{\rho\in\mathcal{R}}$ satisfies a generalized form of the translation and convolution theorems. What is most crucial for our present purposes, however, is that (given the appropriate inner products) $\mathcal{F}$ is unitary, and therefore one–to–one: hence, no information is lost in going from f to the set of matrices $(\widehat{f}_\rho)_{\rho\in\mathcal{R}}$.

Several different systems of irreps for $\mathbb{S}_n$ are described in the literature (James & Kerber, 1981). In the interests of saving space, we only describe their general scheme, without going into the details of how to compute the actual representation matrices. In all the major representation schemes the individual irreps $\rho \in \mathcal{R}$ are indexed by **Young diagrams**, which are n boxes arranged in consecutive left-aligned rows satisfying the condition that no row overhangs the row above it. For example,



(8)

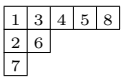
is a valid Young diagram for $n = 8$. We will use the letter λ to refer to Young diagrams and write $\lambda \vdash n$ to denote that λ is a Young diagram with n boxes. To simplify notation somewhat we write $\widehat{f}_\lambda$ for $\widehat{f}_{\rho_\lambda}$.

λ		d_λ
(n)		1
$(n-1,1)$		$n-1$
$(n-2,2)$		$\frac{n(n-3)}{2}$
$(n-2,1,1)$		$\frac{(n-1)(n-2)}{2}$
$(n-3,3)$		$\frac{n(n-1)(n-5)}{6}$
$(n-3,2,1)$		$\frac{n(n-2)(n-4)}{3}$

Table 1. The dimensionalities of some representations of $\mathbb{S}_n$. The diagrams are drawn as if $n = 8$, but the formulae hold for general n.

Young diagrams can also be described by listing the number of boxes in each row, for example, the above diagram is $\lambda = (5, 2, 1)$. For concreteness, when we need to draw Young diagrams we will always depict them as if $n = 8$.

Bijectively filling the boxes of a Young diagram with the numbers $1, 2, \ldots, n$ gives a **Young tableau**, and if a tableau satisfies the condition that in each row the numbers increase from left to right and in each column they increase from top to bottom it is called a **standard tableau**. For example,



is a standard tableau of shape $(5, 2, 1)$. The significance of standard tableaux is that they label the individual dimensions of the irrep of the same shape. Hence, we can find the dimensionality of ρ_λ by counting the number of possible standard tableaux of shape λ (Figure 1). An interesting special property of the symmetric group is that all the irreps can be chosen to be real valued. For generality, we retain the complex notation, but note that the actual system of irreps used in our experiments is real, so we could substitute "orthogonal" for "unitary" and $^\top$ for † throughout.

4. The Bispectrum and the Skew Spectrum

Armed with the irreps and non-commutative Fourier transforms, we can now undertake a more systematic study of left-translation invariant features of functions on the symmetric group. For example, (6) leads to the set of invariant matrices

$$\widehat{a}_\lambda = \widehat{f}_\lambda^\dagger \cdot \widehat{f}_\lambda, \qquad \lambda \vdash n,$$

which, by analogy with the analogous quantity in classical signal processing, is called the **power spectrum**

of f. The problem with the power spectrum is that it is very lossy. To see this, one need only consider $\widehat{f}'_\lambda = M_\lambda \widehat{f}_\lambda$ for any sequence of unitary matrices $(M_\lambda)_{\lambda \vdash n}$. The functions f and f' corresponding to these two Fourier transforms may be very different, yet their power spectrum will be the same.

4.1. The Bispectrum

Kakarala realized that the lossiness of the power spectrum can be addressed by forming tensor products of the various Fourier components, and proposed the alternative system of invariant matrices

$$\widehat{b}_{\lambda_1,\lambda_2} = (\widehat{f}_{\lambda_1} \otimes \widehat{f}_{\lambda_2})^\dagger \, C_{\lambda_1,\lambda_2} \Big[\bigoplus_\lambda \widehat{f}_\lambda\Big] \quad \lambda_1, \lambda_2 \vdash n \quad (9)$$

called the **bispectrum** (Kakarala, 1993)[1]. The bispectrum is based on the observation that $\widehat{f}_{\lambda_1} \otimes \widehat{f}_{\lambda_2}$ transforms according to

$$\widehat{f}^\pi_{\lambda_1} \otimes \widehat{f}^\pi_{\lambda_2} = (\rho_{\lambda_1}(\pi) \otimes \rho_{\lambda_2}(\pi)) \cdot (\widehat{f}_{\lambda_1} \otimes \widehat{f}_{\lambda_2}),$$

and that $\rho_{\lambda_1}(\pi) \otimes \rho_{\lambda_2}(\pi)$ is also a representation, although in general not irreducible. The general formula

$$\rho_{\lambda_1}(\sigma) \otimes \rho_{\lambda_2}(\sigma) = C_{\lambda_1,\lambda_2} \Big[\bigoplus_\lambda \rho_\lambda(\sigma)\Big] C^\dagger_{\lambda_1,\lambda_2} \quad (10)$$

telling us how to reduce it into a direct sum of irreps is called the Clebsch-Gordan decomposition, and the C_{λ_1,λ_2} unitary matrices appearing in (10) and (9) are called **Clebsch-Gordan matrices**.

By plugging (10) into (9) it is easy to see that the bispectrum is indeed invariant to left-translation. A much more remarkable fact, proved in (Kakarala, 1992), is that provided the technical condition that each $\widehat{f}_\lambda$ is invertible is satisfied, the bispectrum is also *complete* (or lossless) in the sense that the matrices $(\widehat{b}_{\lambda_1,\lambda_2})_{\lambda_1,\lambda_2 \vdash n}$ uniquely determine f up to translation.

4.2. The Skew Spectrum

Some of the drawbacks of using the bispectrum in practical applications are that (a) computing (9) may involve multiplying together very large matrices; (b) that the Clebsch-Gordan matrices, despite being universal constants, are not generally available in tabuated form; and (c) that for large n they are extremely difficult to compute. To address these concerns, Kondor (2007b) proposed an alternative set of invariants, called the **skew spectrum**, which are unitarily equivalent to the bispectrum, but much more straightforward to compute. The skew spectrum of $f\colon \mathbb{S}_n \to \mathbb{C}$ is defined as the collection of matrices

$$\widehat{q}_{\nu,\lambda} = \widehat{r}^\dagger_{\nu,\lambda} \cdot \widehat{f}_\lambda, \qquad \lambda \vdash n, \quad \nu \in \mathbb{S}_n, \qquad (11)$$

where $(\widehat{r}_{\nu,\lambda})_{\lambda \vdash n}$ is the Fourier transform of the function $r_\nu(\sigma) = f(\sigma\nu)\, f(\sigma)$. In (Kondor, 2007b) it is shown that if for some subgroup H, f is constant on left σH-cosets (as the function defined in (2) is constant on left $\mathbb{S}_{n-2}$-cosets), then it is sufficient to let ν take on just one value from each

$$H\sigma H = \{\, h_1 \sigma h_2 \mid h_1, h_2 \in H \,\}$$

double-coset, since every other component of $\widehat{q}$ will be linearly dependent on these.

5. The Skew Spectrum of Graphs

By the results of Sections 2 and 4, plugging (2) into (11) will give a relabeling invariant representation of any weighted graph $\mathcal{G}$. As it stands, however, this seems of only academic interest, since ν must extend over $n!$ different values for any one of which the combined size of the $(\widehat{q}_{\nu,\lambda})_{\lambda \vdash n}$ matrices is itself $n!$. Moreover, computing each $(\widehat{q}_{\nu,\lambda})_{\lambda \vdash n}$ requires a separate Fourier transform.

The first clue to how these problems may be remedied is provided by the comment at the end of the last section that if we are only interested in linearly independent invariants, then due to the special structure of f, we need only let ν take on one value from each $\mathbb{S}_{n-2}\, \sigma\, \mathbb{S}_{n-2}$ double coset. It is easy to see that there are only 7 such double cosets in $\mathbb{S}_n$, namely

$$\begin{aligned}
S^{n\mapsto n}_{n-1\mapsto n-1} &= \{\, \sigma \in \mathbb{S}_n \mid \sigma(n) = n,\ \ \sigma(n-1) = n-1 \,\} \\
S^{n\mapsto n-1}_{n-1\mapsto n} &= \{\, \sigma \in \mathbb{S}_n \mid \sigma(n) = n-1,\ \ \sigma(n-1) = n \,\} \\
S^{n\mapsto n}_{n-1\mapsto *} &= \{\, \sigma \in \mathbb{S}_n \mid \sigma(n) = n,\ \ \sigma(n-1) \in [n-2] \,\} \\
S^{n\mapsto n-1}_{n-1\mapsto *} &= \{\, \sigma \in \mathbb{S}_n \mid \sigma(n) = n-1,\ \ \sigma(n-1) \in [n-2] \,\} \\
S^{n\mapsto *}_{n-1\mapsto n-1} &= \{\, \sigma \in \mathbb{S}_n \mid \sigma(n) \in [n-2],\ \sigma(n-1) = n-1 \,\} \\
S^{n\mapsto *}_{n-1\mapsto n} &= \{\, \sigma \in \mathbb{S}_n \mid \sigma(n) \in [n-2],\ \ \sigma(n-1) = n \,\} \\
S^{n\mapsto *}_{n-1\mapsto *} &= \{\, \sigma \in \mathbb{S}_n \mid \sigma(n), \sigma(n-1) \in [n-2] \,\}\ ,
\end{aligned} \qquad (12)$$

where $[n-2] = \{1, 2, \ldots, n-2\}$.

Definition 1 *Given a graph $\mathcal{G}$ of n vertices and adjacency matrix A, the **skew spectrum** of $\mathcal{G}$ is defined as the collection of matrices*

$$\widehat{q}_{\nu,\lambda} = \widehat{r}^\dagger_{\nu,\lambda} \cdot \widehat{f}_\lambda, \qquad \lambda \vdash n, \qquad (13)$$

where $r_\nu(\sigma) = f(\sigma\nu)\, f(\sigma)$; f is defined as in (2); and ν takes on one value from each of the double cosets listed in (12).

The second important consequence of the form of (2) is that using the right system of irreps, $\widehat{f}$ becomes very

[1] The exact definition of the bispectrum varies somewhat between authors. However, the various definitions are all unitarily equivalent to each other.

sparse. To be specific, we use **Young's orthonormal representation** (YOR), which has the special property that if σ is restricted to $\mathbb{S}_{n-1}$, then the $\rho_\lambda(\sigma)$ matrices block-diagonalize in the form

$$\rho_\lambda(\sigma) = \bigoplus_{\lambda^-} \rho_{\lambda^-}(\sigma), \qquad \sigma \in \mathbb{S}_{n-1},$$

where λ^- extends over all valid Young diagrams derivable from λ by the removal of a single box. If the pair of standard tableaux t and t' feature n at the same box, then

$$[\rho_\lambda(\sigma)]_{t,t'} = [\rho_{\lambda^-}(\sigma)]_{t\downarrow_{n-1},t'\downarrow_{n-1}}$$

where $t\downarrow_{n-1}$ is the standard tableau that we get from t by removing the box containing n and λ^- is the corresponding Young diagram. If t and t' feature n at different locations, then $[\rho_\lambda(\sigma)]_{t,t'} = 0$. Applying this relation recursively gives that for $\sigma \in \mathbb{S}_k$,

$$[\rho_\lambda(\sigma)]_{t,t'} = \begin{cases} [\rho_{\lambda^-}(\sigma)]_{t\downarrow_k,t'\downarrow_k} & \text{or} \\ 0 \end{cases} \tag{14}$$

depending on whether $k+1,\ldots,n$ are each in the same boxes in t and t' or not.

Now letting $\mathbb{S}_n/\mathbb{S}_{n-2}$ be a set of $n(n-1)$ permutations, one from each $\sigma\mathbb{S}_{n-2}$ coset, and defining $h_\sigma\colon \mathbb{S}_{n-2} \to \mathbb{C}$ as $h_\sigma(\tau) = f(\sigma\tau)$, the Fourier transform may be written as

$$\widehat{f}_\lambda = \sum_{\sigma\in\mathbb{S}_n/\mathbb{S}_{n-2}} \sum_{\tau\in\mathbb{S}_{n-2}} f(\sigma\tau)\,\rho_\lambda(\sigma)\,\rho_\lambda(\tau) = \sum_{\sigma\in\mathbb{S}_n/\mathbb{S}_{n-2}} \rho_\lambda(\sigma) \sum_{\tau\in\mathbb{S}_{n-2}} h_\sigma(\tau)\,\rho_\lambda(\tau).$$

Plugging in the appropriate decomposition of ρ_λ into a direct sum of irreps of $\mathbb{S}_{n-2}$ gives

$$\widehat{f}_\lambda = \sum_{\sigma\in\mathbb{S}_n/\mathbb{S}_{n-2}} \rho_\lambda(\sigma) \sum_{\tau\in\mathbb{S}_{n-2}} h_\sigma(\tau) \bigoplus_{\lambda^-} \rho_{\lambda^-}(\tau) = \sum_{\sigma\in\mathbb{S}_n/\mathbb{S}_{n-2}} \rho_\lambda(\sigma) \bigoplus_{\lambda^-} \left[\widehat{h}_\sigma\right]_{\lambda^-}, \tag{15}$$

showing that the Fourier transform over $\mathbb{S}_n$ may be broken down into $n(n-1)$ Fourier transforms over $\mathbb{S}_{n-2}$. This relationship is at the heart of the Clausen-type fast Fourier transforms for $\mathbb{S}_n$ (Clausen, 1989).

For f defined by (2), each h_σ is a constant function, and hence its Fourier transform has a very special form: since in YOR the irrep corresponding to $\lambda = (n)$ is the constant representation $\rho_{(n)}(\sigma) = (1)$, the corresponding $\left[\widehat{h}_\sigma\right]_\lambda$ component will be non-zero, but by unitarity all other components of $\widehat{h}_\sigma$ vanish. Plugging this result into (15) and using (14) shows that only those columns of $\widehat{f}$ may be non-zero which are indexed by standard tableau derivable from  by adding a box containing $n-1$ and another box containing n. Here and in the following, when drawing standard tableau, we only indicate the positions of those numbers in them that are not determined by the "numbers increase from left to right and top to bottom" rule. In addition, we use the symbol ■ to denote n and • to denote $n-1$. We summarize the above in the following theorem.

Theorem 1 *If f is defined as in (2), then the only non-zero entries of $\widehat{f}$ in YOR are:*

1. *the single scalar component $\widehat{f}_{(n)}$;*
2. *the*  *column of $\widehat{f}_{(n-1,1)}$;*
3. *the*  *column of $\widehat{f}_{(n-1,1)}$;*
4. *the*  *column of $\widehat{f}_{(n-2,2)}$;*
5. *the*  *column of $\widehat{f}_{(n-2,1,1)}$.*

This remarkable sparsity is the key to computing the skew spectrum of graphs efficiently. At the same time it is rather disappointing, since it manifestly destroys the invertibility of the $\widehat{f}_\lambda$ matrices required for Kakarala's completeness result. The $\widehat{r}_{\nu,\lambda}$ matrices are also column sparse, but their sparsity pattern is somewhat more complicated, so we leave describing it to (Kondor, 2008).

Equation (13) only yields non-zero elements in $\widehat{q}_{\nu,\lambda}$ where a non-zero row of $\widehat{r}^\dagger_{\nu,\lambda}$ meets a non-zero column of $\widehat{f}_\lambda$. By the above, this happens at only a constant number of row/column combinations. The exact result, derived in (Kondor, 2008), is the following.

Theorem 2 *Using YOR and an appropriate choice of $\{\nu\}$ double coset representatives, the skew spectrum of $\mathcal{G}$ has at most 85 non-zero scalar components.*

6. Computational Considerations

The computational properties of the skew spectrum are closely related to the structural results of the previous section. In particular, it is repeated applications of Clausen decompositions similar to (15) together with the sparsity of YOR that yields an efficient algorithm to compute $\widehat{q}$. In contrast to the previous section, we now employ a two-level factorization $\sigma = \sigma_1\sigma_2\tau$, where $\tau \in \mathbb{S}_{n-2}$, $\sigma_2 \in \mathbb{S}_{n-1}/\mathbb{S}_{n-2}$, and $\sigma_1 \in \mathbb{S}_n/\mathbb{S}_{n-1}$. As before, we have $n(n-1)$ functions $h_{\sigma_1\sigma_2}\colon \mathbb{S}_{n-2} \to \mathbb{C}$ defined $h_{\sigma_1\sigma_2}(\tau) = f(\sigma_1\sigma_2\tau)$, and by (2) each of these

is a constant function equal to $[A]_{\sigma_1\sigma_2(n),\,\sigma_1\sigma_2(n-1)}$. However, now we will also have intermediate functions $g_{\sigma_1}\colon \mathbb{S}_{n-1} \to \mathbb{C}$ defined $g_{\sigma_1}(\tau) = f(\sigma_1\tau)$. We then have the following results.

Lemma 1 *Each $\widehat{g}_{\sigma_1}$ can be computed from A in $O(n^2)$ scalar operations.*

Proof. Similarly to (15), we can relate the Fourier transform of g_{σ_1} to the Fourier transforms of $(h_{\sigma_1\sigma_2})_{\sigma_2}$ by

$$[\widehat{g}_{\sigma_1}]_\lambda = \sum_{\sigma_2 \in \mathbb{S}_{n-1}/\mathbb{S}_{n-2}} \rho_\lambda(\sigma_2) \bigoplus_{\lambda^-} \left[\widehat{h}_{\sigma_1\sigma_2}\right]_{\lambda^-}.$$

Since each $\widehat{h}_{\lambda_1\lambda_2}$ is confined to the one dimensional component $[\widehat{h}_{\sigma_1\sigma_2}]_{(n-2)}$, the only non-zero columns of $\widehat{g}_{\sigma_1}$ will be the ones indexed by standard tableaux derivable from  by addition of the single box , namely and  . The first one of these is trivial to compute, since $\rho_{(n-1)}(\sigma_2) \equiv (1)$, collapsing the above sum to

$$[\widehat{g}_{\sigma_1}]_{(n-1)} = \sum_{\sigma_2 \in \mathbb{S}_{n-1}/\mathbb{S}_{n-2}} \left[\widehat{h}_{\sigma_1\sigma_2}\right]_{(n-2)}.$$

This is a sum of $n-1$ scalars, so it can be computed in $O(n)$ time. Computing the second component involves taking the direct sum $M_{\sigma_1\sigma_2} = \bigoplus_{\lambda^-} \left[\widehat{h}_{\sigma_1\sigma_2}\right]_{\lambda^-}$, where λ^- extends over the two diagrams $(n-2)$ and $(n-3,1)$ derivable from  by removing a box. However, $\left[\widehat{h}_{\sigma_1\sigma_2}\right]_{(n-3,1)} = 0$, so $M_{\sigma_1\sigma_2}$ has only one non-zero entry. For given σ_2, multiplying $\rho_{(n-2,1)}(\sigma_2)$ with $M_{\sigma_1\sigma_2}$ thus requires $n-2$ operations. We are summing over $(n-1)$ possible values of σ_2, so the total time complexity is $(n-1)(n-2)$. ■

Lemma 2 *$\widehat{f}$ can be computed from the intermediate transforms $(\widehat{g}_{\sigma_1})_{\sigma_1 \in \mathbb{S}_n/\mathbb{S}_{n-1}}$ in $O(n^3)$ operations.*

The proof of Lemma 2 is similar to that of Lemma 1, but also involves considerations of the sparsity of the YOR matrices. Unfortunately, space limitations prevent us from providing a proof of this result. Putting the two lemmas together gives the following theorem.

Theorem 3 *The Fourier transform of f as defined in (2) can be computed in $O(n^3)$ operations.*

Proof. Each of the n different $\widehat{g}$ transforms can be computed in $O(n^2)$ operations, followed by the single $O(n^3)$ step of computing $\widehat{f}$ from the $\widehat{g}$'s. ■

Computing $\widehat{r}_\nu$ is unfortunately more costly than computing $\widehat{f}$. An extended version of this paper, which is in preparation, will show that the time complexity of this is $O(n^6)$. While for n less than about 20 this might still be feasible, for the type of experiments on which we wish to validate the skew spectrum it is not a viable option. The following subsection shows that most of the components of $\widehat{q}$ can still be computed in $O(n^3)$ operations.

6.1. The Reduced Skew Spectrum

The expensive part of computing $\widehat{r}_\nu$ is computing those columns outside the five listed in Theorem 1. This leads to the idea of simply forcing these columns to be zero.

Definition 2 *Given a graph $\mathcal{G}$ of n vertices and adjacency matrix A, the **reduced skew spectrum** of $\mathcal{G}$ is the collection of matrices*

$$\widehat{q}^*_{\nu,\lambda} = \widehat{r}^*_{\nu,\lambda}{}^\dagger \cdot \widehat{f}_\lambda, \qquad \lambda \vdash n, \tag{16}$$

where f,r, and ν are as in Definition 1, and $\widehat{r}^*_\nu$ denotes the projection of $\widehat{r}_\nu$ to its columns labeled by

 . (17)

Since $\widehat{r}^*_\nu$ is identical to $\widehat{r}_\nu$ except for zeroing out certain columns, $(\widehat{q}^*_\nu)_\nu$ will yield a subset of the 85 scalar invariants in $(\widehat{q}_\nu)_\nu$. For each value of ν, for $\lambda = (n)$ we have one row of $\widehat{r^*}_\nu^\dagger$ meeting one column of $\widehat{f}_\nu$ giving one component; for $\lambda = (n-1,1)$ we have two rows meeting two columns, giving four components, etc. In total the reduced skew spectrum has $7\,(1+4+1+1) = 49$ non-zero scalar components.

The space of functions the Fourier transform of which has the sparsity pattern (16) is exactly the space of functions which are invariant on $\sigma\mathbb{S}_{n-2}$ cosets. This means that for each $\widehat{r}^*_\nu$ there must be a corresponding matrix B_ν related to it the same way that f is related to the adjacency matrix A. These matrices are given by the following theorem, the proof of which we again relegate to a longer publication.

Theorem 4 *For $\widehat{r}^*_\nu$ as defined in Definition 2,*

$$r^*_\nu(\sigma) = [B_\nu]_{\sigma(n),\sigma(n-1)},$$

where the seven possible B_ν matrices corresponding to the seven double cosets listed in (12) are

$$\begin{aligned}
[B_1]_{i,j} &= A_{i,j}\, A_{i,j} \\
[B_2]_{i,j} &= A_{i,j}\, A_{j,i} \\
[B_3]_{i,j} &= \tfrac{1}{n} A_{i,j} \textstyle\sum_{i'=1}^n A_{i',j} \\
[B_4]_{i,j} &= \tfrac{1}{n} A_{i,j} \textstyle\sum_{j'=1}^n A_{i,j'}
\end{aligned}$$

$$[B_5]_{i,j} = \frac{1}{n} A_{j,i} \sum_{i'=1}^{n} A_{i',j}$$
$$[B_6]_{i,j} = \frac{1}{n} A_{j,i} \sum_{j'=1}^{n} A_{i,j'}$$
$$[B_7]_{i,j} = \frac{1}{n(n-1)} A_{i,j} \sum_{i'=1}^{n} \sum_{j'=1}^{n} A_{i',j'}$$

Theorem 4 tells us that the reduced skew spectrum is very simple to compute: simply form the matrices $B_1, \ldots, B_7$, compute the corresponding $\widehat{r}^*_\nu$ the same way as $\widehat{f}$ is computed from A and form the products (16). In total this takes 8 partial Fourier transforms, each of which takes $O(n^3)$ time.

7. Experiments

In our experiments we evaluate the performance of the skew spectrum features on four benchmark datasets of chemical structures of molecules: MUTAG, ENZYMES, NCI1, and NCI109. MUTAG (Debnath et al., 1991) is a dataset of 188 mutagenic aromatic and heteroaromatic nitro compounds. The classification task is to predict for each molecule whether it exerts a mutagenic effect on the Gram-negative bacterium *Salmonella typhimurium*. ENZYMES is a dataset which we obtained from (Borgwardt et al., 2005), and which consists of 600 enzymes from the BRENDA enzyme database (Schomburg et al., 2004). In this case the task is to correctly assign each enzyme to one of the 6 EC top level classes. The average number of nodes of the graphs in this dataset is 32.6 and the average number of edges is 124.3. Finally, we also conducted experiments on two balanced subsets of NCI1 and NCI109, which classify compounds based on whether or not they are active in an anti-cancer screen ((Wale & Karypis, 2006) and `http://pubchem.ncbi.nlm.nih.gov`).

Since in these datasets the number of vertices varies from graph to graph, we set n to be the maximum over the entire dataset and augment each of the smaller graphs with the appropriate number of unconnected "phantom" nodes. The experiments consisted of running SVMs on the above data using the reduced skew spectrum features (linear kernel on these features), the random walk kernel (Gärtner et al., 2003), (with λ set to 10^{-3} on MUTAG/ENZYMES, and 10^{-4} on the NCI datasets for optimal performance), and an equal length shortest-path kernel (Borgwardt & Kriegel, 2005).

Our experimental procedure was as follows. We split each dataset into 10 folds of identical sizes. We then split 9 of these folds again into 10 parts, trained a C-SVM (implemented by LIBSVM (Chang & Lin, 2001)) on 9 parts, and predicted on the 10th part. We repeated this training and prediction procedure for $C \in \{10^{-7}, 10^{-6}, \ldots, 10^{7}\}$, and determined the C reaching maximum prediction accuracy on the 10th part. We then trained an SVM with this best C on all 9 folds (= 10 parts), and predicted on the 10th fold, which acts as an independent evaluation set. We repeated the whole procedure 10 times so that each fold acts as independent evaluation set exactly once. For each dataset and each method, we repeat the whole experiment 10 times and report mean accuracy levels and standard errors in Table 2. In three out of four experiments the skew spectrum beats the other methods, including the shortest-path kernel, which is considered state of the art for graphs of this type. Using a Gaussian RBF kernel instead of the linear kernel yields very similar results.

8. Conclusions

We have presented a new system of graph invariants, called the skew spectrum of graphs, based on a purely algebraic technique. From a mathematical point of view the skew spectrum is interesting because it brings a fundamentally new technique to constructing graph invariants. From a practical machine learning point of view the skew spectrum is interesting because it provides a powerful, yet efficiently computable representation for graph structured data instances.

Acknowledgments

We would like to thank Ramakrishna Kakarala for providing us with a hard copy of his thesis. We would also like to thank Dan Rockmore, Tony Jebara, Rocco Servedio, Maria Chudnovsky and Balázs Szendrői for discussions and the anonymous reviewers for helpful comments.

Abstract

In inductive logic programming, θ-subsumption is a widely used coverage test. Unfortunately, testing θ-subsumption is NP-complete, which represents a crucial efficiency bottleneck for many relational learners. In this paper, we present a probabilistic estimator of clause coverage, based on a randomized restarted search strategy. Under a distribution assumption, our algorithm can estimate clause coverage without having to decide subsumption for all examples. We implement this algorithm in program ReCovEr. On generated graph data and real-world datasets, we show that ReCovEr provides reasonably accurate estimates while achieving dramatic runtimes improvements compared to a state-of-the-art algorithm.

1. Introduction

In most inductive logic programming (ILP) algorithms, learned hypothesis are (sets of) first-order clauses. Usually, θ-subsumption is used to test whether a clause entails an example. Since ILP systems need to evaluate large numbers of clauses during hypothesis search, efficiency of the subsumption procedure is one of the crucial factors for performance of learning. Unfortunately, deciding θ-subsumption is an NP-complete problem.

One line of research has focused on developing algorithms for this problem using sophisticated heuristics from the field of constraint satisfaction problems (CSP). Maloberti et Sebag (2004) exploited the correspondence of θ-subsumption with CSP to develop the algorithm Django. Django is currently considered the fastest subsumption checker, outperforming traditional techniques (based on the Prolog unification mechanism) by orders of magnitude. Therefore we employ Django in comparative experiments later in this paper. Another stream of research dealt with incomplete heuristic algorithms for θ-subsumption. Sebag et al. (1997) presented a tractable approximation of θ-subsumption called stochastic matching. Arias et al. (2007) implemented a randomized table-based method.

Unlike the mentioned incomplete heuristic algorithms, our approach uses a complete, albeit randomized, subsumption procedure that correctly decides both subsumption and non-subsumption if given sufficient finite time. Our ultimate estimation of the clause coverage (i.e. the number of subsumed examples) is however an approximation, rapidly achieved by restarting the subsumption procedure each time with a bounded runtime. Subsequent restarts generate an integer sequence, from which the coverage is estimated by maximum likelihood.

Randomized restarted strategies, exploited in our work, have been extensively studied in the past decade (Gomes et al., 2000). They have been demonstrated to be extremely useful for solving many hard combinatorial problems such as satisfiability of boolean formulas or for solving constraint satisfaction problems. Reported reduction in runtimes are often in orders of magnitude. Randomized restarted strategies have been also used in inductive logic programming (Železný et al., 2006), however, not for subsumption checking. Rather, restarts were applied on the clause-search procedure.

This paper is organized as follows. In Section 2 we formalize subsumption and expose the basic algorithms employed as building blocks in our estimation approach. In Section 3 we conduct a preliminary motivating study of runtime distribution. The estimation

Algorithm 1 *SubsumptionCheck*(C, e): A simple subsumption check algorithm

```
Input: Clause C, example e;
if C ⊆ e then
  return YES
else
  Choose variable V from C using a heuristic function
  for ∀S ∈ PossibleSubs(V, C, e) do
    C' ← Substitute V with S
    if ∀W ∈ Adjacency(V) : PossibleSubs(W, C', e) ≠ ∅ then
      SearchedNodes ← SearchedNodes + 1
      if SubsumptionCheck(C', e) = YES then
        return YES
      end if
    end if
  end for
  return NO
end if
```

algorithm is then developed in Section 4. In Section 5, we compare our algorithm with Django on synthetic and on real-life data. Section 6 concludes the paper.

2. Preliminaries

2.1. Language

In the rest of the paper we assume for simplicity that hypotheses C are clauses without function and constant symbols and examples e are ground clauses. When needed, clauses will be treated as atom sets, e.g. for two clauses C and D, $C \subseteq D$ will denote that C contains all literals contained by D. θ-subsumption is defined as follows

Definition We say that clause C θ-subsumes clause D (denote $C \preceq_\theta D$) iff there exists a substitution θ such that $C\theta \subseteq D$.

2.2. Subsumption Algorithm

We consider a simple heuristic algorithm (Algorithm 1) for verifying whether a clause C subsumes an example e. Similarly to Django (Maloberti & Sebag, 2004) this algorithm is inspired by the CSP framework. It is a backtracking search algorithm with forward checking, a variable selection heuristic and randomization. The heuristic function aims at choosing variables whose substitution makes it likely that an inconsistency, if one exists, is detected soon. For a variable V, the function computes the sum of occurrences of variables in clause C that have already been grounded and that share at least one literal with V. This sum is then multiplied by $1 + \frac{1}{D}$, where D is an upper bound on the size of the domain of V computed in the initialisation phase of the algorithm's run. The variable which maximizes this function is selected; in case of a tie, a random choice is made with uniform probability among the highest scoring variables. Function *PossibleSubs*(V, C, e) returns all terms S (in a random order), which can be substituted for V satisfying that all literals $l \in C$ remain consistent with e. The function prunes away a subset of possible groundings for V whose inclusion in θ would imply $C\theta \not\subseteq e$. In general though, not all such groundings are detected by the function.

3. Subsumption Test Runtimes

We first aimed at obtaining a domain-independent runtime distribution of the subsumption algorithm and thus conducted preliminary experiments with randomly generated hypotheses and examples from the domain of oriented colored graphs. In the clausal representation, each graph acquires the form of a definite clause

$$h \leftarrow l_1 \wedge l_2 \wedge \ldots$$

where h is a fixed head and l_i are first-order atoms, each being one of $edge(t_1, t_2)$, $black(t_3)$, $red(t_4)$. In hypotheses, t_i are variables, in examples these are constants.

For generality, we devised two different graph generators. The first generator generates Erdos-Rényi random graphs where any two vertices are connected with a pre-set probability c (by an edge of a random orientation). The second produces scale-free ("small world") graphs. Here, the graph grows until some desired size is reached; at any step a vertex is added and connected to k vertices already present in the graph. An edge is attached to a vertex with probability increasing with the number of edges already connected to the vertex. In both algorithms, all vertices are colored as black with probability 0.5 and red otherwise. We will refer to the parameter c (k, respectively) of a random uniform (scale-free, respectively) graph as the *connectivity* of the graph.

We subjected Algorithm 1 to experiments with random sets of hypotheses and examples, under various settings of n and c (n and k, respectively), where n denotes number of vertices in the underlying graph and c and k are parameters of the random graphs explained above. Here, we review our principal findings about the respective runtime distributions, since they motivate the design of the estimation algorithm in the next section.

Our first objective was to verify the presence of heavy tails in the runtime distributions $F(t)$. For $t > 0$, the number $F(t)$ is the probability that the tested algorithm resolves a random subsumption instance in no more than t units of time, corresponding to the number of explored search nodes. Informally, a heavy-

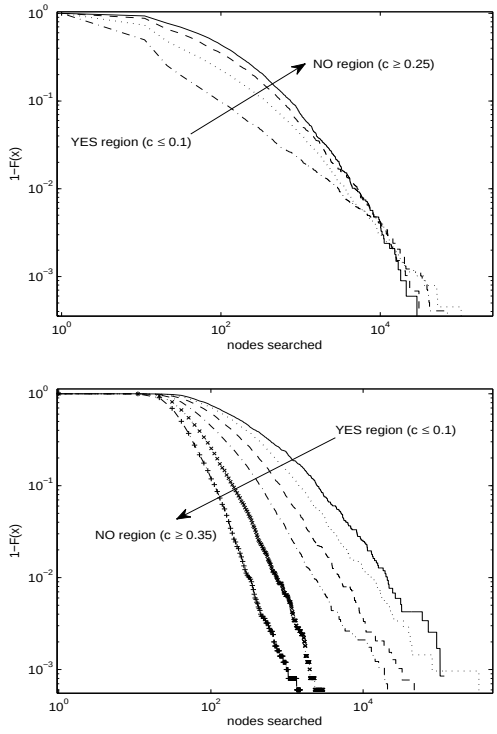

Figure 1. **Top:** The runtime distributions for satisfiable instances with hypotheses built using the Erdos-Rényi random graph generator with $n = 15$ vertices and connectivity consecutively $c \in \{0.1, 0.15, 0.2, 0.25\}$. The graphs corresponding to examples had $n = 50$ vertices and connectivity $p = 0.3$. **Bottom:** The subsumption test runtime distributions for unsatisfiable instances with hypotheses with connectivity consecutively $c \in \{0.15, 0.2, 0.25, 0.3, 0.35, 0.4\}$.

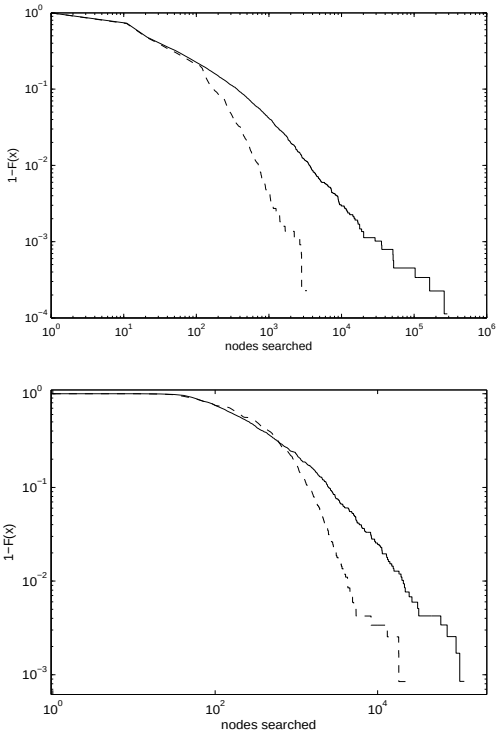

Figure 2. Effect of the restarted strategy for satisfiable (top) and unsatisfiable instances (bottom). The random graphs corresponding to hypotheses had $n = 15$ vertices and connectivity $c = 0.15$. In both cases, the random graphs corresponding to examples had $n = 50$ vertices and connectivity $c = 0.3$. Both hypotheses and examples were randomly generated by the Erdos-Rényi generator.

tailed distribution indicates the non-negligible probability of subsumption instances on which the checking algorithm gets stuck for an extremely long runtime. For example, a heavy tail is exhibited if $1-F(t)$ decays at a power-law rate, i.e. slower than standard distributions which decay exponentially. The presence of a heavy tail in an empirically obtained runtime distribution $F(t)$ is usually checked graphically, by plotting $1 - F(t)$ against t on a log-log scale. In the case of a power-law distribution, this plot then acquires a linear shape (Gomes et al., 2000).

A series of experiments in the phase transition framework (Giordana & Saitta, 2000), which we have performed, revealed a systematic progression from heavy-tailed regimes corresponding to configurations located in the YES region of the phase transition spectrum to non-heavy-tailed regimes corresponding to configurations located in the NO region. This observation agrees with the previous study (Gomes et al., 2005). This progression is shown in Fig. 1 for the Erdos-Rényi graph data. The same trends were observed for the small-world graph data. The plotted runtime distributions refer to subsumption checks between hypotheses with fixed numbers of vertices and connectivity changing among particular distributions, and examples with fixed numbers of vertices and with fixed connectivity. The runtime distributions plotted in the top panel of Fig. 1 refer to satisfiable problem instances, i.e. those where the hypotheses θ-subsume the examples. The distributions in the bottom panel of Fig. 1 refer to unsatisfiable problem instances.

Due to the observed presence of heavy tails in a range of parameters, we next assessed the impact of restarts. For this sake we designed a complete restarted randomized subsumption algorithm, which repeatedly executes Algorithm 1. At each execution $n = 1, 2, \ldots,$ the number of search nodes in the Algorithm 1 is bounded by some pre-defined number $R(n)$. This loop is terminated once answer YES or NO is obtained from

Algorithm 1. Completeness of this restarted approach is guaranteed by the assumption that $R(n) \to \infty$ as $n \to \infty$. Recall that randomization is facilitated by tie-breaking in the heuristic function used in Algorithm 1 and by randomization of the value ordering.

The basic trends we observed for all tested parameter values are represented by Fig. 2: (i) restarts significantly reduce runtime expectation for both satisfiable and unsatisfiable instances, (ii) unsatisfiable instances take much longer to prove in the restarted approach. Observation (i) alone motivates to use the restarted variant of Algorithm 1 as a fast complete method for subsumption testing. We explore this idea elsewhere (Kuželka & Železný, 2009), whereas this paper addresses observation (ii). This observation is easily explained: while satisfiability can in principle be shown in any single restart, unsatisfiability can only be shown after n restarts making $R(n)$ sufficiently high. We would like to avoid the runtime components corresponding to $R(n)$ series growing to excessive values.

4. ReCovEr: A Restarted Coverage Estimator

We first explain the intuition underlying ReCovEr. We are given a clause C, and example set E and we would like to estimate the coverage $cov(C, E) = |\{e \in E \mid C \preceq_\theta e\}|$. Let us run Algorithm 1 on C and e, successively for all $e \in E$. For each e, we however stop the algorithm if no decision has been made in R steps. Let $\mathcal{E} \subseteq E$ be the subset of examples proven to be subsumed by C in this experiment. Denote $s_1 = |\mathcal{E}|$. We now remove all examples in $\mathcal{E}$ from E and repeat this experiment, obtaining analogical number s_2. Further such iterations generate numbers s_3, s_4, etc. Clearly, for the desired value $cov(C, E)$, we have that $cov(C, E) = \lim_{j\to\infty} S_j$ where $S_j = \sum_{i=1}^{j} s_i$. Under a certain assumption, the series S_j is geometrical rather than arbitrary. The main idea of ReCovEr is that the limit of S_j for $j \to \infty$ can thus be estimated by extrapolating the series from its first few elements $S_1, S_2, \ldots$. Thus we achieve a coverage estimate without excessive effort to refute subsumption for the examples not subsumed by C.

In order to precisely derive an estimation algorithm following the above idea, we first need to make the following assumption.

Assumption 4.1 *Given a clause C and a set of examples E, the probability p that Algorithm 1 finds a solution (i.e. returns YES as its answer) before it explores more than R nodes of the search tree, is the same for all $e \in E$ such that C subsumes e.*

Algorithm 2 *ReCovEr*(C, E, R, M, Δ): Algorithm for coverage estimation

Input: Clause C and set of examples E, Integers R ('cutoff'), M, Δ;

```
tries ← 0
Unknown ← Examples
CoveredInIthTry ← []
repeat
  tries ← tries + 1
  CoveredInThisTry ← 0
  for ∀E ∈ Unknown do
    Answer ← Run SubsumptionCheck(C, E) with number of
    searched nodes limited to R
    if Answer = PositiveMatching then
      CoveredInThisTry ← CoveredInThisTry + 1
      Unknown ← Unknown\E
    end if
  end for
  CoveredInIthTry[tries] ← CoveredInThisTry
until TerminationCondition
return LikelihoodEstimate(tries)
```

In other words, we assume that properties of particular examples such as their size are not dramatically different. The assumption will be empirically validated in the next section.

We assume a given clause C and we fix a constant cutoff value R. In the first step, for each $e \in E$ we run $SubsumptionCheck(P, e)$ (Algorithm 1), stopping it as soon as the number of searched nodes has reached R. Then, after $|E|$ restarts (each time with a different $e \in E$), we can derive the probability that the algorithm has produced exactly m_1 'YES' responses in this first step. In particular, this probability $P(m_1)$ is

$$P(m_1) = \binom{A}{m_1} p^{m_1}(1-p)^{A-m_1} \tag{1}$$

where $A = |\{e \in E | C \preceq_\theta e\}|$. In the next step, all m_1 examples shown to be subsumed in the first step are removed from E and the procedure is repeated with the remaining examples. In general, we can derive the probability that exactly m_i YES answers are generated in the i-th step. Thus for $i = 2$, we obtain

$$P(m_2|m_1) = \binom{A-m_1}{m_2} p^{m_2}(1-p)^{A-m_1-m_2} \tag{2}$$

and similarly for an arbitrary $i \geq 1$, we have

$$P(m_i|m_{i-1}, \ldots, m_1) = \binom{A - \sum_{j=1}^{i-1} m_j}{m_i} p^{m_i}(1-p)^{A-\sum_{j=1}^{i} m_j} \tag{3}$$

The probability of a sequence $(m_1, \ldots, m_k)$, where m_i is the number of examples for which YES was produced in the i-th step, is given by

$$P(m_1, \ldots, m_k) = \prod_{i=1}^{k} P(m_i | m_{i-1}, \ldots, m_1) \quad (4)$$

Substituting for $P(m_i|m_{i-1}, \ldots, m_1)$ from Eq. 3 and taking the logarithm Eq. 4 results in

$$\ln\left(P(m_1, \ldots, m_k)\right) = \sum_{i=1}^{k} (\alpha + m_i \ln p + \beta) \quad (5)$$

where

$$\alpha = \ln \begin{pmatrix} A - \sum_{j=1}^{i-1} m_j \\ m_i \end{pmatrix}$$

and

$$\beta = \left(A - \sum_{j=1}^{i} m_j\right) \ln(1-p)$$

To find the parameters A and p for which $P(m_1, \ldots, m_k)$ is maximized, we take the partial derivative of Eq. 5 with respect to p and then find its roots, yielding

$$p = \frac{\sum_{i=1}^{k} m_i}{\sum_{i=1}^{k} m_i + \sum_{i=1}^{k} \left(A - \sum_{j=1}^{i} m_j\right)} \quad (6)$$

Finding the global maximum of $P(m_1, \ldots, m_k)$ from Eq. 4 on the set

$$D = \{(A, p) | A \in \{1, 2, \ldots, |E|\} \wedge p \in [0; 1]\} \quad (7)$$

is now straightforward, since using (6) we can find the maximum on every line

$$L_i = \{(i, p) | p \in [0; 1]\} \quad (8)$$

The maximum on line L_i is located either at the value of p given by (6) or at one of the borders of L_i. It then suffices to evaluate (4) at these three points of L_i for every i ($1 \leq i \leq |E|$). The estimate of A then equals the index i of the L_i on which the maximum is located.

The described estimator is used in ReCovEr (Algorithm 2). The question how to choose k, i.e. how long a sequence $(m_1, \ldots, m_k)$ should be generated as the input to the estimator, is tackled iteratively: the sequence is being extended until a termination condition is met. We have considered several termination conditions, of which two turned out to be quite useful. The first termination condition stops generating the sequence when two subsequent estimates differ by less than some Δ_e, specified as a parameter. The second termination condition stops generating the sequence when estimate and number of examples already shown to be covered by the clause differ again by less than some Δ_c, which ensures that the estimator will never overestimate the actual coverage by more than Δ_c. A minimum length M of the sequence is however imposed in both previous cases, to avoid premature estimates coinciding by chance.

Another degree of freedom in Algorithm 2 is the cutoff R, which may significantly affect the performance of the restarted algorithm. A heuristic method suggests itself that first tries to find a suitable cutoff. Unlike Algorithm 2 it starts with a base cutoff value, and then doubles it after every single restart. If at any restart Algorithm 1 with cutoff set to R covers fewer examples than the same algorithm at previous restart with cutoff set to $\frac{R}{2}$, then we can accept cutoff $\frac{R}{2}$.

5. Experiments

In this section, we first investigate the sensitivity of ReCovEr to a violation of Assumption 4.1. Then we evaluate its performance and precision on graph data generated by the two random graph generators described in Section 2 and on real-world data from organic chemistry and from engineering. We compare performance of ReCovEr with that of the state-of-the-art θ-subsumption algorithm Django.

5.1. Sensitivity Analysis

Here we address Assumption 4.1. Informally, we first want to verify (i) how the assumption deviates from the empirical 'truth', and subsequently, (ii) how much these deviations influence ReCovEr's precision.

(i) According to Assumption 4.1, probability $p \in [0; 1]$ would be a constant. Dismissing this assumption, we treat p as a random variable with some distribution on $[0; 1]$, which we would like to estimate. A standard approach to this task is to parameterize a Beta distribution on $[0; 1]$ from empirical data. To obtain the data, we experimented with the settings from Section 3 with parameters of generated hypotheses $c = 0.35$, $n = 10$, parameters of generated examples $c = 0.3$, $n = 50$ and ReCovEr's cutoff $R = 75$. This resulted in Beta distributions with standard deviation extending up to about 0.25 (i.e. 25% of the p's range). These distributions are plotted in dashed lines in Fig. 3.

(ii) Now we investigate ReCovEr's sensitivity to the modeled deviations. We assume to have $n = 100$ ex-

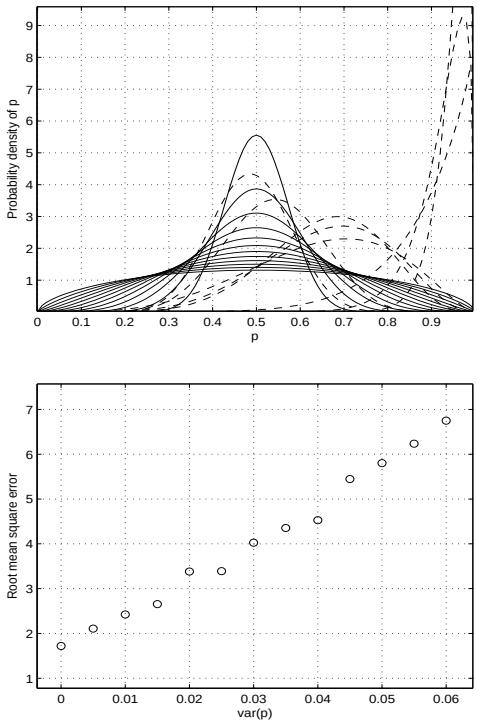

Figure 3. **Top:** Beta distributions with mean $\mu = 0.5$ and variance consecutively $0, 0.005, \ldots, 0.06$, which model the distribution of p (solid lines). Beta distributions fitted to actual probabilities are shown in dashed lines. **Bottom:** Dependence of root mean square error of ReCovEr's estimates on the variance of p.

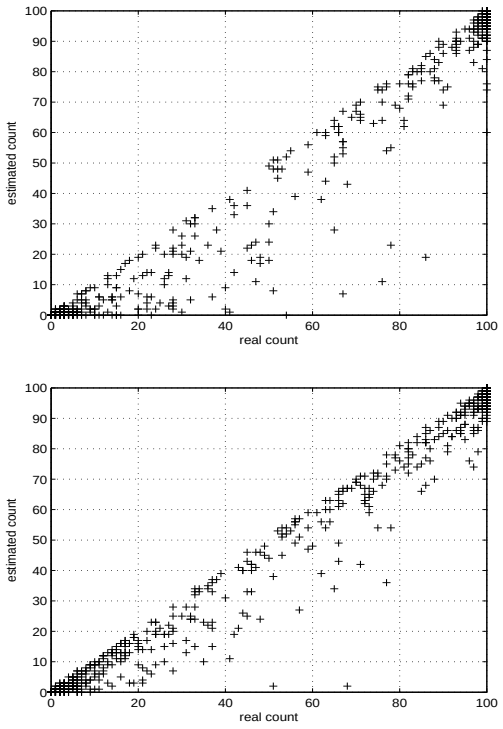

Figure 4. Precision of ReCovEr (Algorithm 2) presented as 1000 points with coordinates (estimated coverage, actual coverage). Hypotheses and examples were generated by the Erdos-Rényi random graph generator with $c = 0.3$, $n = 15$ for hypotheses and $c = 0.3$, $n = 100$ for examples. The 1000 estimates correspond to 1000 different hypotheses tested on a pre-fixed set of 100 examples. **Top:** Base value for cutoff is $R = 100$. **Bottom:** Base value for cutoff is $R = 200$.

amples, of which 50 were covered by a clause C. Further, probabilities p_i that Algorithm 1 finds a solution for a covered example e_i in time less than R were sampled from the Beta distribution with given mean $\mu = 0.5$ and variance consecutively $0, 0.005, \ldots, 0.06$ (i.e. growing up to the 25% standard deviation). Then, we simulated ReCovEr's estimation procedure on these data. The top panel of Fig. 3 displays the beta distributions (solid lines) from which probabilities p_i were sampled. We used the stopping condition based on difference of estimate and lower bound, the parameters were $M = 3$, $\Delta = 1$.

The bottom panel of Fig. 3 displays the dependence of root mean square error on the variance of the beta distributions in the top panel. It is encouraging to see that the root mean square error grows roughly *linearly* with growing variance in p's distribution, indicating ReCovEr's robustness towards this variance. Of course, the ultimate judge of whether this dependence is acceptable is the extent to which a learning algorithm based on ReCovEr would be affected by the estimation imprecision caused by the estimation. This is studied further.

5.2. Experiments with Generated Graph Data

Figure 4 demonstrates the precision of ReCovEr on the graph data generated by the Erdos-Rényi generator by showing 1000 pairs (estimated coverage, actual coverage). Hypotheses and examples were generated with $c = 0.3$ for hypotheses and $c = 0.3$ for examples. The graphs corresponding to hypotheses had 15 vertices, and the graphs corresponding to examples had 100 vertices. The top panel refers to estimates obtained by Algorithm 2 enhanced by cutoff selection with base cutoff $R = 100$, while the bottom panel refers to estimates obtained by the same algorithm with base cutoff $R = 200$. A bias towards coverage under-estimation can be observed, as well as a positive effect of the higher base cutoff on estimation precision.

Table 1 shows average runtimes of ReCovEr and Django. Table 2 shows average runtimes of Django and ReCovEr on artificial graph data with small-world topology generated by Algorithm 5. In this case, the graphs underlying the hypotheses had 15 vertices and their connectivity was $k = 4$. The graphs underlying the examples had 100 vertices and connectivity $k = 20$. A dramatic speedup from Django's runtime is exhibited in both cases.

Note that there is no immediate reason to avoid the under-estimation bias because coverage is usually tested on two example sets (positive and negative). The two results are usually subtracted thus (mostly) canceling the bias. Whether the observed estimation variance is tolerable for the task of clause *ranking* usual in inductive logic programming is the subject of the experiments in the next section.

Algorithm	Avg. Time [s]
ReCovEr, $R = 100$	6.7
ReCovEr, $R = 200$	12.5
Django	483.2

ReCovEr, $R = 200$	16.3
Django	519.8

Table 2. Average coverage test runtimes for the configuration with small world graph data.

5.3. Experiments with Real-World Data

In order to assess performance in conditions of a real-life learning setting, we decided not to generate clauses entirely randomly. Our intention was to simulate general principles of clause production in an inductive logic programming system, while avoiding an overfit to a specific clause search strategy (which would e.g. be a result of adhering to a specific heuristic function for selecting literals). Thus we developed a simple relational learner, which we use for further experiments with ReCovEr. The learner (Algorithm 3) is a randomized variation of a specific-to-general beam search. It starts with the most specific clause $\perp$ and at each search step, it generates at least $n \cdot |Beam|$ new hypotheses by removing random subsets of literals from the hypotheses already present in $Beam$. The output of the algorithm is one best clause, which is why we assess its quality through precision and recall.

Algorithm 3 $Learner(\perp, p, BeamSize, Tries)$: A Clause Learner

Input: Most specific clause $\perp$, Real numbers p, Integers $BeamSize$, $MaxSearched$

$Beam \leftarrow \{\perp\}$
$BestClause \leftarrow \perp$
repeat
  $Candidates \leftarrow Beam$
  for $\forall h_i \in Beam$ **do**
    for $i = 1 \ldots BeamSize$ **do**
      $GenerateClause(h_i)$
      $C \leftarrow$ connected components of c
      Evaluate each $c_i \in C$
      $Candidates \leftarrow candidates \cup C$
    end for
  end for
  for $\forall h \in Candidates$ such that h is estimated to be better than $BestClause$ **do**
    if h is shown to be better than $BestClause$ by a deterministic subsumption algorithm **then**
      $BestClause \leftarrow h$
    end if
  end for
  Choose $BeamSize$ best hypotheses from $Candidates$ and add them to $Beam$
  $Explored \leftarrow Explored + 1$
until $Beam = \{\}$ or $Explored = Tries$

The first set of experiments, which we have conducted with Algorithm 3, deals with the Mutagenesis dataset (Srinivasan et al., 1996). This dataset consists of descriptions of 188 organic molecules, which are marked according to their mutagenicity. In our experiments, we used only the information about atom-bond relationships and about types of atoms. We did not consider numerical parameters such as *lumo* or *logp*. Our relational-logic representation of these molecules consisted of ternary literals for atomic bonds $bond(at1, at2, bondType)$, unary literals representing types of particular bonds and unary literals for atom types. We have considered three variants of relational logic description of the molecules, with growing complexity (size of examples). The first version **Muta-v1** uses a naive representation. Here, each molecular bond is represented by a single literal $bond(at1, at2, bondType)$, thus imposing a bond orientation (atom order) chosen at random. The second source of imprecision of this representation is that two variables in a clause may represent the same (chemical) atom, which does not make intuitive sense. The second version **Muta-v2** deals with the first source of imprecision, as it represents every atomic bond with a pair of literals $bond(at1, at2, bondType)$ and $bond(at2, at1, bondType)$. The third version **Muta-v3** solves the second source of imprecision by adding literals $different(a, b)$ for all pairs of atom-representing constants a, b.

The second set of experiments pertains to class-labeled CAD data (product structures) described in (Žáková

et al., 2007), consisting of 96 CAD examples each containing several hundreds of first-order literals.

The main observation provided by the experiments is that ReCovEr becomes quickly superior to Django as the example size grows, whereas the two algorithms do not significantly differ in terms of the training-set[1] accuracy of the discovered clauses. It is interesting to note that Django's poor runtime performance on the learning tasks with large examples (**CAD** data and **Muta-v2**) was often due to occasional subsumption cases. Clearly, this is a manifestation of heavy tails present in Django's runtime distribution. Unlike Django, ReCovEr was exhibiting steady performance.

Dataset	ReCovEr [s]	**Django** [s]
Muta-v1	42	29
Muta-v2	513	1627
Muta-v3	1695	>5h
CAD	121	>2h

Table 3. Average runtimes of the learner (Algorithm 3, $p = 0.75$, $Tries = 10$) for real-world datasets.

Dataset	**Avg. Precision**	**Avg. Recall**
Muta-v1	0.84	0.61
Muta-v2	0.81	0.65
Muta-v3	0.83	0.84
CAD	0.92	0.7

Table 4. Quality of learned hypotheses for ReCovEr

Dataset	**Avg. Precision**	**Avg. Recall**
Muta-v1	0.86	0.6
Muta-v2	0.82	0.65
Muta-v3	n.a.	n.a.
CAD	n.a.	n.a.

Table 5. Quality of learned hypotheses for Django

6. Conclusions

In this paper, we have introduced ReCovEr, an algorithm exploiting restarts for a maximum-likelihood based estimation of clause coverage. ReCovEr avoids heavy tails as well as laborious proving of certain unsatisfiable subsumption instances. We have shown that ReCovEr provides favorable runtimes while achieving reasonable precision, which is illustrated by experiments on synthetic graph data and on real-life data from organic chemistry and engineering. In future work we mainly want to develop theoretical bounds for ReCovEr's estimation precision.

Abstract

This paper is concerned with the generalization ability of learning to rank algorithms for information retrieval (IR). We point out that the key for addressing the learning problem is to look at it from the viewpoint of *query*. We define a number of new concepts, including query-level loss, query-level risk, and query-level stability. We then analyze the generalization ability of learning to rank algorithms by giving query-level generalization bounds to them using query-level stability as a tool. Such an analysis is very helpful for us to derive more advanced algorithms for IR. We apply the proposed theory to the existing algorithms of Ranking SVM and IRSVM. Experimental results on the two algorithms verify the correctness of the theoretical analysis.

1. Introduction

Recently, learning to rank has gained increasing attention in machine learning and information retrieval (IR). When applied to IR, learning to rank is a task as follows. Given a set of training queries, their associated documents, and the corresponding relevance judgments, a ranking model is created which best represents the relevance of documents with respect to queries. When a user submits a query to the IR system, the trained model assigns a score to each document associated with the query, sorts the documents based on their scores, and presents the top ranked documents to the user. Average ranking accuracy over a large number of queries is usually used to evaluate the effectiveness of a ranking model. Therefore, from the application's perspective, both training and evaluation should be conducted at query level.

Many learning to rank algorithms have been proposed in recent years. Examples include the pointwise ranking algorithms like MCRank (Li et al., 2007), the pairwise ranking algorithms like Ranking SVM (Herbrich et al., 1999) and RankBoost (Freund et al., 2003), and the listwise ranking algorithms like ListNet (Cao et al., 2007). Analysis on the algorithms in the light of statistical learning theory, however, was not sufficient, particularly that on the generalization ability of the proposed algorithms. The pointwise and pairwise approaches transform the ranking problem to classification or regression, and thus existing theory on classification and regression can be applied. However, it deviates from the direction of enhancing ranking accuracy at query level. Furthermore, the listwise approach lacks of analysis on generalization ability.

In this paper, we investigate the generalization ability of learning to rank algorithms, in particular from the viewpoint of query-level training and evaluation.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.
*The work was performed when the first and the third authors were interns at Microsoft Research Asia.

We propose a new probabilistic formulation of learning to rank for IR. The formulation can naturally represent the pointwise, pairwise and listwise approaches in a unified framework. Within the framework, we introduce the concepts of query-level loss, query-level risk, and particularly query-level stability. Query-level stability measures whether the output of a learning algorithm changes largely with small changes in the training queries. With query-level stability as a tool we can conduct analysis on query-level generalization bounds of learning algorithms. A query-level generalization bound indicates how well one can enhance the expected ranking accuracy (corresponding to the expected risk) by enhancing the average ranking accuracy in training (corresponding to the empirical risk).

We take the algorithms of Ranking SVM (Joachims, 2002; Herbrich et al., 1999) and IRSVM (Cao et al., 2006; Qin et al., 2007) as examples, and apply the proposed theory to them. Our theoretical result shows that the query-level generalization bound of Ranking SVM is not reasonably good, mainly because Ranking SVM is trained at document pair level, not query level. Furthermore, IRSVM does have a better generalization bound than Ranking SVM, due to its stronger query-level stability. We also conducted experiments and our experimental results agree with the theoretical findings.

The contributions of this paper are listed as follows. (1) A proposal on conducting analysis on learning to rank algorithms at query level is made. (2) A new probabilistic formulation of learning to rank is proposed. (3) A new methodology for analyzing generalization ability of learning to rank algorithms on the basis of query-level stability is proposed. (4) The proposed theory is applied to learning to rank algorithms of Ranking SVM and IRSVM. The correctness of the theory has been verified by experiments.

2. Previous Work

2.1. Ranking in IR

Ranking is a central issue for IR. Many methods for creating ranking models have been proposed, including heuristics and learning based methods, (Baeza-Yates & Ribeiro-Neto, 1999; Herbrich et al., 1999; Joachims, 2002; Freund et al., 2003; Burges et al., 2005; Cao et al., 2007). Typically a ranking model is defined as a function of features based on query-document pair, and is learned with training data containing a number of queries, associated documents, and corresponding relevance judgments. Measures for evaluating the performance of a ranking model, such as Precision, MAP (Baeza-Yates & Ribeiro-Neto, 1999), and NDCG (Järvelin & Kekäläinen, 2002) have been defined and used. All the measures are query-based; if the evaluation measure for a query q is $EV(q)$, then the averaged $EV(q)$ on a number of queries is used. From the application's perspective, both training and testing in learning to rank should be conducted at query level.

2.2. Learning to Rank

So far learning to rank has been addressed by the pointwise, pairwise, and listwise approaches. In the pointwise approach (Li et al., 2007), ranking is transformed to regression or classification, and the loss function in learning is defined as a function of a single document. In the pairwise approach (Herbrich et al., 1999; Joachims, 2002; Freund et al., 2003; Cao et al., 2006), ranking is transformed to pairwise classification, and the loss function is defined on a document pair. In the listwise approach (Cao et al., 2007; Qin et al., 2007), document lists are viewed as learning instances and the loss function is defined on that basis.

Although many learning methods have been proposed, theoretical investigations on them were not sufficient. Since training and testing should be conducted at query level, studies on query-level generalization ability of learning algorithms are really needed. Unfortunately, it was missing in the previous work.

2.3. Stability Theory

The notion of stability (Devroye & Wagner, 1979) has been proposed for analyzing the generalization bounds of learning algorithms.

Bousquet et al. (Bousquet & Elisseeff, 2002) propose the theory of uniform leave-one-out stability. Based on it, the generalization bounds of classification algorithms such as Support Vector Machines (SVM) can be derived. Agarwal et al. (Agarwal & Niyogi, 2005) apply the stability tool to bipartite ranking.

We can apply the existing stability theory to get document level and document pair level generalization bounds. However, they may be not suitable for the task of IR. In this paper, we propose query-level stability and reveal the relation between query-level stability and query-level generalization bound.

3. Probabilistic Formulation for Ranking

As explained in Section 2, ranking in IR is evaluated at query level. Therefore, to design and evaluate a learning to rank algorithm, we should also look at it from

the query perspective. To this end, we give a novel probabilistic formulation of ranking for IR, which contains queries and their *associates* (documents, document pairs, or document sets) in two layers. We then introduce the notions of query-level loss and query-level risk.

Assume that query q is a random sample from the query space $\mathcal{Q}$ according to a probability distribution $P_{\mathcal{Q}}$. For query q, an associate $\omega^{(q)}$ and its ground-truth $g(\omega^{(q)})$ are sampled from space $\Omega \times \mathcal{G}$ according to a joint probability distribution D_q, where Ω is the space of associates and $\mathcal{G}$ is the space of ground truth. Here the associate $\omega^{(q)}$ can be a single document, a pair of documents, or a set of documents, and correspondingly the ground truth $g(\omega^{(q)})$ can be a relevance score (or class label), an order on a pair of documents, or a permutation (list) of documents. Let $l(f; \omega^{(q)}, g(\omega^{(q)}))$ denote a loss (referred to as *associate-level loss*) defined on $(\omega^{(q)}, g(\omega^{(q)}))$ and a ranking function f.

Expected query-level loss is defined as:

$$L(f;q) = \int_{\Omega \times \mathcal{G}} l(f; \omega^{(q)}, g(\omega^{(q)}))\, D_q(d\omega^{(q)}, dg(\omega^{(q)})).$$

Empirical query-level loss is defined as:

$$\hat{L}(f;q) = \frac{1}{n_q} \sum_{j=1}^{n_q} l(f; \omega_j^{(q)}, g(\omega_j^{(q)})),$$

where $(\omega_j^{(q)}, g(\omega_j^{(q)})), j = 1 \cdots, n_q$ stands for n_q associates of q, which are sampled i.i.d. according to D_q. The empirical query-level loss can be an estimate of the expected query-level loss. It can be proven that the estimation is consistent.

The goal of learning to rank is to select the ranking function f which can minimize the *expected query-level risk* defined as:

$$R_l(f) = E_{\mathcal{Q}} L(f;q) = \int_{\mathcal{Q}} L(f;q)\, P_{\mathcal{Q}}(dq). \tag{1}$$

In practice, $P_{\mathcal{Q}}$ is unknown. What we have are the training samples $(q_1, S_1), \cdots, (q_r, S_r)$, where $S_i = \{(\omega_1^{(i)}, g(\omega_1^{(i)})), \cdots, (\omega_{n_i}^{(i)}, g(\omega_{n_i}^{(i)}))\}, i = 1, \cdots, r$, and n_i is the number of associates for query q_i. Here $q_1, \cdots, q_r$ can be viewed as data sampled *i.i.d.* according to $P_{\mathcal{Q}}$, and $(\omega_j^{(i)}, g(\omega_j^{(i)}))$ as data sampled *i.i.d.* according to $D_{q_i}, j = 1, \cdots, n_i, i = 1, \cdots, r$.

Empirical query-level risk is defined as:

$$\widehat{R_l}(f) = \frac{1}{r} \sum_{i=1}^{r} \hat{L}(f; q_i). \tag{2}$$

The empirical query-level risk is an estimate of the expected query-level risk. It can be proven that the estimation is consistent.

This probabilistic formulation can cover most of existing learning to rank algorithms. If we let the associate to be a single document, a document pair, or a document set, we can respectively define pointwise, pairwise, or listwise losses, and develop pointwise, pairwise, or listwise approaches to learning to rank.

(a) *Pointwise Case*

Let $\mathcal{D}$ denote the document space. We use a feature mapping function $\phi : \mathcal{Q} \times \mathcal{D} \to \mathcal{X}(= R^d)$ to create a d-dimensional feature vector for each query-document pair. For each query q, suppose that the feature vector of a document is $x^{(q)}$ and its relevance score (or class label) is $y^{(q)}$, then $(x^{(q)}, y^{(q)})$ can be viewed as a random sample from $\mathcal{X} \times R$ according to a probability distribution D_q. If $l(f; x^{(q)}, y^{(q)})$ is a pointwise loss (square loss for example), then the expected query-level loss becomes:

$$L(f;q) = \int_{\mathcal{X} \times R} l\left(f; x^{(q)}, y^{(q)}\right)\, D_q\left(dx^{(q)}, dy^{(q)}\right).$$

Given training samples $(q_1, S_1), \cdots, (q_r, S_r)$, where $S_i = \{(x_1^{(i)}, y_1^{(i)}), \cdots, (x_{n_i}^{(i)}, y_{n_i}^{(i)})\}, i = 1, \cdots, r$, the empirical query-level loss of query $q_i, (i = 1, \cdots, r)$ turns out to be:

$$\hat{L}(f;q_i) = \frac{1}{n_i} \sum_{j=1}^{n_i} l(f; x_j^{(i)}, y_j^{(i)}).$$

(b) *Pairwise Case*

For each query q, $z^{(q)} = (x_1^{(q)}, x_2^{(q)})$ stands for a document pair associated with it. Moreover, $y^{(q)} = 1$ if $x_1^{(q)}$ is ranked above $x_2^{(q)}$, $y^{(q)} = -1$ otherwise. Let $\mathcal{Y} = \{1, -1\}$. $(x_1^{(q)}, x_2^{(q)}, y^{(q)})$ can be viewed as a random sample from $\mathcal{X}^2 \times \mathcal{Y}$ according to a probability distribution D_q. If $l(f; z^{(q)}, y^{(q)})$ is a pairwise loss (hinge loss for example, (Herbrich et al., 1999)), then the expected query-level loss becomes:

$$L(q) = \int_{\mathcal{X}^2 \times \mathcal{Y}} l\left(f; z^{(q)}, y^{(q)}\right)\, D_q\left(dz^{(q)}, dy^{(q)}\right).$$

Given training samples $(q_1, S_1), \cdots, (q_r, S_r)$, where $S_i = \{(z_1^{(i)}, y_1^{(i)}), \cdots, (z_{n_i}^{(i)}, y_{n_i}^{(i)})\}, i = 1, \cdots, r$, the empirical query-level loss of query $q_i, (i = 1, \cdots, r)$ turns out to be:

$$\hat{L}(f;q_i) = \frac{1}{n_i} \sum_{j=1}^{n_i} l(f; z_j^{(i)}, y_j^{(i)}).$$

(c) *Listwise Case*

For each query q, let $s^{(q)}$ denote a set of m documents associated with it, $\pi(s^{(q)}) \in \Pi$ denote a permutation of documents in $s^{(q)}$ according to their relevance degrees to the query, where Π is the space of all permutations

on m documents. $(s^{(q)}, \pi(s^{(q)}))$ can be viewed as a random sample from $\mathcal{X}^m \times \Pi$ according to a probability distribution D_q. If $l(f; s^{(q)}, \pi(s^{(q)}))$ is a listwise loss (cross entropy loss for example, (Cao et al., 2007)), then the expected query-level loss becomes:

$$L(q) = \int_{\mathcal{X}^m \times \Pi} l\left(f; s^{(q)}, \pi\left(s^{(q)}\right)\right) D_q\left(ds^{(q)}, d\pi\left(s^{(q)}\right)\right).$$

Given training samples $(q_1, S_1), \cdots, (q_r, S_r)$, where $S_i = \{(s_1^{(i)}, \pi(s_1^{(i)})), \cdots, (s_{n_i}^{(i)}, \pi(s_{n_i}^{(i)}))\}, i = 1, \cdots, r$, the empirical query-level loss of query $q_i, (i = 1, \cdots, r)$ turns out to be:

$$\hat{L}(f, q_i) = \frac{1}{n_i} \sum_{j=1}^{n_i} l(f; s_j^{(i)}, \pi(s_j^{(i)})).$$

4. Stability Theory For Query-level Generalization Bound Analysis

Based on the probabilistic formulation, we propose a novel concept named query-level stability. We further discuss how to use query-level stability to analyze the generalization ability of a learning to rank algorithm.

First, we give a definition to uniform leave-one-query-out associate-level loss stability. The stability of a learning algorithm represents the degree of change in the loss of prediction when randomly removing a query and its associates from the training data.

Definition 1. *Let $\mathcal{A}$ be a learning to rank algorithm, $\{(q_i, S_i), i = 1, \cdots, r\}$ be the training set, l be the associate-level loss function, and τ be a function mapping an integer to a real number. We say that $\mathcal{A}$ has uniform leave-one-query-out associate-level loss stability with coefficient τ with respect to l, if $\forall q_j \in \mathcal{Q}, S_j \in (\Omega \times \mathcal{G})^{n_j}, j = 1, \cdots, r, q \in \mathcal{Q}, (\omega^{(q)}, g(\omega^{(q)})) \in \Omega \times \mathcal{G}$, the following inequality holds:*

$$\left| l(f_{\{(q_i,S_i)\}_{i=1}^r}, \omega^{(q)}, g(\omega^{(q)})) - l(f_{\{(q_i,S_i)\}_{i=1,i\neq j}^r}, \omega^{(q)}, g(\omega^{(q)})) \right| \leq \tau(r).$$

Here $\{(q_i, S_i)\}_{i=1,i\neq j}^r$ stands for the samples $(q_1, S_1), \cdots, (q_{j-1}, S_{j-1}), (q_{j+1}, S_{j+1}), \cdots, (q_r, S_r)$, where (q_j, S_j) is deleted. $f_{\{(q_i,S_i)\}_{i=1}^r}$ stands for the ranking function learned from $\{(q_i, S_i)\}_{i=1}^r$. We will use the notations hereafter.

With the definition, we can obtain the following lemma. It states that, if an algorithm has uniform leave-one-query-out associate-level loss stability, it will be stable in terms of expected query-level loss and empirical query-level loss. For ease of explanation, we simply call the uniform leave-one-query-out associate-level loss stability *query-level stability*.

Lemma 1. *Let $\mathcal{A}$ be a learning to rank algorithm, $\{(q_i, S_i), i = 1, \cdots, r\}$ be the training set, and l be the associate-level loss function. If $\mathcal{A}$ has leave-one-query-out associate-level loss stability with coefficient τ with respect to l, then the following inequalities hold:*

$$\left| L(f_{\{(q_i,S_i)\}_{i=1}^r}, q) - L(f_{\{(q_i,S_i)\}_{i=1,i\neq j}^r}, q) \right| \leq \tau(r),$$
$$\left| \hat{L}(f_{\{(q_i,S_i)\}_{i=1}^r}, q) - \hat{L}(f_{\{(q_i,S_i)\}_{i=1,i\neq j}^r}, q) \right| \leq \tau(r).$$

Based on the concept of query-level stability, we can derive a query-level generalization bound, as shown in Theorem 1. The theorem states that if an algorithm has query-level stability, then with high probability over the samples, the expected query-level risk can be bounded by the empirical risk and a term which depends on the query number and parameters of the algorithm. Furthermore, the theorem quantifies the expected loss on new queries, which is exactly what we mean by query-level generalization.

Theorem 1. *Let $\mathcal{A}$ be a learning to rank algorithm, $(q_1, S_1), \cdots, (q_r, S_r)$ be r training samples, and let l be the associate-level loss function. If (1) $\forall (q_1, S_1), \cdots, (q_r, S_r), q \in \mathcal{Q}, (\omega^{(q)}, g\left(\omega^{(q)}\right) \in \Omega \times \mathcal{G}$, $\left| l\left(f_{(q_i,S_i)_{i=1}^r}, \omega^{(q)}, g\left(\omega^{(q)}\right)\right)\right| \leq B$, (2) $\mathcal{A}$ has query-level stability with coefficient τ, then $\forall \delta \in (0, 1)$ with probability at least $1 - \delta$ over the samples of $\{(q_i, S_i)\}_{i=1}^r$ in the product space $\prod_{i=1}^r \{\mathcal{Q} \times (\Omega \times \mathcal{G})^\infty\}$, the following inequality holds:*

$$R_l\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) \leq \widehat{R_l}\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) + 2\tau(r) + (4r\tau(r) + B)\sqrt{\frac{\ln\frac{1}{\delta}}{2r}}.$$

Proof. For clarity of the proof, we first give the following definitions:

$$\rho(\{(q_i, S_i)\}_{i=1}^r) \triangleq R_l\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) - \widehat{R_l}\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right),$$
$$\int_{\Omega_1} \triangleq \int_{\mathcal{Q}} \int_{(\Omega\times\mathcal{G})^{n_1}} \cdots \int_{\mathcal{Q}} \int_{(\Omega\times\mathcal{G})^{n_r}}, \int_{\Omega_2} \triangleq \int_{\mathcal{Q}} \int_{\Omega\times\mathcal{G}},$$

$$P_1(d\omega) \triangleq D_{q^r}^{n_r}(dS_r) P_{\mathcal{Q}}(dq_r) \cdots D_{q^1}^{n_1}(dS_1) P_{\mathcal{Q}}(dq_1),$$
$$P_2(d\omega') \triangleq D_q(d\omega^{(q)}, dg(w^{(q)})) P_{\mathcal{Q}}(dq).$$

We then prove the theorem in two steps.

1) *Get the bound of*

$$\left| \rho(\{(q_i, S_i)\}_{i=1}^r) - \int_{\Omega_1} \rho(\{(q_i, S_i)\}_{i=1}^r) P_1(d\omega) \right|.$$

For this purpose, we get the upper bound of the following term first:

$$\left| \rho(\{(q_i, S_i)\}_{i=1}^r) - \rho(\{(q_i, S_i)\}_{i=1}^{r,j,q_j'}) \right|$$

where $\{(q_i,S_i)\}_{i=1}^{r,j,q_j'}$ means that query (q_j,S_j) is changed for another query (q_j',S_j'), where S_j' refers to $(w_1^{(j')},g(w_1^{(j')})),\cdots,(w_{n_j'},g(w_{n_j'}^{(j')}))$.

To utilize the query-level stability, we divide ρ into two terms: $\rho=\rho_1-\rho_2$, and discuss either of them separately, as follows.

$$\begin{aligned}&\rho_1(\{(q_i,S_i)\}_{i=1}^r)\triangleq R_l\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right)\\&=\int_{\Omega_2}l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega^{(q)},g(\omega^{(q)}))P_2(d\omega^{'}).\\&\rho_2(\{(q_i,S_i)\}_{i=1}^r)\triangleq \widehat{R_l}\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right)\\&=\frac{1}{r}\sum_{i=1}^{r}\frac{1}{n_i}\sum_{j=1}^{n_i}l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega_j^{(i)},g(\omega_j^{(i)})).\end{aligned}$$

Based on query-level stability, we can obtain that $\forall q_j\in\mathcal{Q},S_j\in(\Omega\times\mathcal{G})^{n_j},j=1,\cdots,r,q,q_j'\in\mathcal{Q},S_j'\in\{\mathcal{Q}\times(\Pi\times\mathcal{G})^{n_j'}\},(\omega^{(q)},g(\omega^{(q)}))\in\Omega\times\mathcal{G}$, the following inequality holds:

$$\begin{aligned}&\Big|l(f_{\{(q_i,S_i)\}_{i=1}^r},\omega^{(q)},g(\omega^{(q)}))\\&-l(f_{\{(q_i,S_i)\}_{i=1}^{r,j,q_j'}},\omega^{(q)},g(\omega^{(q)}))\Big|\le 2\tau(r).\end{aligned}\tag{3}$$

With (3), as ρ_1 is an integral function, the following inequality holds:

$$|\rho_1(\{(q_i,S_i)\}_{i=1}^r)-\rho_1(\{(q_i,S_i)\}_{i=1}^{r,j,q_j'})|\le 2\tau(r).\tag{4}$$

As for ρ_2, we have

$$\begin{aligned}&|\rho_2(\{(q_i,S_i)\}_{i=1}^r)-\rho_2(\{(q_i,S_i)\}_{i=1}^{r,j,q_j'})|\\&\le\frac{1}{r}\sum_{i=1,i\neq j}^{r}\frac{1}{n_i}\sum_{j=1}^{n_i}|l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega_j^{(i)},g(\omega_j^{(i)}))\\&-l(f_{\{(q_i,S_i)\}_{i=1}^{r,j,q_j'}};\omega_j^{(i)},g(\omega_j^{(i)}))|\\&+\frac{1}{r}|\frac{1}{n_j}\sum_{s=1}^{n_j}l(f_{\{(q_i,S_i)\}_{i=1}^{n_j}};\omega_s^{(j)},g(\omega_s^{(j)}))\\&-\frac{1}{n_j'}\sum_{s=1}^{n_j'}l(f_{\{(q_i,S_i)\}_{i=1}^{r,j,q_j'}};\omega_s^{(j')},g(\omega_s^{(j')}))|\\&\le 2\tau(r)+\frac{B}{r}.\end{aligned}\tag{5}$$

By jointly considering (4) and (5), we obtain:

$$|\rho(\{(q_i,S_i)\}_{i=1}^r)-\rho(\{(q_i,S_i)\}_{i=1}^{r,j,q_j'})|\le 4\tau(r)+\frac{B}{r}.$$

Based on McDiarmid's inequality(McDiarmid, 1989), with probability at least $1-\delta$ over the samples of $\{(q_i,S_i)\}_{i=1}^r$ in the product space $\prod_{i=1}^r\{\mathcal{Q}\times(\Omega\times\mathcal{G})^\infty\}$, we have

$$\begin{aligned}\rho(\{(q_i,S_i)\}_{i=1}^r)\quad&\le\quad\int_{\Omega_1}\rho(\{(q_i,S_i)\}_{i=1}^r)\,P_1(d\omega).\\&+\quad(4r\tau(r)+B)\sqrt{\frac{\ln\frac{1}{\delta}}{2r}}.\end{aligned}\tag{6}$$

2) *Get the bound of* $\left|\int_{\Omega_1}\rho(\{(q_i,S_i)\}_{i=1}^r)\,P_1(d\omega)\right|$

$$\begin{aligned}&\int_{\Omega_1}\rho[\{(q_i,S_i)\}_{i=1}^r]P_1(d\omega)\\&=\int_{\Omega_1}\int_{\Omega_2}[l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega^{(q)},g(\omega^{(q)}))]\,P_2(d\omega^{'})\,P_1(d\omega)\\&-\int_{\Omega_1}l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega_j^{(i)},g(\omega_j^{(i)}))\,P_1(d\omega)\\&=\int_{\Omega}\int_{\Omega_2}[l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega^{(q)},g(\omega^{(q)}))\\&-l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega_j^{(i)},g(\omega_j^{(i)}))]\,P_2(d\omega^{'})\,P_1(d\omega).\\&=\int_{\Omega_1}\int_{\Omega_2}[l(f_{\{(q_i,S_i)\}_{i=1}^r};\omega^{(q)},g(\omega^{(q)}))\\&-l(f_{\{(q_i,S_i)\}_{i=1}^{r,i,q}};\omega_j^{(q)},g(\omega_j^{(q)}))]\,P_2(d\omega^{'})\,P_1(d\omega).\end{aligned}$$

The reason that the last equality holds is as follows. Because the integral is conducted over all of the samples, and the samples are *i.i.d.*, we can change the ith query in the training set for $(q,\omega^{(q)},g(\omega^{(q)}))$. Then by further using (3), we have:

$$\left|\int_{\Omega_1}\rho[\{(q_i,S_i)\}_{i=1}^r]P_1(d\omega)\right|\le 2\tau(r).\tag{7}$$

Merging Eq. (6) and (7) yields the inequality in the theorem. □

5. Case Study

Without loss of generality, we take existing algorithms of Ranking SVM (Joachims, 2002; Herbrich et al., 1999) and IRSVM (Cao et al., 2006; Qin et al., 2007) as examples to show how to analyze the query-level generalization bound of an algorithm, using the tool of query-level stability. Both of the two algorithms belong to the pariwise case of our probabilistic formulation. It should be noted that the framework is neither limited to these two algorithms nor to the pair-wise case, we leave the discussions on other algorithms or other approaches to our future work.

5.1. Generalization Bound of Ranking SVM

Ranking SVM is widely used in ranking for IR, which views document pair as associate of the query and minimizes:

$$\min_{f\in\mathcal{F}}\frac{1}{n}\sum_{i=1}^{n}l_h(f;z_i,y_i)+\lambda\|f\|_K^2,\tag{8}$$

where $l_h(f;z_i,y_i)$ is the hinge loss, and K is a kernel function in the Reproducing Kernel Hilbert Space (RKHS).

Using the conventional stability theory (Bousquet & Elisseeff, 2002), we can get the following lemma which shows the query-level stability of Ranking SVM.

Lemma 2. *If* $\forall x \in \mathcal{X}, K(x,x) \leq \kappa^2 < \infty$, *then Ranking SVM has query-level stability with coefficient* $\tau(r) = \frac{4\kappa^2}{\lambda r} \times \max_{\forall n_i, S_i} \frac{n_i}{\frac{1}{r}\sum_{i=1}^{r} n_i}$.

As for this lemma, we have the following discussions. (1) When r approaches infinity, suppose the mean and variance of the distribution of n_q are μ and σ^2 respectively. Then by the Law of Large Numbers and Chebyshev's inequality, $\forall 0 < \delta < 1, \forall \epsilon > 0, \exists R(\epsilon)$, if $r > R(\epsilon)$, with probability at least $1-\delta$, the following inequality holds:

$$max_{\forall n_i, S_i} \frac{n_i}{\frac{1}{r}\sum_{i=1}^{r} n_i} \leq \frac{1 + \frac{\sigma}{\mu\sqrt{\frac{\delta}{r}}}}{1 - \frac{\varepsilon}{\mu}}.$$

Therefore, $\tau(r) \leq \frac{4\kappa^2}{\lambda r} \frac{1+\frac{\sigma}{\mu\sqrt{\frac{\delta}{r}}}}{1-\frac{\varepsilon}{\mu}}$. That is, $\tau(r)$ will approach zero, with a convergence rate of $O(\frac{1}{\sqrt{r}})$, when r goes to infinity.

(2) When r is finite (which is the case in practice), we have no reasonable statistical estimation of the term $\max_{\forall n_i, S_i} \frac{n_i}{\frac{1}{r}\sum_{i=1}^{r} n_i}$. As a result, we can only get a loose bound for $\tau(r)$ as $\frac{4\kappa^2}{\lambda}$. That is, when r increases but is still finite, $\tau(r)$ does not necessarily decrease.

Based on the above lemma, we can further derive the generalization bound of Ranking SVM. In particular, as the function $f_{\{(q_i,S_i)\}_{i=1}^r}$ is learned from the training samples $(q_1, S_1), \cdots, (q_r, S_r)$, there is a constant C, such that, $\forall (q_1, S_1), \cdots, (q_r, S_r)$, $\left\| f_{\{(q_i,S_i)\}_{i=1}^r} \right\|_K \leq C$. Then, $\forall (q_1, S_1), \cdots, (q_r, S_r), z \in \mathcal{Z}, y \in \mathcal{Y}$, $l_h\left(f_{\{(q_i,S_i)\}_{i=1}^r}, z, y\right) \leq 1 + 2C\kappa$. By further considering Theorem 1, we obtain the following theorems.

Theorem 2. *If* $\forall x \in \mathcal{X}, K(x,x) \leq \kappa^2 < \infty$, *then for Ranking SVM,* $\forall \delta \in (0,1), \forall \epsilon > 0, \exists R(\epsilon)$, *if* $r > R(\epsilon)$, *then with probability at least* $1-2\delta$ *over the samples of* $\{(q_i, S_i)\}_{i=1}^r$ *in the product space* $\prod_{i=1}^r \{\mathcal{Q} \times (\mathcal{X} \times \mathcal{X} \times \mathcal{Y})^\infty\}$, *we have:*

$$R_l\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) \leq \widehat{R_l}\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) + \frac{8\kappa^2}{\lambda r} \frac{1+\frac{\sigma}{\mu\sqrt{\frac{\delta}{r}}}}{1-\frac{\varepsilon}{\mu}} + \left(\frac{16\kappa^2 \frac{1+\frac{\sigma}{\mu\sqrt{\frac{\delta}{r}}}}{1-\frac{\varepsilon}{\mu}} + \lambda(1+2C\kappa)}{\lambda}\right)\sqrt{\frac{\ln\frac{1}{\delta}}{2r}}.$$

Theorem 3. *If* $\forall x \in \mathcal{X}, K(x,x) \leq \kappa^2 < \infty$ *and we have no constraint on* r, *then for Ranking SVM,* $\forall \delta \in (0,1)$, *with probability at least* $1-\delta$ *over the samples of* $\{(q_i, S_i)\}_{i=1}^r$ *in the product space* $\prod_{i=1}^r \{\mathcal{Q} \times (\mathcal{X} \times \mathcal{X} \times \mathcal{Y})^\infty\}$, *we only have:*

$$R_l\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) \leq \widehat{R_l}\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) + \frac{8\kappa^2}{\lambda} + \left(\frac{16r\kappa^2 + \lambda(1+2C\kappa)}{\lambda}\right)\sqrt{\frac{\ln\frac{1}{\delta}}{2r}}.$$

Theorem 2 states that when the number of training queries tends to be infinity, with high probability the empirical query-level risk of Ranking SVM will converge to its expected query-level risk. However, when the number of training queries is finite, the expected query-level risk and empirical query-level risk are not necessarily close to each other, and the bound in Theorem 3 quantifies the difference, which is an increasing function of the number of training queries.

5.2. Generalization Bound of IRSVM

In IR application, the numbers of document pairs associated with different queries vary largely (See LETOR or other public dataset). In consideration of this, IRSVM, studied in (Cao et al., 2006) and (Qin et al., 2007), is an adaptive version of Ranking SVM to the IR applications, which minimizes:

$$\min_{f \in \mathcal{F}} \frac{1}{r}\sum_{i=1}^{r} \frac{1}{n_i}\sum_{j=1}^{n_i} l_h(f; z_j^{(i)}, y_j^{(i)}) + \| f \|_K^2 . \qquad (9)$$

We can prove the query-level stability of IRSVM as shown in Lemma 3. Due to space limitations, we omit the proof.

Lemma 3. *If* $\forall x \in \mathcal{X}, K(x,x) \leq \kappa^2 < \infty$, *then IRSVM has query-level stability* $\tau(r) = \frac{4\kappa^2}{\lambda r}$.

With a similar analysis to that for Ranking SVM, we obtain the following theorem.

Theorem 4. *If* $\forall x \in \mathcal{X}, K(x,x) \leq \kappa^2 < \infty$, *then for IRSVM,* $\forall \delta \in (0,1)$, *with probability at least* $1-\delta$ *over the samples of* $\{(q_i, S_i)\}_{i=1}^r$ *in the product space* $\prod_{i=1}^r \{\mathcal{Q} \times (\mathcal{X} \times \mathcal{X} \times \mathcal{Y})^\infty\}$, *we have:*

$$R_l\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) \leq \widehat{R_{l_h}}\left(f_{\{(q_i,S_i)\}_{i=1}^r}\right) + \frac{8\kappa^2}{\lambda r} + \frac{16\kappa^2 + \lambda(1+2C\kappa)}{\lambda}\sqrt{\frac{\ln\frac{1}{\delta}}{2r}}.$$

The theorem states that when the number of training queries tends to be infinity, with high probability the empirical query-level risk of IRSVM will converge to its expected query-level risk. When the number of queries is finite, the bound in the theorem quantifies the difference between the two risks, which is a decreasing function of the number of training queries.

Remark 1. *By comparing Theorem 2 and Theorem 4, we can find that the convergence rates of the empirical query-level risk to the expected query-level risk for Ranking SVM and IRSVM are the same, i.e.* $O(\frac{1}{\sqrt{r}})$. *However, by comparing Theorem 3 to Theorem 4, we can see that for the case of finite* r, *the bound of IRSVM is much tighter than that of Ranking SVM.*

6. Experiments and Discussion

We conducted experiments on Ranking SVM and IRSVM to verify our theoretical results.

6.1. Query-level Stability

First, we conducted an experiment to compare the stabilities of Ranking SVM and IRSVM. We randomly sampled 1,200 queries from a search engine's data repository, each query associated with hundreds of documents and their relevance labels. There are five labels: "perfect", "excellent", "good", "fair", and "bad". We split the queries into three sets: a training set with 200 queries, a validation set with 500 queries, and a test set with 500 queries (we denote the test set as $\mathcal{T}$). The validation set was used to select the regularization parameter λ for Ranking SVM and IRSVM.

We first trained two ranking models with Ranking SVM and IRSVM, denoted as f_0 and $f_0^{'}$ respectively. Then we randomly deleted one query from the training set, and trained two new models with Ranking SVM and IRSVM, denoted as f_1 and $f_1^{'}$ respectively. We repeated this process 30 times, and created the models $f_1, f_2, \cdots, f_{30}$ an $f_1^{'}, f_2^{'}, \cdots, f_{30}^{'}$. Then on the test set, we compared the associate-level loss for f_0 with that for f_i, and obtained the difference Δ_i for Ranking SVM. Similarly, we computed $\Delta_i^{'}$ for IRSVM.

$$\Delta_i = \max_{q \in \mathcal{T}} \max_{z \in S_q} |l_h(f_0, z^{(q)}, y^{(q)}) - l_h(f_i, z^{(q)}, y^{(q)})|,$$

$$\Delta_i^{'} = \max_{q \in \mathcal{T}} \max_{z \in S_q} |l_h(f_0^{'}, z^{(q)}, y^{(q)}) - l_h(f_i^{'}, z^{(q)}, y^{(q)})|.$$

According to Definition 1, Δ_i can bound from below the query-level stability $\tau(r)(r = 200)$ of Ranking SVM. Similarly, $\Delta_i^{'}$ can bound from below the query-level stability $\tau(r)(r = 200)$ of IRSVM. In this regard, we can compare stabilities of Ranking SVM and IRSVM by comparing Δ_i and $\Delta_i^{'}$.

We list all the 30 values of Δ_i and $\Delta_i^{'}$ in Table 1. From it, we can see that Δ_i is always much larger than $\Delta_i^{'}$. The mean (or maximum) value of Δ_i over the 30 trials is 1.23 (or 4.53). It is about more than ten times higher than the mean (or maximum) value of $\Delta_i^{'}$, which is only 0.12 (or 0.27). Furthermore, the variance of Δ_i (i.e. 0.72) is also larger than that of $\Delta_i^{'}$ (i.e. 0.003). These results indicate that the query-level stability of RankSVM is not so good as that of IRSVM. (Note that Lemmas 2 and 3 hold for any r, the number of training queries. We simply set $r = 200$.)

6.2. Query-level Generalization Bounds

Next, we compared the performances of Ranking SVM and IRSVM, to verify the theoretical results on their query-level generalization bounds.

From Theorems 3 and 4 we can see that the bound for Ranking SVM is much looser than that for IRSVM, especially when the number of training queries r is large but finite. We interpret the result as follow.

The actual empirical risk and expected risk with respect to Ranking SVM are as follows.

$$\widehat{R_{l_h}}(f) = \frac{1}{n} \sum_{i=1}^{n} l_h(f; z^{(i)}, y^{(i)})), n = \sum_{i=1}^{r} n_i.$$

$$R_{l_h}(f) = \int_{\mathcal{X}^2 \times \mathcal{Y}} l_h(f; z, y) P(dz, dy).$$

In the definitions, only document pair but no query appears, and thus we call them the *pair-level risks*. For comparison, we also list the *query-level risks* for the learning to rank problem (See also Section 3) where hinge loss is used as associate-level loss.

$$\widehat{R_{l_h}}(f) = \frac{1}{r} \sum_{i=1}^{r} \frac{1}{n_i} \sum_{j=1}^{n_i} l_h(f; z^{(i)}, y^{(i)}).$$

$$R_{l_h}(f) = \int_{\mathcal{Q}} \int_{\mathcal{X}^2 \times \mathcal{Y}} l_h(f; z^{(q)}, y^{(q)})\, D_q(dz^{(q)}, dy^{(q)})\, P_{\mathcal{Q}}(dq).$$

By comparing the above formulas, we can clearly see that what is optimized in Ranking SVM (i.e. the pair-level risk) is not equal to what should be optimized (i.e. the query-level risks), unless every training query has the same number of document pairs, which is not true in practice. In contrast, it is easy to verify that what is optimized in IRSVM is exactly the query-level risk. Therefore, no surprisingly IRSVM has a better query-level generalization bound.

In summary, the theoretical results indicate that the performance of Ranking SVM on the test set in terms of a query-level measure should not be so good as that of IRSVM. We have verified this through experiments. We tested the ranking performances of Ranking SVM (RankSVM for short) and IRSVM on the test set, in terms of Precision and NDCG. The results are shown in Figure 1. Furthermore, MAP [1] for Ranking SVM is 0.39 and MAP for IRSVM is 0.41. From the results, we can see that IRSVM achieves better ranking performance than RankSVM, in terms of all the query-level measures. This is also consistent with the results reported in (Cao et al., 2006) and (Qin et al., 2007).

7. Conclusions

In this paper, we have studied the generalization ability of learning to rank algorithms for IR. A probabilistic formulation for ranking has been proposed, which covers ranking algorithms belonging to the pointwise,

[1] To compute MAP, we treated "perfect", "excellent" and "good" as relevant, and "fair" and "bad" as irrelevant.

pairwise and listwise approaches. The tool of query-level stability has been developed, which has been further used to analyze the generalization bound of a ranking algorithm. We have applied the tool to two existing ranking algorithms (Ranking SVM and IRSVM) and obtained theoretical results. We have also verified the correctness of the results by experiments.

As far as we know, this is the first work on query-level generalization bound of learning to rank algorithms. There are still many issues to investigate. (1) We have taken SVM based ranking algorithms as examples. We will try to obtain similar results for other algorithms, such as RankBoost. (2) We have focused on the pairwise approach. The proposed formulation for ranking and the tool of query-level stability can also be used to analyze other approaches. (3) It is worth checking whether new learning to rank algorithms can be derived under the guide of the theoretical study.

Modeling Interleaved Hidden Processes

Niels Landwehr NIELS.LANDWEHR@CS.KULEUVEN.BE
Department of Computer Science, Katholieke Universiteit Leuven, Celestijnenlaan 200A 3001 Heverlee, Belgium

Abstract

Hidden Markov models assume that observations in time series data stem from some hidden process that can be compactly represented as a Markov chain. We generalize this model by assuming that the observed data stems from *multiple* hidden processes, whose outputs interleave to form the sequence of observations. Exact inference in this model is NP-hard. However, a tractable and effective inference algorithm is obtained by extending structured approximate inference methods used in factorial hidden Markov models. The proposed model is evaluated in an activity recognition domain, where multiple activities interleave and together generate a stream of sensor observations. It is shown to be more accurate than a standard hidden Markov model in this domain.

1. Introduction

Hidden Markov models (HMMs) are among the most popular approaches for modeling time series data, and have seen widespread application in areas such as speech recognition, bioinformatics, or robotics. They assume that observed data stems from a hidden process which is stationary and Markov. However, in some application domains this single-process model is not appropriate. Consider for instance a log of web server requests, and assume we have no definite knowledge about which request has been issued by which user (e.g. because of proxy use). Clearly, there is no single hidden Markov process that accounts for the sequence of observed requests. Instead, there are multiple processes, one per user, which interleave to generate the sequence of observations. Another example, and the main motivation for the work presented in this paper, is *activity recognition*: the task of inferring a user's current activity from a stream of dense sensor data. In many situations, users switch back and forth between multiple activities, which causes sensor observations associated with the individual activities to interleave in time. The specific scenario considered in this paper is that objects used in activities of daily living are equipped with small RFID tags, which are picked up by a wearable RFID reader whenever a user interacts with the object. The task is to infer the sequence of activities carried out given the observed object interactions. In the light of recent advances in RFID technology, which allow tags to be cheaply mass-produced and readers to be made wearable, such application scenarios are attracting increasing research interest from both academia and industry (Wang et al., 2007).

HMMs have been widely used in activity recognition: activities are modeled as hidden states that emit the object tags observed by the RFID reader (Patterson et al., 2005). This is an appropriate model if activities are atomic and carried out sequentially. In many domains, however, activities are hierarchically structured, as sets of *basic* activities can be grouped into *high-level* activities. High-level activities typically interleave in time as a user is switching between them, as illustrated in Figure 1. In this example, a user is having breakfast, which consists of high-level activities makeToast, makeJuice, and getNews with corresponding basic activities. The domain could be modeled with a standard HMM by "flattening" the three activities into one process with 7 states, but in this case part of the problem structure would be lost. Alternatively, we can model the activities as three *different* processes which interleave in time. This has the advantage of decoupling transition dynamics within one high-level activity from the interleaving behavior, yielding a more concise representation with fewer parameters.

In this paper, we present a probabilistic model in which observations are generated by multiple, interleaved hidden processes. The hidden processes are stationary Markov chains, and the switching mechanism by which they interleave is again Markov. Although there exists a large body of related work, to the best

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

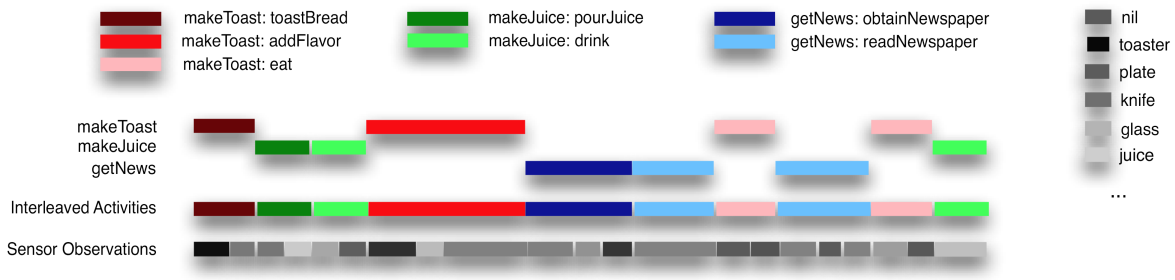

Figure 1. Interleaving in an activity recognition domain. Three high-level activities (makeToast, makeJuice, getNews) with corresponding basic activities are interleaved in time as a user switches between them. Different activities can produce identical sensor observations, and therefore neither the interleaving nor the actual activities are directly observable from the sensor data.

of our knowledge this interleaved setting has not been addressed before. A simplified version has been discussed in (Batu et al., 2004); however, tractable inference algorithms are not explored in this work. Simplicial mixtures of Markov chains, which employ a generative semantics similar to latent Dirichlet allocation, also address a similar problem (Girolami & Kabán, 2003). However, they restrict the constituent processes to be Markov rather than hidden Markov. A further class of models assumes several hidden processes that run in parallel, and that observations stem from their joint state. Examples include *factorial hidden Markov models* (Ghahramani & Jordan, 1997), *hidden Markov decision trees* (Jordan et al., 1996), *coupled hidden Markov models* (Brand, 1997) and *mixed hidden Markov models* (Altman, 2007). In contrast to our approach, these models focus on factorizing complex state spaces into cross-products of simpler components, rather than modeling interleaved processes. Another related technique are *switching state-space models* (SSSMs) (Ghahramani & Hinton, 1998), in which several processes run in parallel and an additional *switch* variable selects one *active* process from which the current observation is generated. SSSMs are different in that processes run concurrently, while an interleaving of processes is characterized by the fact that an inactive process is stopped and only resumes when it becomes active again. This creates additional dependencies between processes which cannot be modeled in a SSSM. Finally, *hierarchical hidden Markov models* model hierarchical structure within the hidden process that generates the observations (Fine et al., 1998). However, the component processes cannot interleave, and thus the model is not appropriate in our domain.

The next section introduces the proposed model more formally. Afterwards, we discuss the key problem of hidden state inference: given a sequence of observations, find the most likely configuration of hidden processes to have generated the data. Unfortunately, exact inference can be shown to be NP-hard; however, efficient structured approximate inference techniques can be applied (Section 3). Finally, the proposed technique is evaluated in an activity recognition domain, and shown to outperform standard HMM-based approaches (Section 4).

2. The Model

Let $Y_1, ..., Y_T$ denote a sequence of observations, where the Y_t take on one of D discrete values. A hidden Markov model μ (Rabiner, 1989) defines a sequence $X_1, ..., X_T$ of hidden state variables, with $X_t \in \{1, ..., K\}$ and K the number of different states the hidden process can take on. To simplify notation, assume that there is a special start state 0 the process is in at time $t = 0$, that is, $X_0 = 0$. The first transition is from X_0 to $X_1 \in \{1, ..., K\}$, and afterwards the first output Y_1 is emitted. The HMM is characterized by initial state probabilities $a_{0i} = P(X_1 = i \mid X_0 = 0)$, state transition probabilities $a_{ij} = P(X_t = j \mid X_{t-1} = i)$ for $t \geq 2$ and emission probabilities $b_{il} = P(Y_t = l \mid X_t = i)$ for $t \geq 1$. The joint distribution of observations $\mathbf{Y} = Y_1, ...Y_T$ and hidden states $\mathbf{X} = X_1, ..., X_T$ is given by

$$P(\mathbf{X}, \mathbf{Y}) = \prod_{t=1}^{T} P(X_t \mid X_{t-1}) P(Y_t \mid X_t).$$

We will also refer to $\mathbf{X}$ as the hidden process that generated the observations $\mathbf{Y}$.

We propose a model for multiple, interleaved hidden processes. Intuitively, an additional *switching process* controls a token that is handed from process to process, and determines which of the processes is active at a particular point t in time. The active process tran-

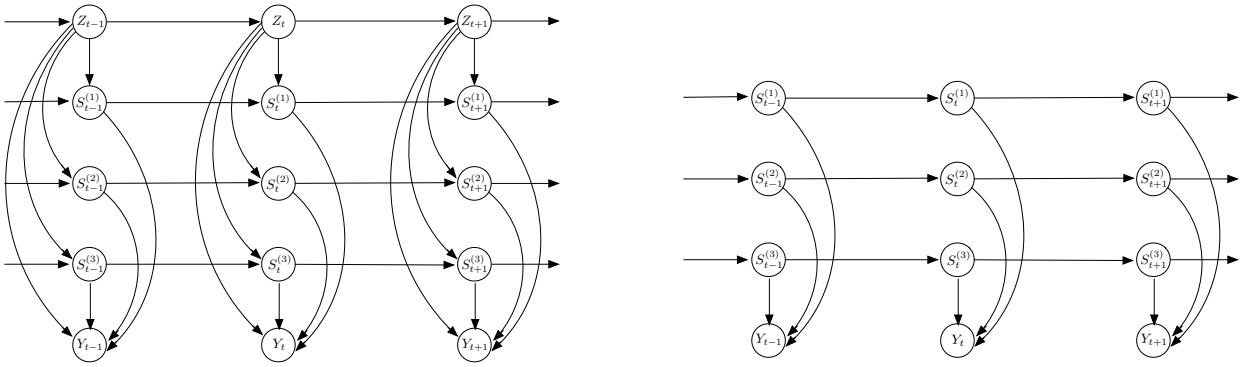

Figure 2. Interleaved mixture of hidden Markov models (left) and factorial hidden Markov model (right) in dynamic Bayesian network notation (for $M = 3$).

sitions to a new state and outputs the observation Y_t, while all other processes remain "frozen" in time.

More formally, let $\mu_1, ..., \mu_M$ be hidden Markov models with initial state probabilities $a_{0i}^{(m)}$, transition probabilities $a_{ij}^{(m)}$ and emission probabilities $b_{il}^{(m)}$. For ease of notation, we assume the number of states K is identical for all μ_m, but the model trivially generalizes to processes with state spaces of different size. Let furthermore $\bar{\mu}$ be a Markov process with states $\{1, ..., M\}$, initial state probabilities d_{0i} and transition probabilities d_{ij}. Let Z_t denote a random variable representing the state of $\bar{\mu}$ at time t, and $S_t^{(m)}$ denote random variables representing the state of process μ_m at time t for $1 \leq m \leq M$. $Z_t \in \{1, ..., M\}$ determines the *active* process at time t, and we will refer to $\bar{\mu}$ as the *switching process*. At every step t in time, a new active process is sampled from $\bar{\mu}$ with probability $P(Z_t = j \mid Z_{t-1} = i) = d_{ij}$. Afterwards, the states of $\mu_1, ..., \mu_M$ are updated according to

$$P(S_t^{(m)} = j \mid S_{t-1}^{(m)} = i, Z_t = k) = \begin{cases} a_{ij}^{(m)} & k = m; \\ \delta_{ij} & k \neq m, \end{cases} \tag{1}$$

where $\delta_{ii} = 1$ and $\delta_{ij} = 0$ for $i \neq j$. In other words, a process μ_m transitions to a new state with probability given by its transition matrix if it is active at time t, and stays in its old state otherwise.

Finally, the probability of emitting symbol Y_t is

$$P(Y_t = l \mid S_t^{(1)} = i_1, ..., S_t^{(M)} = i_M, Z_t = k) = b_{i_k l}^{(k)} \tag{2}$$

That is, it is given by the emission probability of the process that is active at time t. Let $\mathbf{S}_t = S_t^{(1)}, ..., S_t^{(M)}$, $\mathbf{Z} = Z_1, ..., Z_T$ and $\mathbf{S} = \mathbf{S}_1, ..., \mathbf{S}_T$. Then

$$P(\mathbf{Z}, \mathbf{S}, \mathbf{Y}) = \prod_{t=1}^{T} P(Z_t \mid Z_{t-1}) P(Y_t \mid \mathbf{S}_t, Z_t) \prod_{m=1}^{M} P(S_t^{(m)} \mid S_{t-1}^{(m)}, Z_t) \tag{3}$$

We will refer to this model as an *interleaved mixture of hidden Markov models*. It is represented by the dynamic Bayesian network structure given in Figure 2 (left). The model is structurally related to a factorial hidden Markov model (Ghahramani & Jordan, 1997), shown in Figure 2 (right). However, the structure is extended by the additional chain of Z_t nodes that determine the currently active process. Although the structure is densely connected, the set of parameters is simply the union of the parameter sets of the constituent HMMs $\mu_1, ..., \mu_M$ and the switching process $\bar{\mu}$.

The following alternative interpretation of the model can be given. Let $\mathbf{z}$ denote an interleaving[1] and let $t_1^m, ..., t_{T^m}^m$ denote the sequence positions for which $z_t = m$. That is, $\mathbf{Y}_{\downarrow \mu_m} = Y_{t_1^m}, ..., Y_{t_{T^m}^m}$ is the projection of $\mathbf{Y}$ to elements generated by μ_m, and $\mathbf{S}_{\downarrow \mu_m} = S_{t_1^m}^{(m)}, ..., S_{t_{T^m}^m}^{(m)}$ the corresponding hidden state variables. It is easily verified that

$$P(\mathbf{Z}, \mathbf{S}, \mathbf{Y}) = P(\mathbf{Z}) \prod_{m=1}^{M} P_{\mu_m}(\mathbf{Y}_{\downarrow \mu_m}, \mathbf{S}_{\downarrow \mu_m}),$$

where $P_{\mu_m}(\mathbf{Y}_{\downarrow \mu_m}, \mathbf{S}_{\downarrow \mu_m})$ is the joint distribution of hidden states $\mathbf{S}_{\downarrow \mu_m}$ and observations $\mathbf{Y}_{\downarrow \mu_m}$ in the original HMM μ_m. This reformulation gives rise to an intuitive approach for sampling from $\mathbf{Y}$: first sample an interleaving pattern $\mathbf{z}$ from $\bar{\mu}$, and afterwards $\mathbf{Y}_{\downarrow \mu_m}$ from μ_m for $1 \leq m \leq M$.

[1] In general, we denote random variables with uppercase letters, and their instantiations with lower-case letters.

3. Inference and Parameter Estimation

A key task in the activity recognition domains we have in mind is *hidden state inference*: find

$$(\mathbf{z}^*, \mathbf{s}^*) = \operatorname*{argmax}_{\mathbf{z},\mathbf{s}} P(\mathbf{z}, \mathbf{s} \mid \mathbf{y}) \tag{4}$$

for a given sequence $\mathbf{y}$ of observations. This involves simultaneously finding a segmentation of $\mathbf{y}$ into subsequences $\mathbf{y}_{\downarrow\mu_m}$ generated by μ_m (the $\mathbf{z}^*$), and most likely hidden states for $\mathbf{y}_{\downarrow\mu_m}$ in μ_m (the $\mathbf{s}^*$).

3.1. Exact Inference

Two special cases of the problem are trivial. For $M = 1$, the model coincides with a hidden Markov model, and the Viterbi algorithm returns the most likely hidden states in time $O(K^2T)$. Moreover, if the output symbol sets of $\mu_1, ..., \mu_M$ are disjoint, the interleaving $\mathbf{z}$ is directly observable, and $\mathbf{s}$ can be obtained by running M instances of Viterbi in time $O(MK^2T)$.

The more interesting case of $M \geq 2$ and non-disjoint output symbol sets is inherently more difficult due to its combinatorial nature—the M constituent chains are coupled via the switching process and observations, and thus cannot be handled independently. Accordingly, exact graphical model inference (e.g. with the junction tree algorithm) applied to the model in Figure 2 (left) has costs exponential in M, because the cliques at Y_t are of size $O(M)$. In fact, for *general* graphical model structures of this form there is no tractable inference algorithm available. However, the conditional distributions $P(Y_t \mid \mathbf{S}_t, Z_t)$ have a particularly simple form, which could make the problem easier. Unfortunately, this is not the case:

Theorem. *Exact inference for interleaved mixtures of hidden Markov models is NP-hard.*

The theorem is proved by reduction from the strongly NP-hard *3-partition problem* (Garey & Johnson, 1975):

Problem (3-partition problem)**.** *Let S be a multiset of $M = 3N$ positive integers. Is there a partition of S into subsets $S_1, ..., S_N$ of size 3 each such that the sum over the integers in each subset is the same?*

A detailed proof is omitted for lack of space. Intuitively, the relationship is that an interleaving of $\mu_1, ..., \mu_M$ "partitions" a given sequence into the parts generated by the different processes (cf. Figure 1). Note that a key issue is the strong NP-hardness of 3-partition: the problem is NP-hard even if numbers in the input are given in unary notation (or, equivalently, if integers in S are polynomially bounded in M).

3.2. Approximate Inference

Approximate inference in graphical models has received much attention, and a variety of techniques are available. The most simple class of methods are Markov chain Monte Carlo (MCMC) approaches. In Gibbs sampling, for instance, iterative conditional resampling of random variables defines a Markov process whose stationary distribution—under certain conditions—will be the conditional distribution in Equation (4). However, MCMC is not an effective inference method in our case, because the Markov process defined by the Gibbs sampler is not ergodic. There can be two state configurations with positive probability that cannot be transformed into each other by single-variable changes without passing through an invalid (probability zero) configuration, such as any configuration with $S_{t-1}^{(m)} \neq S_t^{(m)}$ but $Z_t \neq m$. This effectively traps the Gibbs sampler in a subspace of all configurations and prevents MCMC convergence.

The problem is that Gibbs sampling, by updating only one variable at a time, ignores the specific model structure. Instead, we have to resort to approximate inference methods that better exploit model structure. Examples include structured variational approximations (Ghahramani & Jordan, 1997) and an iterative approximate inference method known as the chainwise Viterbi algorithm (Saul & Jordan, 1999). These algorithms are used in factorial HMMs for computing EM statistics and hidden state inference. In the rest of the Section, we present an extension of chainwise Viterbi for solving the problem given by Equation (4).

The idea behind chainwise Viterbi is to repeatedly solve tractable sub-problems of the (intractable) global optimization problem. For factorial hidden Markov models, the natural sub-problem to solve is to optimize hidden states in one chain $\mathbf{S}^{(m)} = S_1^{(m)}, ..., S_T^{(m)}$ conditioned on the current states of the other chains:

$$\begin{aligned}\mathbf{s}_{new}^{(m)} &= \operatorname*{argmax}_{\mathbf{s}^{(m)}} P(\mathbf{s}^{(m)} \mid \{\mathbf{s}^{(l)} : l \neq m\}, \mathbf{y}) \\ &= \operatorname*{argmax}_{\mathbf{s}^{(m)}} P(\mathbf{s}^{(1)}, ..., \mathbf{s}^{(M)}, \mathbf{y}).\end{aligned}$$

In the dynamic Bayesian network representing an interleaved mixture of HMMs (Figure 2, left), there are two different types of hidden chains: the chains $\mathbf{S}^{(1)}, ..., \mathbf{S}^{(M)}$ representing the constituent processes $\mu_1, ..., \mu_M$ and the chain $\mathbf{Z}$ representing the switching process $\bar{\mu}$. Assume first that $\mathbf{Z}$ is kept fix, and the goal is to conditionally optimize a chain $\mathbf{S}^{(m)}$. This is straightforward: for a given interleaving pattern, the chains $\mathbf{S}^{(1)}, ..., \mathbf{S}^{(M)}$ become independent given $\mathbf{Z}$ and $\mathbf{Y}$ due to the special form of the conditional distribu-

Algorithm 1 Chainwise Viterbi for interleaved mixtures of hidden Markov models

Input: model $\mathcal{M}$, observations $\mathbf{Y}$
$(\mathbf{S}, \mathbf{Z}) :=$ consistent-configuration($\mathcal{M}$)
while not converged **do**
  choose $m, n \in \{1, ..., M\}, m \neq n$
  let $(\mathbf{S}^{(m)}, \mathbf{S}^{(n)}, \mathbf{Z}) := \underset{\mathbf{S}^{(m)}, \mathbf{S}^{(n)}, \mathbf{Z}}{\operatorname{argmax}} P(\mathbf{S}, \mathbf{Z}, \mathbf{Y})$
end while
return $\mathbf{S}, \mathbf{Z}$

tions $P(Y_t \mid \mathbf{S}_t, Z_t)$, cf. Equation (2). They can thus be optimized independently with standard Viterbi.

We therefore focus on the task of optimizing $\mathbf{Z}$ given $\mathbf{S}^{(1)}, ..., \mathbf{S}^{(M)}$. A straightforward update

$$\mathbf{z}_{new} = \underset{\mathbf{z}}{\operatorname{argmax}} P(\mathbf{z}, \mathbf{s}^{(1)}, ..., \mathbf{s}^{(M)}, \mathbf{y})$$

is not very effective: as a process μ_m can only change state at time t if it is active, we know from $S_t^{(m)} \neq S_{t-1}^{(m)}$ that $Z_t = m$. Thus, the joint state of $\mathbf{S}^{(1)}, ..., \mathbf{S}^{(M)}$ essentially determines $\mathbf{Z}$. To change the state of Z_t from m to n, it is necessary to also update $S_t^{(m)}$ and $S_t^{(n)}$ to reflect that μ_n is now active at time t. The solution is to jointly optimize *two* constituent chains $\mathbf{S}^{(m)}$, $\mathbf{S}^{(n)}$ and the switching chain $\mathbf{Z}$ by

$$(\mathbf{s}_{new}^{(m)}, \mathbf{s}_{new}^{(n)}, \mathbf{z}_{new}) = \underset{\mathbf{s}^{(m)}, \mathbf{s}^{(n)}, \mathbf{z}}{\operatorname{argmax}} P(\mathbf{s}, \mathbf{y}, \mathbf{z}). \qquad (5)$$

Intuitively speaking, this update allows to re-assign observations that have so far been attributed to process μ_m to process μ_n, by changing some Z_t from m to n and updating $\mathbf{S}^{(m)}$ and $\mathbf{S}^{(n)}$ accordingly. If it is repeatedly applied with different process indices m, n, the interleaving can be arbitrarily revised. Algorithm 1 describes this chainwise update scheme in pseudocode. The method consistent-configuration($\mathcal{M}$) initializes the states of the hidden variables to some positive-probability configuration[2]. When choosing $m, n \in \{1, ..., M\}$ different strategies are possible; we assume the algorithm repeatedly cycles through all pairs $n \neq m$. If the update step (5) is implemented exactly, $P(\mathbf{s}, \mathbf{z}, \mathbf{y})$ will increase unless the hidden state configuration is left unchanged. Thus, the algorithm will always converge (though not necessarily to the true global optimum).

An efficient implementation of the update step (5) is crucial for fast inference. This can be achieved by dynamic programming in the spirit of the Viterbi algorithm (Rabiner, 1989). Moreover, the particularly restrictive form of the model (basically, that only the active chain changes state at any point in time) can be exploited. This allows much faster inference than for *general* graphical models with the DAG structure given in Figure 2 (left), as will be briefly outlined now.

To simplify notation, assume that $n = 1$ and $m = 2$. In analogy to the Viterbi algorithm, define

$$\delta_{ijk}[t] = \max_{\mathbf{D}} P(\mathbf{D}, S_t^{(1)} = i, S_t^{(2)} = j, Z_t = k, \mathbf{Y}, \mathbf{S}^{(3)}, ..., \mathbf{S}^{(M)})$$

with

$$\mathbf{D} = \{S_1^{(1)}, ..., S_{t-1}^{(1)}, S_1^{(2)}, ..., S_{t-1}^{(2)}, Z_1, ..., Z_{t-1}\}.$$

Initialization of $\delta_{ijk}[1]$ is straightforward. For the recursive definition of $\delta_{ijk}[t]$, let

$$C[k] = \prod_{m=3}^{M} P(S_t^{(m)} = s_t^{(m)} \mid S_{t-1}^{(m)} = s_{t-1}^{(m)}, Z_t = k),$$

where $s_{t-1}^{(m)}$, $s_t^{(m)}$ for $m \geq 3$ denote the current values of the fixed chains $\mu_3, ..., \mu_M$. Now two cases have to be considered. If $k \geq 3$, chains $1, 2$ cannot have changed state, and

$$\delta_{ijk}[t] = \max_{k'=1,...,M} \delta_{ijk'}[t-1] d_{k'k} b_{sy}^{(k)} C[k]$$

with $s = S_t^{(k)}$ and $y = Y_t$. This quantity can be computed in time $O(M)$. If $k \in \{1, 2\}$, we have to take into account state changes on the chains being optimized. Assume without loss of generality that $k = 1$. Now

$$\delta_{ij1}[t] = \max_{k'=1,...,M} \max_{i'=1,...,K} \delta_{i'jk'}[t-1] d_{k'1} a_{i'i}^{(1)} b_{iy}^{(1)} C[1],$$

with $y = Y_t$. This quantity can be computed in time $O(KM)$. There are $O(K^2MT)$ values of the form $\delta_{ijk}[t]$ to compute. However, time for computing all values is bounded by $O(K^2M(M+K)T)$, as the case $k \in \{1, 2\}$ only appears $O(K^2T)$ times.

The maximum probability of a hidden state configuration is

$$\max_{\mathbf{s}^{(1)}, \mathbf{s}^{(2)}, \mathbf{z}} P(\mathbf{s}, \mathbf{z}, \mathbf{y}) = \max_{ijk} \delta_{ijk}[T],$$

and a maximizing configuration is found by keeping track of where maxima occur in backtrace variables.

It is instructive to compare the complexity of the outlined chainwise Viterbi algorithm to inference in an HMM where hidden states are "flattened" into a single process. This HMM has a state space of size KM, and standard Viterbi has thus complexity $O(K^2M^2T)$, similar to the $O(K^2M(M+K)T)$ for a single update step in chainwise Viterbi. However, several such update steps will be needed before convergence.

[2] This is trivial if observation probabilities are always non-zero, as e.g. in Laplace-smoothed models.

3.3. Parameter Estimation

There are different possible settings for learning the proposed model from data. In the activity recognition setting discussed in Section 4, both sensor observations and activities are given for the training set. In this fully observable case maximum-likelihood model parameters can essentially be determined by counting. More generally, if the interleaving is known for the training data (that is, we know which part of each sequence has been generated by which process), the problem reduces to independently estimating the parameters of $\mu_1, ..., \mu_M$ with the standard Baum-Welch algorithm (Rabiner, 1989). In an unsupervised learning setting, expectation-maximization including the unknown interleaving $\mathbf{Z}$ is a natural choice. However, for the same reasons as discussed in Section 3, exact computation of the expectation step will be infeasible. In factorial hidden Markov models, this problem is solved elegantly by a structured variational approximation, and exploring variational inference methods for the interleaved mixture model presented in this paper is an interesting direction for future work. A simple alternative is to employ *hard EM*: instead of computing exact expectations, hidden states are set to their max-likelihood values given the observations, and expectations determined by counting. Together with the chainwise Viterbi algorithm discussed in Section 3.2 this yields a tractable method which is straightforward to implement.

4. Experimental Evaluation

The proposed model has been evaluated in an activity of daily living (ADL) recognition domain, where the goal is to infer a user's activity from a stream of dense RFID sensor data. The dataset has been collected in a real RFID environment at Intel Research Seattle (Landwehr et al., 2007). Objects are equipped with small RFID tags, and the user is wearing a lightweight RFID reader in a bracelet around the wrist. Whenever the reader comes close (10–15 centimeters) to a tagged object, the object tag is recorded. The sequence of observed tags thus indicates the objects a user has been interacting with while performing the activity.

We recorded activities involved in making breakfast at home, as this domain showcases the kind of interleaving behavior we are interested in (cf. Figure 1). The dataset consists of 20 sequences of RFID tag observations collected from 5 different persons having breakfast. Sequences are hand-labeled with the true current activity based on a human observer. There are 18 basic activities organized into 6 high-level activities, 24 different classes of tagged objects (including *nil* if no object was observed), and a total of 4597 timepoints to be classified. Timepoints at which no activity is taking place and activities with a coverage of less than 1% were removed, leaving 14 activities and 3545 timepoints in the dataset. The average number of segments into which a high-level activity is broken up because of interleaving is 3.95. There is significant overlap between observations associated with different activities, either because the same object is used in different activities or noise in the sensor data. More specifically, the average overlap in the set of observations associated with two different activities is 40.6%.

A standard approach in ADL recognition is based on HMMs: each basic activity corresponds to a hidden state, and sensor data to observations. In the described domain this means that all activities are "flattened" into one hidden process, and their hierarchical structure is lost. This approach will serve as a baseline, denoted by HMM. Alternatively, high-level activities can be modeled as separate hidden processes using the model described in Section 2. Here we consider a slight extension of this model: state transition probabilities in the active hidden process μ_{Z_t} depend not only on the previous state but also on whether or not the process has just become active; that is, $Z_t \neq Z_{t-1}$. The motivation for this extension is that high-level activities are typically interrupted at a point where the basic activity changes as well. It is straightforward to generalize the model and algorithms discussed in Section 2 and Section 3 to include this dependency.

Each high-level activity A is represented as a process μ_A, and the state space of μ_A are the basic activities associated with A. Note that the method, when applied to a given observation sequence, will automatically chose the (approximately) most likely subset of high-level activities that explains the observations. This model, together with the approximate inference technique discussed in Section 3.2 will be denoted as HMMmix. In the chainwise Viterbi algorithm, hidden states are initialized to the most likely activity given the current sensor observation (as observed in the training data). Furthermore, a version with exact inference (denoted HMMmix*) is run for comparison.

The experimental study seeks to answer the following two questions:

(Q1) Does reconstruction accuracy increase if high-level activities are modeled as separate processes?

(Q2) Does the approximate inference algorithm for HMMmix yield results similar to exact inference?

The rationale behind (**Q1**) is that modeling high-level

Table 1. Average cross-validated accuracy for MAJORITY, MAJORITY/OBSERVATION, HMM, HMMMIX and HMMMIX* on the ADL dataset. • indicates that result for HMMMIX is significantly better than result for other method (paired two-sided t-test, $p = 0.05$).

Method	Accuracy
MAJORITY	21.2 ± 25.4•
MAJORITY/OBSERVATION	71.4 ± 10.3•
HMM	84.0 ± 9.8•
HMMMIX	$\mathbf{86.0} \pm 8.6$
HMMMIX*	$\mathbf{86.0} \pm 8.6$

activities as separate processes will capture transition dynamics more concisely, as it decouples dynamics within a high-level activity from the switching dynamics. This is reflected in the number of model parameters: The "flattened" HMM representation requires $O((MK)^2) = O(M^2K^2)$ parameters to specify transition dynamics, while HMMMIX only requires $O(M^2 + MK^2)$ parameters.

To evaluate the different approaches, we performed a leave-one-sequence-out cross-validation. On the respective training set, models are estimated from fully observable training data, i.e., information on both sensor observations and activities is available. Given a test sequence, the most likely joint state of hidden variables in the model is determined, yielding a prediction of the current basic activity at every point in time. This is compared against the known true activity, and average prediction accuracy is computed. Table 1 shows reconstruction accuracy for HMM, HMMMIX and HMMMIX*. Additionally, accuracy for always predicting the most frequent activity (MAJORITY), and the most frequent activity given a particular sensor observation (MAJORITY/OBSERVATION) are shown. HMMMIX significantly outperforms HMM (paired two-sided t-test, $p = 0.05$), and predictions made by HMMMIX and HMMMIX* are identical in this experiment. This affirmatively answers questions **Q1** and **Q2**. Figure 3 shows the convergence behavior of chainwise Viterbi. The normalized log-likelihood of the current configuration of hidden states and the reconstruction accuracy given by this configuration are plotted as a function of the algorithm iteration. As expected, both likelihood and accuracy increase as the algorithm repeatedly revises the current interleaving. Furthermore, convergence occurs after a small number of iterations.

There are two sources of information for predicting the activity at a point t in time: the current sensor observation, and transition dynamics for activities

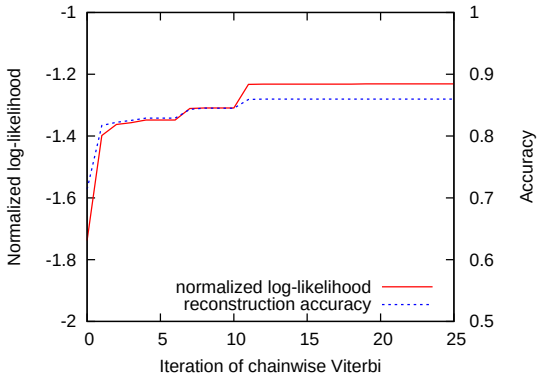

Figure 3. Normalized log-likelihood and reconstruction accuracy of the current hidden state configuration as a function of the number of iterations in chainwise Viterbi. Results are averaged over all test sequences.

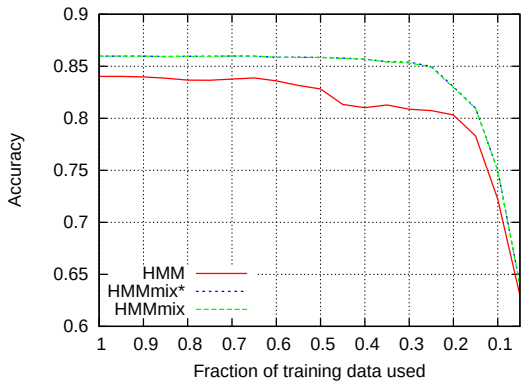

Figure 4. Reconstruction accuracy as a function of the fraction γ of training sequences used to estimate model transition parameters, while emission probabilities are estimated from all available training data. Results are averaged over 5 runs of cross-validation.

(which capture the influence of past and future observations on the current prediction). The MAJORITY/OBSERVATION approach already performs well; this indicates that much information is obtained simply from the current sensor observation. To further investigate the influence of transition dynamics on reconstruction accuracy, the following experiment was carried out. When estimating a model from data, only a randomly selected fraction γ of the training sequences is used to estimate transition probabilities, while all available data is used to estimate emission probabilities. Figure 4 shows reconstruction accuracy as a function of γ. The experiment confirms that HMMMIX outperforms HMM, and that approximate inference gives solutions very close to those of exact inference (solutions differ slightly, but the curves for HMMMIX and HMMMIX* in Figure 4 are indistin-

guishable). Moreover, the difference between HMM and HMMmix is most pronounced if only 20% to 40% of training sequences are used to estimate transition parameters. This supports the hypothesis that the more concise representation of transition dynamics in HMMmix (with fewer model parameters) explains its superior performance, as a concise representation matters most if training data is sparse.

5. Conclusions and Related Work

We have introduced a model for interleaved mixtures of hidden processes, which was shown to be superior to a single-process model in an activity recognition domain. The model should be generally applicable in situations where only the interleaved output of several independent processes can be observed. Related work includes several extensions of hidden Markov models (as discussed in Section 1), and activity recognition approaches based on HMMs such as (Patterson et al., 2005) and (Zhang et al., 2007) or dynamic Bayesian networks (Wang et al., 2007). The proposed method not only labels sequence positions but returns a structured parse of the sequence in terms of a set of hidden processes. Thus, it is also related to segmentation models, grammar-based approaches, and more generally models for predicting structured data (see (Bakir et al., 2007) for an overview). Directions for future work include semi- and unsupervised learning settings, and testing the model in different domains and on larger activity recognition datasets.

Acknowledgments The author would like to thank Matthai Philipose and Intel Research Seattle for making the activity recognition dataset available, and Luc De Raedt, Ingo Thon, Bernd Gutmann and Siegfried Nijssen for helpful discussions. The comments from the anonymous reviewers also helped to improve the paper. This work was supported by the Research Foundation-Flanders (FWO-Vlaanderen), and GOA/08/008 project "Probabilistic Logic Learning".

Abstract

We examine the problem of evaluating a policy in the contextual bandit setting using only observations collected during the execution of another policy. We show that policy evaluation can be impossible if the exploration policy chooses actions based on the side information provided at each time step. We then propose and prove the correctness of a principled method for policy evaluation which works when this is not the case, even when the exploration policy is deterministic, as long as each action is explored sufficiently often. We apply this general technique to the problem of offline evaluation of internet advertising policies. Although our theoretical results hold only when the exploration policy chooses ads independent of side information, an assumption that is typically violated by commercial systems, we show how clever uses of the theory provide non-trivial and realistic applications. We also provide an empirical demonstration of the effectiveness of our techniques on real ad placement data.

1. Introduction

The k-armed bandit problem (Lai & Robbins, 1985; Berry & Fristedt, 1985; Auer et al., 2002; Even-Dar et al., 2006) has been studied in great detail, primarily because it can be viewed as a minimal formalization of the exploration problem faced by any autonomous agent. Unfortunately, while its minimalism admits tractability and insight, it misses details that are necessary for application to many realistic problems. For instance, the problem of internet advertising can be viewed as a type of bandit problem in which choosing an ad or set of ads to display corresponds to choosing an arm to pull. However, this formalization is inadequate in practice, as vital information is ignored. In particular, a successful ad placement policy might choose ads based on the content of the web page on which the ads are displayed. The standard k-armed bandit formulation ignores this useful information.

This shortcoming can be rectified by modeling the problem as an instance of the *contextual bandit problem* (Langford & Zhang, 2007), a generalization of the k-armed bandit problem that allows an agent to first observe an *input* or *side information* before choosing an arm. This problem has been studied under different names, including associative reinforcement learning (Kaelbling, 1994), bandits with side information (Wang et al., 2005), and bandits with experts (Auer et al., 1995), yet its analysis is far from complete.

In this paper, we study *policy evaluation* in the contextual bandit setting. Policy evaluation is the problem of evaluating a new strategy for behavior, or *policy*, using only observations collected during the execution of another policy. The difficulty of this problem stems from the lack of control over available data. Given complete freedom, an algorithm could evaluate a policy simply by executing it for a sufficient number of trials. However, in real-world applications, we often do not have the luxury of executing arbitrary policies, or we may want to distinguish or search among many more policies than we could evaluate independently.

We begin by providing impossibility results characterizing situations in which policy evaluation is *not* possible. In particular, we show that policy evaluation can be impossible when the exploration policy depends on the current input. We then provide and prove the correctness of a principled method for policy evaluation when this is not the case. This technique, which we

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

call "exploration scavenging," can be used to accurately estimate the value of any new policy as long as the exploration policy does not depend on the current input and chooses each action sufficiently often, even if the exploration policy is deterministic. The ability to depend on deterministic policies makes this approach more applicable than previous techniques based upon known and controlled randomization in the exploring policy. We also show that exploration scavenging can be applied if we wish to choose between multiple policies, even when these policies depend on the input, which is a property shared by most real ad-serving policies. This trick allows exploration scavenging to be applied to a broader set of real-life problems.

The motivating application for our work is *internet advertising*. Each time a user visits a web page, an advertising engine places a limited number of ads in a *slate* on the page. The ad company receives a payment for every ad clicked by the user. Exploration scavenging is well-suited for this application for a few reasons. First, an advertising company may want to evaluate a new method for placing ads without incurring the risk and cost of actually using the new method. Second, there exist logs containing huge amounts of historical click data resulting from the execution of existing ad-serving policies. It is economically sensible to use this data, if possible, when evaluating new policies.

In Section 4, we discuss the application of our methods to the ad display problem, and present empirical results on data provided by Yahoo!, a web search company. Although this application actually violates the requirement that the exploration policy be independent of the current input, the techniques show promise, leading us to believe that exploration scavenging can be useful in practice even when the strong assumptions necessary for the theoretical results do not hold.

To our knowledge, the only similar application work that has been published is that of Dupret et al. (2007) who tackle a similar problem from a Bayesian perspective using different assumptions which lead to different solution techniques. Our approach has the advantage that the estimated value is the output of a simple function rather than an EM optimization, facilitating interpretation of the evaluation method.

2. The Contextual Bandit Setting

Let $\mathcal{X}$ be an arbitrary input space, and $\mathcal{A} = \{1, \cdots, k\}$ be a set of actions. An instance of the contextual bandit problem is specified by a distribution D over tuples $(x, \vec{r})$ where $x \in \mathcal{X}$ is an input and $\vec{r} \in [0,1]^k$ is a vector of rewards. Events occur on a round by round basis where on each round t:

1. The world draws $(x_t, \vec{r}_t) \sim D$ and announces x_t.
2. The algorithm chooses an action $a_t \in \mathcal{A}$, possibly as a function of x_t and historical information.
3. The world announces the reward r_{t,a_t} of action a_t.

The algorithm does not learn what reward it would have received if it had chosen an action $a \neq a_t$.

The standard goal in this setting is to maximize the sum of rewards r_{t,a_t} over the rounds of interaction. An important subgoal, which is the focus of this paper, is policy evaluation. Here, we assume that we are given a data set $S \in (\mathcal{X} \times \mathcal{A} \times [0,1])^T$, which is generated by following some fixed policy π for T steps. Now, given a different policy $h : \mathcal{X} \to \mathcal{A}$, we would like to estimate the *value* of policy h, that is,

$$V_D(h) := E_{(x,\vec{r})\sim D}[r_{h(x)}].$$

The standard k-armed bandit is a special case of the contextual bandit setting in which $|\mathcal{X}| = 1$.

3. Evaluating Policies

In this section, we characterize situations in which policy evaluation may not be possible, and provide techniques for estimating the value of a policy when it is. To start, we show that when the exploration policy π depends on the input x, policy evaluation can be impossible. Later, we show that when the exploration policy π has no dependence on the current input, there exists a technique for accurately estimating the value of a new policy h as long as the exploration policy chooses each action sufficiently often. Finally, we show that exploration scavenging can be applied in the situation in which we are choosing between multiple exploration policies, even when the exploration policies themselves depend on the current input.

3.1. Impossibility Results

First, note that policy evaluation is not possible when the exploration policy π chooses some action a with zero probability. This is true even in the standard k-armed bandit setting. If the exploration policy always chooses action 1, and the policy to evaluate always chooses action 2, then policy evaluation is hopeless.

It is natural to ask if it is possible to build a policy evaluation procedure that is guaranteed to accurately evaluate a new policy given data collected using an arbitrary exploration policy π as long as π chooses each action sufficiently often. The following theorem shows that this goal is unachievable. In particular, it shows

that if the exploration policy π depends on the current input, then there are cases in which new policies h cannot be evaluated using observations gathered under π, even if π chooses each action frequently. Specifically, there can exist two contextual bandit distributions D and D' that result in indistinguishable observation sequences even though $V_D(h)$ and $V_{D'}(h)$ are far apart. Later we show that in the same context, if we disallow input-dependent exploration policies, policy evaluation becomes possible

Theorem 1 *There exist contextual bandit problems D and D' with $k = 2$ actions, a hypothesis h, and a policy π dependent on the current observation x_t with each action visited with probability $1/2$, such that observations of π on D are statistically indistinguishable from observations of π on D', yet $|V_D(h) - V_{D'}(h)| = 1$.*

Proof: The proof is by construction. Suppose x_t takes on the values 0 and 1, each with probability 0.5 under both D and D'. Let $\pi(x) = x$ be the exploration policy, and let $h(x) = 1 - x$ be the policy we wish to evaluate. Suppose that rewards are deterministic given x_t, as summarized in the following table.

	Under D		Under D'	
	$r_{t,0}$	$r_{t,1}$	$r_{t,0}$	$r_{t,1}$
$x_t = 0$	0	0	0	1
$x_t = 1$	0	1	1	1

Then $V_D(h) = 0$, while $V_{D'}(h) = 1$, but observations collected using exploration policy π are indistinguishable for D and D'. ■

3.2. Techniques for Policy Evaluation

We have seen that policy evaluation can be impossible in general if the exploration policy π depends on the current input or fails to choose each action sufficiently often. We now discuss techniques for policy evaluation when this is not the case. Theorem 2 shows that in some very special circumstances, it is possible to create an unbiased estimator for the value of a policy h using exploration data from another policy. The main result of this section, Theorem 3, shows that this estimator is often close to the value of the policy, even when the stringent conditions in the Theorem 2 are not satisfied.

Theorem 2 *For any contextual bandit distribution D over $(x, \vec{r})$, any policy h, any exploration policy π such that (1) for each action a, there is a constant $T_a > 0$ for which $|\{t : a_t = a\}| = T_a$ with probability 1, and (2) π chooses a_t independent of x_t,*

$$V_D(h) = E_{\{x_t,\vec{r}_t\}\sim D^T}\left[\sum_{t=1}^{T}\frac{r_{t,a_t}I(h(x_t)=a_t)}{T_{a_t}}\right].$$

Proof:

$$\begin{aligned}
&E_{\{x_t,\vec{r}_t\}\sim D^T}\left[\sum_{t=1}^{T}\frac{r_{t,a_t}I(h(x_t)=a_t)}{T_{a_t}}\right] \\
&= E_{\{x_t,\vec{r}_t\}\sim D^T}\left[\sum_{a=1}^{k}\sum_{\{t:a_t=a\}}\frac{r_{t,a}I(h(x_t)=a)}{T_a}\right] \\
&= \sum_{a=1}^{k}E_{\{x_t,\vec{r}_t\}\sim D^T}\left[\sum_{\{t:a_t=a\}}\frac{r_{t,a}I(h(x_t)=a)}{T_a}\right] \\
&= \sum_{a=1}^{k}E_{(x,\vec{r})\sim D}\left[T_a\frac{r_aI(h(x)=a)}{T_a}\right] \\
&= E_{x,\vec{r}\sim D}\left[\sum_{a=1}^{k}r_aI(h(x)=a)\right] = V_D(h).
\end{aligned}$$

The first equality is a reordering of the sum. The second and fourth follow from linearity of expectation.

The third equality is more subtle. Consider a fixed action a. The term $\sum_{\{t:a_t=a\}} r_{t,a}I(h(x_t) = a)/T_a$ involves drawing T bandit samples $(x_t, \vec{r}_t)$ and summing the term $r_{t,a}I(h(x_t) = a)/T_a$ over only the times t for which the exploration policy chose action a. There are precisely T_a such trials. The equality then follows from the fact that the quantity $r_{t,a}I(h(x_t) = a)/T_a$ is identically distributed for all t such that $a_t = a$. It is critical that the exploration policy π chooses a_t independent of x_t (to make the numerator identical) and that T_a is fixed (to make the denominator identical). If a_t depends on x_t, then these values are no longer identically distributed and the equality does not hold. This is important, as we have seen that evaluation is not possible in general if a_t can depend on x_t. ■

Conditions (1) and (2) in the theorem are satisfied, for example, by any policy which visits each action and chooses actions independent of observations. This theorem represents the limit of what we know how to achieve with a strict equality. It can replace the sample selection bias (Heckman, 1979) lemma used in the analysis of the Epoch-Greedy algorithm (Langford & Zhang, 2007), but cannot replace the analysis used in EXP4 (Auer et al., 1995) without weakening their theorem statement to hold only in IID settings.

The next theorem, which is the main theoretical result of this paper, shows that in a much broader set of circumstances, the estimator in the previous lemma is useful for estimating $V_D(h)$. Specifically, as long as the exploration does not depend on the current input and chooses each action sufficiently frequently, the estimator can be used for policy evaluation.

Theorem 3 *For every contextual bandits distribution D over $(x, \vec{r})$ with rewards $r_a \in [0,1]$, for every sequence of T actions a_t chosen by an exploration policy π that may be a function of history but does not depend on x_t, for every hypothesis h, then for any $\delta \in (0,1)$, with probability $1-\delta$,*

$$\left| V_D(h) - \sum_{t=1}^{T} \frac{r_{t,a_t} I(h(x_t) = a_t)}{T_{a_t}} \right| \leq \sum_{a=1}^{k} \sqrt{\frac{2\ln(2kT/\delta)}{T_a}}$$

where $T_a = |\{t : a_t = a\}|$.

Proof: First notice that

$$V_D(h) = \sum_{a=1}^{k} E_{x,\vec{r}\sim D}\left[r_a I(h(x) = a)\right]. \qquad (1)$$

Fix an action a. Let t_i denote the ith time step that action a was chosen, with $t_i = 0$ if $i > T_a$. Note that t_i is a random variable. For $i = 1, \ldots, T$ define

$$Z_i = \begin{cases} r_{t_i,a} I(h(x_{t_i}) = a) \\ \qquad -E_{x,\vec{r}\sim D}[r_a I(h(x) = a)] & \text{if } i \leq T_a, \\ 0 & \text{otherwise.} \end{cases}$$

Note that $Z_i \in [-1,1]$ and $E[Z_i] = 0$ for all i. Now fix a positive integer $t \in \{1, \ldots, T\}$. We apply Azuma's inequality (see, for example, Alon and Spencer (2000)) to show that for any $\delta' \in (0,1)$, with probability $1-\delta'$,

$$\frac{1}{t}\left|\sum_{i=1}^{t} Z_i\right| \leq \sqrt{\frac{2\ln(2/\delta')}{t}}\ , \qquad (2)$$

and so if $t \leq T_a$,

$$\left| E_{x,\vec{r}\sim D}[r_a I(h(x) = a)] - \frac{1}{t}\sum_{i=1}^{t} r_{t_i,a} I(h(x_{t_i}) = a) \right|$$

is upper bounded by $\sqrt{2\ln(2/\delta')/t}$. Applying the union bound with $\delta' = \delta/(Tk)$, we see that Equation 2 holds for *all* $t \in \{1, \ldots, T\}$ and thus for $t = T_a$ with probability δ/k. Applying the union bound again yields a bound that holds for all actions. Summing over actions and applying Equation 1 yields the lemma. ∎

Note that the counter-example given in Theorem 1 satisfies all conditions of Theorem 3 except for the assumption on π. Thus, we cannot solve the policy exploration problem, in general, unless we make assumptions that limit π's dependence on input.

Corollary 4 *For every contextual bandit distribution D over $(x, \vec{r})$, for every exploration policy π choosing action a_t independent of the current input, for every policy h, if every action $a \in \{1, \cdots, k\}$ is guaranteed to be chosen by π at least a constant fraction of the time, then as $T \to \infty$, the estimator*

$$\hat{V}_D(h) = \sum_{t=1}^{T} \frac{r_{t,a_t} I(h(x_t) = a_t)}{T_{a_t}}$$

grows arbitrarily close to $V_D(h)$ with probability 1.

These observations can be utilized in practice in a simple way. Given a data set S of observations (x_t, a_t, r_{a_t}) for $t = \{1, \cdots, T\}$, we can calculate $\hat{V}_D(h)$ as above and use this as an estimator of $V_D(h)$. For sufficiently large data sets S, as long as each action is chosen sufficiently often, this estimator is accurate.

3.3. Tighter Bounds in Special Cases

In some special cases when there is sufficient randomization in the exploration policy or the policy h, it is possible to achieve tighter bounds using a slightly modified estimator. Theorem 5 shows that the dependence on the number of actions k can be improved in the special case in which $\Pr(h(x) = a_t) = 1/k$ independent of x. This is true, for instance, when either the exploration policy π or the policy h chooses actions uniformly at random. We suspect that tighter bounds can be achieved in other special cases as well.

Theorem 5 *For every contextual bandits distribution D over $x, \vec{r}$ with rewards $r_a \in [0,1]$, for every sequence of actions a_t chosen by an exploration policy π that may be a function of history but does not depend on x_t and every hypothesis h, if $\Pr(h(x) = a_t) = 1/k$ independent of x and if $|\{t : a_t = a\}| > 0$ for all a, then for any $\delta \in (0,1)$, with probability $1-\delta$,*

$$\left| V_D(h) - \sum_{t=1}^{T} \frac{k r_{t,a_t} I(h(x_t) = a_t)}{T} \right| \leq k\sqrt{\frac{2\ln(2k/\delta)}{T}}\ .$$

Proof: Since we have assumed that $\Pr(h(x_t) = a_t) = 1/k$ independent of x_t,

$$\begin{aligned} V_D(h) &= E_{x,\vec{r}\sim D}[k r_{h(x)} I(h(x) = a_t)] \\ &= E_{x,\vec{r}\sim D}[k r_{a_t} I(h(x) = a_t)]\ . \end{aligned}$$

For all t, define

$$Z_t = k r_{t,a_t} I(h(x_t) = a_t) - E_{x,\vec{r}\sim D}[k r_{a_t} I(h(x) = a_t)]\ .$$

$Z_t \in [-k, k]$ and $E[Z_{t,a}] = 0$. Applying Azuma's inequality and the union bound yields the lemma. ∎

3.4. Multiple Exploration Policies

So far, all of our positive theoretical results have required that the exploration policy choose actions independent of the current input. There do exist special cases in which exploration data is provably useful for policy evaluation even when the exploration policy depends on context. We briefly describe one such case.

Suppose we have collected data from a system that has rotated through K known exploration policies $\pi_1, \pi_2, \cdots, \pi_K$ over time. For example, we may have logs of historical ad display data from a company that has used K different ad display policies. Each individual exploration policy π_i may depend on context, but we assume that the choice of which policy was used by the system at any given time does not.

We can redefine the action of the bandit problem as a choice of one of the K base policies to follow; action a_i now corresponds to choosing the ad chosen by policy π_i. Since historically the decision about which policy to use was made independent of the context x, we can view the exploration policy as oblivious with respect to x. Theorem 3 then implies that we can accurately estimate the value of any policy π which chooses from the set of actions chosen by the K base policies. This can be more powerful than competing with each historic policy, because π can make context-dependent choices about which policy to follow, potentially achieving better performance than any single policy.

4. Application to Internet Advertising

Technology companies are interested in finding better ways to search both over the myriad pages of the internet and over the increasingly large selection of potential ads to display. However, given a candidate algorithm (or *ad-serving policy* in the case of online advertising), a company faces a real-life "exploration-exploitation" dilemma. The new algorithm could be better than existing ones, but it could be worse. To evaluate the performance of an algorithm, the company might decide to adopt it for a short time on a subset of web traffic. This method produces accurate estimates of performance, but the evaluation phase can be costly in terms of lost revenue if the candidate algorithm performs poorly, and this cost grows linearly in the number of candidate algorithms that the company would like to evaluate. Clearly, a method of determining the strengths or weaknesses of an algorithm without adopting it would be highly useful.

In this section, we tackle the problem of evaluating a new ad-serving policy using data logged from an existing system. We state our results in terms of the online advertising problem, but everything we discuss can be applied to web search with little or no modification.

We begin by showing how to directly apply exploration scavenging techniques to the problem, and discuss the primary drawbacks of this simple approach. Instead, we consider a standard simplifying assumption whose adoption leads to a more realistic method for policy evaluation. This assumption, that click-through rates are factorable, leads to another interesting theoretical problem, estimating the attention decay coefficients of the click-through rates, which can also be accomplished using techniques from Section 3.

4.1. The Direct Approach

The online advertising problem can be directly mapped to the contextual bandit problem, allowing us to apply results from Section 3. Here the input space is the universe of all possible web pages and the action space contains all slates of ads. The reward is a bit vector that identifies whether or not each returned ad was clicked.[1] This bit vector can be converted to a single real-valued reward r in a number of ways, for instance, by simply summing the components, yielding the total number of clicks received, and normalizing. The example would then be used to compute a number $r \cdot I(h(x) = s)/\text{Count}(s)$, where $\text{Count}(s)$ is the number of times the slate s was displayed during all trials. According to Theorem 3, summing this quantity over all trials yields a good estimator of the value of the new policy h.

There is a significant drawback to this approach. Due to the indicator variable, the contribution to the sum for a single example is zero unless $h(x) = s$, which means that the slate chosen by the candidate algorithm h is *exactly* the same as the slate produced by the current system π. With a large set of ads and a large slate size, it is very unlikely that the same slate is chosen many times, and thus the resulting estimator for the value of h has an extremely high variance and may not exist for most slates. In the next section, we show how a standard assumption in the online advertising community can be used to reduce the variance.

4.2. The Factoring Assumption

The problem described above can be avoided by making a *factoring assumption*. Specifically, we assume that the probability of clicking an ad can be decomposed or factored into two terms, an intrinsic *click-through rate* (CTR) that depends only on the web

[1] The reward function can be modified easily to reflect the actual revenue generated by each click.

page x and the ad a, and a position-dependent multiplier C_i for position i, called the *attention decay coefficient* (ADC). This assumption is commonly used in the sponsored search literature (Borgs et al., 2007; Lahaie & Pennock, 2007).

Formally, let $\mathcal{P}(x, a, i)$ be the probability that ad a is clicked when placed in position i on web page x. We assume that $\mathcal{P}(x, a, i) = C_i \cdot \mathcal{P}(x, a)$, where $\mathcal{P}(x, a)$ is the intrinsic (position independent) click-through rate for ad a given input x, and C_i is a position-dependent constant. Here $C_1 = 1$, so $\mathcal{P}(x, a) = \mathcal{P}(x, a, 1)$.

A key observation is that this assumption allows us to transition from dealing directly with slates of ads to focusing on single ads. Let ℓ be the number of ads shown in a slate. Given an example $(x, s, \vec{r})$, we can form ℓ transformed examples of the form (x, a_i, r'_i) where a_i is the ith ad in the slate and $r'_i = r_i/C_i$. In other words, r'_i is $1/C_i$ if the ith ad was clicked, and 0 otherwise; the division by the ADC puts the rewards on the same scale, so the expected value of the reward for a fixed pair (x, a_i) is $\mathcal{P}(x, a_i)$.

Let $\sigma(a, x)$ be the slot in which the evaluation policy h places ad a on input x; if h does not display a on input x, then $\sigma(a, x) = 0$. For convenience, define $C_0 = 0$. We define a new estimator of the value of h as

$$\hat{V}_D(h) = \sum_{t=1}^{T} \sum_{i=1}^{\ell} \frac{r'_i C_{\sigma(a_i,x)}}{T_{a_i}} , \qquad (3)$$

where T_a is the total number of impressions received by a (i.e., the total number of times add a is displayed). Here C_i takes the place of the indicator function used in the estimates in Section 3, giving higher weights to the rewards of ads that h places in better slots.

Using the results from Section 3, it is straight-forward to show that this estimator is consistent as long as the current ad-serving policy does not depend on the input webpage x and every ad is displayed. However, to apply this transformation, we require knowledge of the ADCs. In the next section we show how to estimate them, again using nonrandom exploration.

4.3. Estimating Attention Decay Coefficients

Assume that a data set S is available from the execution of an ad-serving policy π that chooses the tth slate of ads to display independent of the input x_t (though possibly dependent on history). As before, S includes observations $(x_t, \vec{a}_t, \vec{r}_{t,a_t})$ for $t = \{1, \cdots, T\}$, where $\vec{a}_t$ is the slate of ads displayed at time t and $\vec{r}_{t,a_t}$ is the reward vector. Our goal is to use this data to estimate the attention decay coefficients $C_2, \ldots, C_\ell$.

We first discuss a naive ADC estimator, and then go on to show how it can be improved. In the following sections, let $C(a, i)$ be the number of clicks on ad a observed during rounds in which ad a is displayed in position i. Let $M(a, i)$ be the number of impressions of ad a in slot i, i.e., the number of times that the exploration policy chooses to place ad a in slot i. Finally, let $\mathrm{CTR}(a, i) = C(a, i)/M(a, i)$ be the observed click-through rate of ad a in slot i, with $\mathrm{CTR}(a, i)$ defined to be 0 when $M(a, i) = 0$.

4.3.1. The Naive Estimator

Initially, one might think that the ADCs can be calculated by taking the ratio between the global empirical click-through rate for each position i and the global empirical click-through rate for position 1. Formally,

$$\mathrm{Est}_{\mathrm{naive}}(\mathrm{i}) := \frac{\sum_a C(a, i)/\sum_a M(a, i)}{\sum_a C(a, 1)/\sum_a M(a, 1)}.$$

Unfortunately, as we will see in Section 4.4, this method has a bias which is often quite large in practice. In particular, it often underestimates the ratios C_i due to the fact that existing ad-serving policies generally already place better ads (with higher $\mathcal{P}(x, a)$) in the better slots. To overcome this bias, we must design a new estimator.

4.3.2. A New Estimator

Consider a fixed ad a and a fixed position $i > 1$. Clearly if a is placed in position i sufficiently many times, it is possible to estimate the probability of a being clicked in position i fairly accurately. If we also estimate the corresponding click-through rate for ad a in position 1, we may estimate C_i using a ratio of these two click-through rates, since $C_i = E_{x\sim D}[\mathcal{P}(x, a, i)]/E_{x\sim D}[\mathcal{P}(x, a, 1)]$. If we perform this procedure for all ads, we can average the resulting estimates to form a single, typically very accurate, estimate. Formally, we propose an estimator of the form

$$\mathrm{Est}_{\vec{\alpha}}(i) = \frac{\sum_a \alpha_a \mathrm{CTR}(a, i)}{\sum_a \alpha_a \mathrm{CTR}(a, 1)}, \qquad (4)$$

where $\vec{\alpha}$ is a vector of nonnegative constants α_a for each ad $a \in \mathcal{A}$.

Theorem 6 *If the ad-display policy chooses slates independent of input and $\vec{\alpha}$ has all positive entries, then the estimator $\mathrm{Est}_{\vec{\alpha}}$ in Equation 4 is consistent.*

Proof: Consider any fixed ad a and position i, and suppose that we are only interested in revenue generated by position i. Let h be the constant hypothesis that always places ad a in position i. $V_D(h)$ is then

$E_{x\sim D}\mathcal{P}(x,a,i)$. From Corollary 4, it is clear that

$$\hat{V}_D(h) = \sum_{t=1}^{T} \frac{(r_t I(h(x_t) = a_t))}{|\{t' : a_{t'} = a_t\}|}$$

converges to $V_D(h)$. Here $\hat{V}_D(h)$ is precisely $\mathrm{CTR}(a,i)$, so $\mathrm{CTR}(a,i)$ converges to $E_{x\sim D}\mathcal{P}(x,a,i)$ for all a and i. This implies that $\mathrm{Est}_{\vec{\alpha}}(p)$ converges to

$$\frac{\sum_a \alpha_a E_{x\sim D}\mathcal{P}(x,a,i)}{\sum_a \alpha_a E_{x\sim D}\mathcal{P}(x,a,1)} = \frac{\sum_a \alpha_a E_{x\sim D} C_i \mathcal{P}(x,a)}{\sum_a \alpha_a E_{x\sim D} C_1 \mathcal{P}(x,a)} = \frac{C_i}{C_1} = C_i \ .$$

■

Theorem 6 leaves open the question of how to choose $\vec{\alpha}$. If every component of $\vec{\alpha}$ is set to the same value, then the estimate for C_i can be viewed as the mean of all estimates of C_i for each ad a. However, it may be the case that the estimates for certain ads are more accurate than others, in which case we'd like to weight those more heavily. In particular, we may want to pick $\vec{\alpha}$ to minimize the variance of our final estimator. Since it is difficult to analytically compute the variance of a quotient, we approximate it by the variance of the sum of the numerator and denominator, as this tends to reduce the variance of the quotient. The proof of the following theorem is omitted due to lack of space.

Theorem 7 *The variance of the expression*

$$\sum_a \alpha_a \mathrm{CTR}(a,i) + \sum_a \alpha_a \mathrm{CTR}(a,1)$$

subject to $\sum_a \alpha_a = 1$ *is minimized when*

$$\alpha_a := \frac{2M(a,i)\cdot M(a,1)}{M(a,i)\sigma^2_{a,1} + M(a,1)\sigma^2_{a,i}},$$

where $\sigma^2_{a,i}$ *is the variance of the indicator random variable that is 1 when ad* a *is clicked given that ad* a *is placed in position* i*.*

It is undesirable that π is required to have no dependence on the current web page x_t when choosing the slate of ads to display, since most current ad-serving algorithms violate this assumption. However, as we have seen in Section 3.1, when this assumption is violated, exploration scavenging is no longer guaranteed to work. In the worst case, we cannot trust our estimated ADCs from data generated by an x-dependent π. Luckily, in practice, it is generally not the case that extreme scenarios like the counterexample in the proof of Theorem 1 arise. It is more likely that the existing ad-serving algorithm and the new algorithm choose among the same small set of ads to display for any given context (for example, the set of ads for which advertisers have placed bids for the current search term in the sponsored search setting) and the primary difference between policies is the order in which these ads are displayed. In such settings it is also the case that additional opportunities for exploration arise naturally. For example, sometimes ads run out of budget, removing them from consideration and forcing the ad-serving algorithm to display an alternate slate of ads.

4.4. Empirical comparison

We are interested in comparing the methods developed in this work to standard methods used in practice. A common technique for estimating ADCs borrowed from the information retrieval literature is discounted cumulative gain (Järvelin & Kekäläinen, 2002). In relation to our work, discounted cumulative gain (DCG) can be viewed as a particular way to specify the ADCs that is *not* data-dependent. In particular, given a parameter b, DCG would suggest defining $C_i = 1/log_b(b+i)$ for all i. As shown next, when we estimated the ADCs using our new method on a large set of data we get values that are very close to those calculated using DCG with $b = 2$.

We present coefficients that were computed from training on about 20 million examples obtained from the logs of "Content Match", Yahoo!'s online advertisement engine. Since we don't know the true variances $\sigma^2_{a,p}$ for the distributions over clicks, we heuristically assume they are all equal and use the estimator defined by $\alpha_a = M(a,p)\cdot M(a,1)/(M(a,p)+M(a,1))$. The following table summarizes the coefficients computed for the first four slots using the naive estimator and the new estimator, along with the DCG coefficients. As suspected, the coefficients for the new estimator are larger than the old, suggesting a reduction in bias.

	C_1	C_2	C_3	C_4
Naive	1.0	0.512090	0.369638	0.271847
New	1.0	0.613387	0.527310	0.432521
DCG	1.0	0.630930	0.5	0.430677

4.5. Toward A Realistic Application

To reduce the high variance of the direct application of exploration scavenging to internet advertising, we made use of the factoring assumption and derived the estimator given in Equation 3. Unfortunately this new estimator may still have an unacceptably large variance. By examining Equation 3, we observe that the method only benefits from examples in which the exploration policy and the new policy h choose overlapping sets of ads to display. When ads are drawn from

a large database, this may be too rare of an event.

Instead of considering policies which rank from the set of all ads, we can consider policies h_π reordering the ads which π chooses to display. A good reordering policy plausibly provides useful information to guide the choice of a new ranking policy.

We define an alternate estimator

$$\hat{V}_D(h_\pi) = \sum_{t=1}^{T} \sum_{i=1}^{\ell} r'_i C_{\sigma'(a_i,x)} \ ,$$

where $\sigma'(a_i, x)$ is the slot that h_π would assign to ad a_i in this new model. This method gives us an (unnormalized) estimate of the value of first using π to choose k ads to display in a slate and then using h_π to reorder them. This approach has small variance and quickly converges.

To illustrate our method we used a training set of 20 million examples gathered using Yahoo!'s current ad-serving algorithm π. We let the policy h_π be the policy that reorders ads to display those with the highest empirical click-through rate first, ignoring the context x. We used $r = C_{j'}/C_i$, (with coefficients given by the new unbiased method) to compute the number of clicks we expect the new policy (using h_π to reorder π's slate) to receive per click of the old policy π. Here j' is the relative position of ad a_i when the ads in the slate shown by π are reordered (in descending order) by h_π. This number, which was computed using a test set of about two million examples, turned out to be 1.086. When we computed the same quantity for the policy h'_π that reorders ads at random, we obtained 1.016. Thus, exploration scavenging strongly suggests using policy h_π over h'_π, matching our intuition.

5. Conclusion

We study the process of "exploration scavenging," reusing information from one policy to evaluate a new policy, and provide procedures that work *without* randomized exploration, as is commonly required. This new ability opens up the possibility of using machine learning techniques in new domains which were previously inaccessible.

Using the derandomized exploration techniques described here, we show how to estimate the value of a policy reordering displayed ads on logged data *without* any information about random choices made in the past. There are several caveats to this approach, but the results appear to be quite reasonable.

Note that this methodology is simply *impossible* without considering methods for derandomized exploration, so the techniques discussed here open up new possibilities for solving problem.

Acknowledgments

We are grateful to Michael Kearns for a useful discussion of the theoretical results, and to our anonymous reviewers for their thought-provoking questions.

Classification using Discriminative Restricted Boltzmann Machines

Hugo Larochelle LAROCHEH@IRO.UMONTREAL.CA

Abstract

Recently, many applications for Restricted Boltzmann Machines (RBMs) have been developed for a large variety of learning problems. However, RBMs are usually used as feature extractors for another learning algorithm or to provide a good initialization for deep feed-forward neural network classifiers, and are not considered as a stand-alone solution to classification problems. In this paper, we argue that RBMs provide a self-contained framework for deriving competitive non-linear classifiers. We present an evaluation of different learning algorithms for RBMs which aim at introducing a discriminative component to RBM training and improve their performance as classifiers. This approach is simple in that RBMs are used directly to build a classifier, rather than as a stepping stone. Finally, we demonstrate how discriminative RBMs can also be successfully employed in a semi-supervised setting.

1. Introduction

Restricted Boltzmann Machines (RBMs) (Smolensky, 1986) are generative models based on latent (usually binary) variables to model an input distribution, and have seen their applicability grow to a large variety of problems and settings in the past few years. From binary inputs, they have been extended to model various types of input distributions (Welling et al., 2005; Hinton et al., 2006). Conditional versions of RBMs have also been developed for collaborative filtering (Salakhutdinov et al., 2007) and to model motion capture data (Taylor et al., 2006) and video sequences (Sutskever & Hinton, 2007).

RBMs have been particularly successful in classification problems either as feature extractors for text and image data (Gehler et al., 2006) or as a good initial training phase for deep neural network classifiers (Hinton, 2007). However, in both cases, the RBMs are merely the first step of another learning algorithm, either providing a preprocessing of the data or an initialization for the parameters of a neural network. When trained in an unsupervised fashion, RBMs provide no guarantees that the features implemented by their hidden layer will ultimately be useful for the supervised task that needs to be solved. More practically, model selection can also become problematic, as we need to explore jointly the space of hyper-parameters of both the RBM (size of the hidden layer, learning rate, number of training iterations) and the supervised learning algorithm that is fed the learned features. In particular, having two separate learning phases (feature extraction, followed by classifier training) can be problematic in an online learning setting.

In this paper, we argue that RBMs can be used successfully as stand-alone non-linear classifiers alongside other standard classifiers like neural networks and Support Vector Machines, and not only as feature extractors. We investigate training objectives for RBMs that are more appropriate for training classifiers than the common generative objective. We describe Discriminative Restricted Boltzmann Machines (DRBMs), i.e. RBMs that are trained more specifically to be good classification models, and Hybrid Discriminative Restricted Boltzmann Machines (HDRBMs) which explore the space between discriminative and generative learning and can combine their advantages. We also demonstrate that RBMs can be successfully adapted to the common semi-supervised learning setting (Chapelle et al., 2006) for classification problems. Finally, the algorithms investigated in this paper are well suited for online learning on large datasets.

2. Restricted Boltzmann Machines

Restricted Boltzmann Machines are undirected generative models that use a layer of hidden variables to model a distribution over visible variables. Though they are most often trained to only model the inputs

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

of a classification task, they can also model the joint distribution of the inputs and associated target classes (e.g. in the last layer of a Deep Belief Network in Hinton et al. (2006)). In this section, we will focus on such joint models.

We assume given a training set $\mathcal{D}_{train} = \{(\mathbf{x}_i, y_i)\}$, comprising for the i-th example an input vector $\mathbf{x}_i$ and a target class $y_i \in \{1, \ldots, C\}$. To train a generative model on such data we consider minimization of the negative log-likelihood

$$\mathcal{L}_{gen}(\mathcal{D}_{train}) = -\sum_{i=1}^{|\mathcal{D}_{train}|} \log p(y_i, \mathbf{x}_i). \quad (1)$$

An RBM with n hidden units is a parametric model of the joint distribution between a layer of hidden variables (referred to as neurons or features) $\mathbf{h} = (h_1, \ldots, h_n)$ and the observed variables made of $\mathbf{x} = (x_1, \ldots, x_d)$ and y, that takes the form

$$p(y, \mathbf{x}, \mathbf{h}) \quad \propto \quad e^{-E(y,\mathbf{x},\mathbf{h})}$$

where

$$E(y, \mathbf{x}, \mathbf{h}) \quad = \quad -\mathbf{h}^T\mathbf{W}\mathbf{x} - \mathbf{b}^T\mathbf{x} - \mathbf{c}^T\mathbf{h} - \mathbf{d}^T\vec{y} - \mathbf{h}^T\mathbf{U}\vec{y}$$

with parameters $\Theta = (\mathbf{W}, \mathbf{b}, \mathbf{c}, \mathbf{d}, \mathbf{U})$ and $\vec{y} = (1_{y=i})_{i=1}^{C}$ for C classes. This model is illustrated in Figure 2. For now, we consider for simplicity binary input variables, but the model can be easily generalized to non-binary categories, integer-valued, and continuous-valued inputs (Welling et al., 2005; Hinton et al., 2006). It is straightforward to show that

$$p(\mathbf{x}|\mathbf{h}) \quad = \quad \prod_i p(x_i|\mathbf{h})$$

$$p(x_i = 1|\mathbf{h}) \quad = \quad \text{sigm}(b_i + \sum_j W_{ji} h_j) \quad (2)$$

$$p(y|\mathbf{h}) \quad = \quad \frac{e^{d_y + \sum_j U_{jy} h_j}}{\sum_{y^*} e^{d_{y^*} + \sum_j U_{jy^*} h_j}} \quad (3)$$

where sigm is the logistic sigmoid. Equations 2 and 3 illustrate that the hidden units are meant to capture predictive information about the input vector as well as the target class. $p(\mathbf{h}|y, \mathbf{x})$ also has a similar form:

$$p(\mathbf{h}|y, \mathbf{x}) \quad = \quad \prod_j p(h_j|y, \mathbf{x})$$

$$p(h_j = 1|y, \mathbf{x}) \quad = \quad \text{sigm}(c_j + U_{jy} + \sum_i W_{ji} x_i).$$

When the number of hidden variables is fixed, an RBM can be considered a parametric model, but when it is allowed to vary with the data, it becomes a non-parametric model. In particular, Freund and Haussler (1994); Le Roux and Bengio (2008) showed that

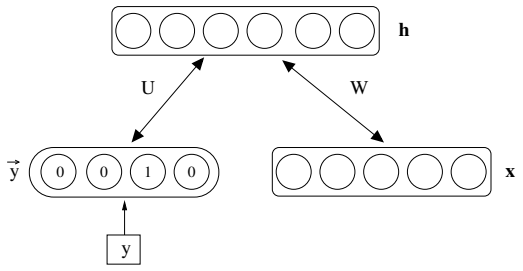

Figure 1. Restricted Boltzmann Machine modeling the joint distribution of inputs and target classes

an RBM with enough hidden units can represent any distribution over binary vectors, and that adding hidden units guarantees that a better likelihood can be achieved, unless the generated distribution already equals the training distribution.

In order to minimize the negative log-likelihood (eq. 1), we would like an estimator of its gradient with respect to the model parameters. The exact gradient, for any parameter $\theta \in \Theta$ can be written as follows:

$$\frac{\partial \log p(y_i, \mathbf{x}_i)}{\partial \theta} \quad = \quad -\mathbf{E}_{\mathbf{h}|y_i,\mathbf{x}_i}\left[\frac{\partial}{\partial \theta} E(y_i, \mathbf{x}_i, \mathbf{h})\right] + \mathbf{E}_{y,\mathbf{x},\mathbf{h}}\left[\frac{\partial}{\partial \theta} E(y, \mathbf{x}, \mathbf{h})\right].$$

Though the first expectation is tractable, the second one is not. Fortunately, there exists a good stochastic approximation of this gradient, called the contrastive divergence gradient (Hinton, 2002). This approximation replaces the expectation by a sample generated after a limited number of Gibbs sampling iterations, with the sampler's initial state for the visible variables initialized at the training sample $(y_i, \mathbf{x}_i)$. Even when using only one Gibbs sampling iteration, contrastive divergence has been shown to produce only a small bias for a large speed-up in training time (Carreira-Perpiñan & Hinton, 2005).

Online training of an RBM thus consists in cycling through the training examples and updating the RBM's parameters according to Algorithm 1, where the learning rate is controlled by λ.

Computing $p(y, \mathbf{x})$ is intractable, but it is possible to compute $p(y|\mathbf{x})$, sample from it, or choose the most probable class under this model. As shown in Salakhutdinov et al. (2007), for reasonable numbers of classes C (over which we must sum), this conditional distribution can be computed exactly and efficiently, by writing it as follows:

$$p(y|\mathbf{x}) \quad = \quad \frac{e^{d_y} \prod_{j=1}^{n} \left(1 + e^{c_j + U_{jy} + \sum_i W_{ji} x_i}\right)}{\sum_{y^*} e^{d_{y^*}} \prod_{j=1}^{n} \left(1 + e^{c_j + U_{jy^*} + \sum_i W_{ji} x_i}\right)}.$$

Algorithm 1 Training update for RBM over $(y, \mathbf{x})$ using Contrastive Divergence

Input: training pair $(y_i, \mathbf{x}_i)$ and learning rate λ
% Notation: $a \leftarrow b$ means a is set to value b
% $a \sim p$ means a is sampled from p

% Positive phase
$y^0 \leftarrow y_i$, $\mathbf{x}^0 \leftarrow \mathbf{x}_i$, $\widehat{\mathbf{h}}^0 \leftarrow \text{sigm}(\mathbf{c} + W\mathbf{x}^0 + \mathbf{U}\vec{y^0})$

% Negative phase
$\mathbf{h}^0 \sim p(\mathbf{h}|y^0, \mathbf{x}^0)$, $y^1 \sim p(y|\mathbf{h}^0)$, $\mathbf{x}^1 \sim p(\mathbf{x}|\mathbf{h}^0)$
$\widehat{\mathbf{h}}^1 \leftarrow \text{sigm}(\mathbf{c} + W\mathbf{x}^1 + \mathbf{U}\vec{y^1})$

% Update
for $\theta \in \Theta$ **do**
$\theta \leftarrow \theta - \lambda \left(\frac{\partial}{\partial \theta} E(y^0, \mathbf{x}^0, \widehat{\mathbf{h}}^0) - \frac{\partial}{\partial \theta} E(y^1, \mathbf{x}^1, \widehat{\mathbf{h}}^1) \right)$
end for

Precomputing the terms $c_j + \sum_i W_{ji} x_i$ and reusing them when computing $\prod_{j=1}^{n} \left(1 + e^{c_j + U_{jy^*} + \sum_i W_{ji} x_i}\right)$ for all classes y^* permits to compute this conditional distribution in time $O(nd + nC)$.

3. Discriminative Restricted Boltzmann Machines

In a classification setting, one is ultimately only interested in correct classification, not necessarily to have a good $p(\mathbf{x})$. Because our model's $p(\mathbf{x})$ can be inappropriate, it can then be advantageous to optimize directly $p(y|\mathbf{x})$ instead of $p(y, \mathbf{x})$:

$$\mathcal{L}_{disc}(\mathcal{D}_{train}) = - \sum_{i=1}^{|\mathcal{D}_{train}|} \log p(y_i|\mathbf{x}_i). \quad (4)$$

We refer to RBMs trained according to $\mathcal{L}_{disc}$ as Discriminative RBMs (DRBMs). Since RBMs (with enough hidden units) are universal approximators for binary inputs, it follows also that DRBMs are universal approximators of conditional distributions with binary inputs.

A DRBM can be trained by contrastive divergence, as has been done in conditional RBMs (Taylor et al., 2006), but since $p(y|\mathbf{x})$ can be computed exactly, we can compute the exact gradient:

$$\begin{aligned} \frac{\partial \log p(y_i|\mathbf{x}_i)}{\partial \theta} &= \sum_j \text{sigm}(o_{yj}(\mathbf{x}_i)) \frac{\partial o_{yj}(\mathbf{x}_i)}{\partial \theta} \\ &- \sum_{j, y^*} \text{sigm}(o_{y^* j}(\mathbf{x}_i)) p(y^*|\mathbf{x}_i) \frac{\partial o_{y^* j}(\mathbf{x}_i)}{\partial \theta} \end{aligned}$$

where $o_{yj}(\mathbf{x}) = c_j + \sum_k W_{jk} x_k + U_{jy}$. This gradient can be computed efficiently and then used in a stochastic gradient descent optimization. This discriminative approach has been used previously for fine-tuning the top RBM of a Deep Belief Network (Hinton, 2007).

4. Hybrid Discriminative Restricted Boltzmann Machines

The advantage brought by discriminative training usually depends on the amount of available training data. Smaller training sets tend to favor generative learning and bigger ones favor discriminative learning (Ng & Jordan, 2001). However, instead of solely relying on one or the other perspective, one can adopt a hybrid discriminative/generative approach simply by combining the respective training criteria. Though this method cannot be interpreted as a maximum likelihood approach for a particular generative model as in Lasserre et al. (2006), it proved useful here and elsewhere (Bouchard & Triggs, 2004). In this paper, we used the following criterion:

$$\mathcal{L}_{hybrid}(\mathcal{D}_{train}) = \mathcal{L}_{disc}(\mathcal{D}_{train}) + \alpha \mathcal{L}_{gen}(\mathcal{D}_{train}) \quad (5)$$

where the weight α of the generative criterion can be optimized (e.g., based on the validation set classification error). Here, the generative criterion can also be seen as a data-dependent regularizer for a DRBM. We will refer to RBMs trained using the criterion of equation 5 as Hybrid DRBMs (HDRBMs).

To train an HDRBM, we can use stochastic gradient descent and add for each example the gradient contribution due to $\mathcal{L}_{disc}$ with α times the stochastic gradient estimator associated with $\mathcal{L}_{gen}$ for that example.

5. Semi-supervised Learning

A frequent classification setting is where there are few labeled training data but many unlabeled examples of inputs. Semi-supervised learning algorithms (Chapelle et al., 2006) address this situation by using the unlabeled data to introduce constraints on the trained model. For example, for purely discriminative models, these constraints are often imposed on the decision surface of the model. In the RBM framework, a natural constraint is to ask that the model be a good generative model of the unlabeled data, which corresponds to the following objective:

$$\mathcal{L}_{unsup}(\mathcal{D}_{unlab}) = - \sum_{i=1}^{|\mathcal{D}_{unlab}|} \log p(\mathbf{x}_i) \quad (6)$$

where $\mathcal{D}_{unlab} = \{(\mathbf{x}_i)\}_{i=1}^{|\mathcal{D}_{unlab}|}$ contains unlabeled examples of inputs. To train on this objective, we can once again use a contrastive divergence approximation

of the log-likelihood gradient:

$$\frac{\partial \log p(\mathbf{x}_i)}{\partial \theta} = -\mathbb{E}_{y,\mathbf{h}|\mathbf{x}_i}\left[\frac{\partial}{\partial \theta} E(y_i, \mathbf{x}_i, \mathbf{h})\right] + \mathbb{E}_{y,\mathbf{x},\mathbf{h}}\left[\frac{\partial}{\partial \theta} E(y, \mathbf{x}, \mathbf{h})\right]$$

The contrastive divergence approximation is slightly different here. The first term can be computed in time $O(Cn + nd)$, by noticing that it is equal to

$$\mathbb{E}_{y|\mathbf{x}_i}\left[\mathbb{E}_{\mathbf{h}|y,\mathbf{x}_i}\left[\frac{\partial}{\partial \theta} E(y_i, \mathbf{x}_i, \mathbf{h})\right]\right]$$

One could either average the usual RBM gradient $\frac{\partial}{\partial \theta} E(y_i, \mathbf{x}_i, \mathbf{h})$ for each class y (weighted by $p(y|\mathbf{x}_i)$), or sample a y from $p(y|\mathbf{x}_i)$ and only collect the gradient for that value of y. In the sampling version, the online training update for this objective can be described by replacing the statement $y^0 \leftarrow y_i$ with $y^0 \sim p(y|\mathbf{x}_i)$ in Algorithm 1. We used this version in our experiments.

In order to perform semi-supervised learning, we can weight and combine the objective of equation 6 with those of equations 1, 4 or 5

$$\mathcal{L}_{semi-sup}(\mathcal{D}_{train}, \mathcal{D}_{unlab}) = \mathcal{L}_{\text{TYPE}}(\mathcal{D}_{train}) + \beta \mathcal{L}_{unsup}(\mathcal{D}_{unlab}) \quad (7)$$

where TYPE $\in \{gen, disc, hybrid\}$. Online training according to this objective simply consists in applying the appropriate update for each training example, based on whether it is labeled or not.

6. Related Work

As mentioned earlier, RBMs (sometimes also referred to as harmoniums (Welling et al., 2005)) have already been used successfully in the past to extract useful features for another supervised learning algorithm. One of the main contributions of this paper lies in the demonstration that RBMs can be used on their own without relying on another learning algorithm, and provide a self-contained framework for deriving competitive classifiers. In addition to ensuring that the features learned by the RBM's hidden layer are discriminative, this approach facilitates model selection since the discriminative power of the hidden layer units (or features) can be tracked during learning by observing the progression of classification error on a validation set. It also makes it easier to tackle online learning problems relatively to approaches where learning features (hidden representation) and learning to classify are done in two separate phases (Hinton et al., 2006; Bengio et al., 2007).

Gehler et al. (2006); Xing et al. (2005) have shown that the features learned by an RBM trained by ignoring the labeled targets can be useful for retrieving documents or classifying images of objects. However, in both these cases, the extracted features were linear in the input, were not trained discriminatively and had to be fed to another learning algorithm which ultimately performed classification. McCallum et al. (2006) presented Multi-Conditional Learning (MCL)[1] for harmoniums in order to introduce a discriminative component to harmoniums' training, but the learned features still had to be fed to another learning algorithm.

RBMs can also provide a good initialization for the parameters of neural network classifiers (Hinton, 2007), however model selection issues arise, for instance when considering the appropriate number of learning updates and the magnitude of learning rates of each training phase. It has also been argued that the generative learning aspect of RBM training was a key element to their success as good starting points for neural network training (Bengio et al., 2007), but the extent to which the final solution for the parameters of the neural network is influenced by generative learning is not well controlled. HDRBMs can be seen as a way of addressing this issue.

Finally, though semi-supervised learning was never reported for RBMs before, Druck et al. (2007) introduced semi-supervised learning in hybrid generative/discriminative models using a similar approach to the one presented in section 5. However, they worked with log-linear models, whereas the RBMs used here can perform non-linear classification. Log-linear models depend much more on the discriminative quality of the features that are fed as input, whereas an RBM can learn useful features using their hidden variables, at the price of non-convex optimization.

7. Experiments

We present experiments on two classification problems: character recognition and text classification. In all experiments, we performed model selection on a validation set before testing. For the different RBM models, model selection[2] consisted in finding good values for

[1] We experimented with a version of MCL for the RBMs considered in this paper, however the results did not improve on those of HDRBMs.

[2] Model selection was done with a grid-like search over λ (between 0.0005 and 0.1, on a log scale), n (50 to 6000), α for HDRBMs (0 to 0.5, on a log scale) and β for semi-supervised learning (0, 0.01 or 0.1). In general, bigger values of n were found to be more appropriate with more generative learning. If no local minima was apparent, the

the learning rate λ, the size of the hidden layer n and good weights for the different types of learning (generative and semi-supervised weights). Also, the number of iterations over the training set was determined using early stopping according to the validation set classification error, with a look ahead of 15 iterations.

7.1. Character Recognition

We evaluated the different RBM models on the problem of classifying images of digits. The images were taken from the MNIST dataset, where we separated the original training set into training and validation sets of 50000 and 10000 examples and used the standard test set of 10000 examples. The results are given in Table 1. The ordinary RBM model is trained generatively (to model (x, y)), whereas RBM+NNet is an unsupervised RBM used to initialize a one-hidden layer supervised neural net (as in (Bengio et al., 2007)). We give as a comparison the results of a Gaussian kernel SVM and of a regular neural network (random initialization, one hidden layer, hyperbolic tangent hidden activation functions).

First, we observe that a DRBM outperforms a generative RBM. However, an HDRBM appears able to make the best out of discriminative and generative learning and outperforms the other models.

We also experimented with a sparse version of the HDRBM model, since sparsity is known to be a good characteristic for features of images. Sparse RBMs were developed by Lee et al. (2008) in the context of deep neural networks. To introduce sparsity in the hidden layer of an RBM in Lee et al. (2008), after each iteration through the whole training set, the biases $\mathbf{c}$ in the hidden layer are set to a value that maintains the average of the conditional expected value of these neurons to an arbitrarily small value. This procedure tends to make the biases negative and large. We follow a different approach by simply subtracting a small constant δ value, considered as an hyper-parameter[3], from the biases after each update, which is more appropriate in an online setting or for large datasets.

This sparse version of HDRBMs outperforms all the other RBM models, and yields significantly lower classification error then the SVM and the standard neural network classifiers. The performance achieved by the sparse HDRBM is particularly impressive when compared to reported performances for Deep Belief Networks (1.25% in Hinton et al. (2006)) or of a deep neural network initialized using RBMs (around 1.2% in Bengio et al. (2007) and Hinton (2007)) for the MNIST dataset with 50000 training examples.

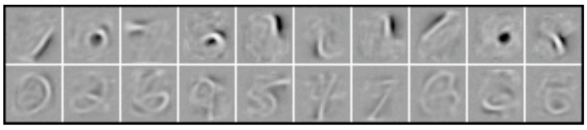

Figure 2. Filters learned by the HDRBM on the MNIST dataset. The top row shows filters that act as spatially localized stroke detectors, and the bottom shows filters more specific to a particular shape of digit.

Table 1. Comparison of the classification performances on the MNIST dataset. SVM results for MNIST were taken from http://yann.lecun.com/exdb/mnist/. On this dataset, differences of 0.2% in classification error is statistically significant.

Model	Error
RBM ($\lambda = 0.005$, $n = 6000$)	3.39%
DRBM ($\lambda = 0.05$, $n = 500$)	1.81%
RBM+NNet	1.41%
HDRBM ($\alpha = 0.01$, $\lambda = 0.05$, $n = 1500$)	1.28%
Sparse HDRBM (idem + $n = 3000$, $\delta = 10^{-4}$)	**1.16%**
SVM	1.40%
NNet	1.93%

The discriminative power of the HDRBM can be better understood by looking a the rows of the weight matrix $\mathbf{W}$, which act as filter features. Figure 2 displays some of these learned filters. Some of them are spatially localized stroke detectors which can possibly be active for a wide variety of digit images, and others are much more specific to a particular shape of digit.

7.2. Document Classification

We also evaluated the RBM models on the problem of classifying documents into their corresponding newsgroup topic. We used a version of the 20-newsgroup dataset[4] for which the training and test sets contain documents collected at different times, a setting that is more reflective of a practical application. The original training set was divided into a smaller training

grid was extended. The biases $\mathbf{b}$, $\mathbf{c}$ and $\mathbf{d}$ were initialized to 0 and the initial values for the elements of the weight matrices $\mathbf{U}$ and $\mathbf{W}$ were each taken from uniform samples in $\left[-m^{-0.5}, m^{-0.5}\right]$, where m is the maximum between the number of rows and columns of the matrix.

[3]To chose δ, given the selected values for λ and α for the "non sparse" HDRBM, we performed a second grid-search over δ (10^{-5} and 0.1, on a log scale) and the hidden layer size, testing bigger hidden layer sizes then previously selected.

[4]This dataset is available in Matlab format here: http://people.csail.mit.edu/jrennie/20Newsgroups/20news-bydate-matlab.tgz

set and a validation set, with 9578 and 1691 examples respectively. The test set contains 7505 examples. We used the 5000 most frequent words for the binary input features. The results are given in Figure 3(a). We also provide the results of a Gaussian kernel SVM[5] and of a regular neural network for comparison.

Once again, HDRBM outperforms the other RBM models. However, here the generatively trained RBM performs better then the DRBMs. The HDRBM also outperforms the SVM and neural network classifiers.

In order to get a better understanding of how the HDRBM solves this classification problem, we first looked at the weights connecting each of the classes to the hidden neurons. This corresponds to the columns $\mathbf{U}_{\cdot y}$ of the weight matrix $\mathbf{U}$. Figure 3(b) shows a similarity matrix $\mathbf{M}(\mathbf{U})$ for the weights of the different newsgroups, where $\mathbf{M}(\mathbf{U})_{y_1 y_2} = \text{sigm}(\mathbf{U}_{\cdot y_1}^T \mathbf{U}_{\cdot y_2})$. We see that the HDRBM does not use different neurons for different newsgroups, but shares some of those neurons for newsgroups that are semantically related. Another interesting visualization of this characteristic is given in Figure 3(c), where the columns of $\mathbf{U}$ were projected on their two principal components. In both cases, we see that the HDRBM tends to share neurons for similar topics, such as computer (`comp.*`), science (`sci.*`) and politics (`talk.politics.*`), or secondary topics such as sports (`rec.sports.*`) and other recreational activities (`rec.autos` and `rec.motorcycles`).

Table 2 also gives the set of words used by the HDRBM to recognize some of the newsgroups. To obtain this table we proceeded as follows: for each newsgroup y, we looked at the 20 neurons with the largest weight among $\mathbf{U}_{\cdot y}$, aggregated (by summing) the associated input-to-hidden weight vectors, sorted the words in decreasing order of their associated aggregated weights and picked the first words according to that order. This procedure attempts to approximate the positive contribution of the words to the conditional probability of each newsgroup.

7.3. Semi-supervised Learning

We evaluated our semi-supervised learning algorithm for the HDRBM on both the digit recognition and document classification problems. We also experimented with a version (noted MNIST-BI) of the MNIST dataset proposed by Larochelle et al. (2007) where background images have been added to MNIST digit images. This version corresponds to a much harder problem, but it will help to illustrate the advantage brought by semi-supervised learning in HDRBMs. The HDRBM trained on this data used truncated exponential input units (see (Bengio et al., 2007)).

In this semi-supervised setting, we reduced the size of the labeled training set to 800 examples, and used some of the remaining data to form an unlabeled dataset $\mathcal{D}_{unlab}$. The validation set was also reduced to 200 labeled examples. Model selection[6] covered all the parameters of the HDRBM as well as the unsupervised objective weight β of equation 7. For comparison purposes, we also provide the performance of a standard non-parametric semi-supervised learning algorithm based on function induction (Bengio et al., 2006b), which includes as a particular case or is very similar to other non-parametric semi-supervised learning algorithms such as Zhu et al. (2003). We provide results for the use of a Gaussian kernel (NP-Gauss) and a data-dependent truncated Gaussian kernel (NP-Trunc-Gauss) used in Bengio et al. (2006b), which essentially outputs zero for pairs of inputs that are not near neighbors. The experiments on the MNIST and MNIST-BI (with background images) datasets used 5000 unlabeled examples and the experiment on 20-newsgroup used 8778. The results are given in Table 3, where we observe that semi-supervised learning consistently improves the performance of the HDRBM.

The usefulness of non-parametric semi-supervised learning algorithms has been demonstrated many times in the past, but usually so on problems where the dimensionality of the inputs is low or the data lies on a much lower dimensional manifold. This is reflected in the result on MNIST for the non-parametric methods. However, for high dimensional data with many factors of variation, these methods can quickly suffer from the curse of dimensionality, as argued by Bengio et al. (2006a). This is also reflected in the results for the MNIST-BI dataset which contains many factors of variation, and for the 20-newsgroup dataset where the input is very high dimensional.

Finally, it is important to notice that semi-supervised learning in HDRBMs proceeds in an online fashion and hence could scale to very large datasets, unlike more standard non-parametric methods.

7.4. Relationship with Feed-forward Neural Networks

There are several similarities between discriminative RBMs and neural networks. In particular, the computation of $p(y|\mathbf{x})$ could be implemented by a single layer neural network with softplus and softmax acti-

[5] We used `libSVM` v2.85 to train the SVM model

[6] $\beta = 0.1$ for MNIST and 20-newsgroup and $\beta = 0.01$ for MNIST-BI was found to perform best.

Model	Error
RBM ($\lambda = 0.0005$, $n = 1000$)	24.9%
DRBM ($\lambda = 0.0005$, $n = 50$)	27.6%
RBM+NNet	26.8%
HDRBM ($\alpha = 0.005$, $\lambda = 0.1$, $n = 1000$)	**23.8%**
SVM	32.8%
NNet	28.2%

Table 2. Most influential words in the HDRBM for predicting some of the document classes

Class	**Words**
alt.atheism	bible, atheists, benedikt, atheism, religion
misc.forsale	sell, condition, floppy, week, am, obo
sci.crypt	sternlight, bontchev, nsa, escrow, hamburg
comp.graphics	tiff, ftp, window, gif, images, pixel
rec.autos	cars, ford, autos, sho, toyota, roads
talk.politics.guns	firearms, handgun, firearm, gun, rkba

Table 3. Comparison of the classification errors in semi-supervised learning setting. The errors in bold are statistically significantly better.

Model	MNIST	MNIST-BI	20-news
HDRBM	9.73%	42.4%	40.5%
Semi-sup HDRBM	8.04%	**37.5%**	**31.8%**
NP-Gauss	10.60%	66.5%	85.0%
NP-Trunc-Gauss	**7.49%**	61.3%	82.6%

vation functions in its hidden and output layers respectively, with a special structure in the output and hidden weights where the value of the output weights is fixed and many of the hidden layer weights are shared.

The advantage of working in the framework of RBMs is that it provides a natural way to introduce generative learning, which we used here to derive a semi-supervised learning algorithm. As mentioned earlier, a form of generative learning can be introduced in standard neural networks simply by using RBMs to initialize the hidden layer weights. However the extent to which the final solution for the parameters of the neural network is influenced by generative learning is not well controlled. This might explain the superior performance obtained by a HDRBM compared to a single hidden layer neural network initialized with an RBM (RBM+NNet in the tables).

8. Conclusion and Future Work

We argued that RBMs can and should be used as stand-alone non-linear classifiers alongside other standard and more popular classifiers, instead of merely being considered as simple feature extractors. We evaluated different training objectives that are more appropriate to train an RBM in a classification setting. These discriminative versions of RBMs integrate the process of discovering features of inputs with their use in classification, without relying on a separate classi-

fier. This insures that the learned features are discriminative and facilitates model selection. We also presented a novel but straightforward semi-supervised learning algorithm for RBMs and demonstrated its usefulness for complex or high dimensional data.

For future work, we would like to investigate the use of discriminative versions of RBMs in more challenging settings such as in multi-task or structured output problems. The analysis of the target weights for the 20-newsgroup dataset seem to indicate that RBMs would be good at capturing the conditional statistical relationship between multiple tasks or in the components in a complex target space. Exact computation of the conditional distribution for the target is not tractable anymore, but there exists promising techniques such as mean-field approximations that could estimate that distribution. Moreover, in the 20-newsgroup experiment, we only used 5000 words in input because generative training using Algorithm 1 does not exploit the sparsity of the input, unlike an SVM or a DRBM (since in that case the sparsity of the input makes the discriminative gradient sparse too). Motivated by this observation, we intend to explore ways to introduce generative learning in RBMs and HDRBMs which would be less computationally expensive when the input vectors are large but sparse.

Acknowledgments

We thank Dumitru Erhan for discussions about sparse RBMs and anonymous reviewers for helpful comments.

Abstract

The main objective of transfer in reinforcement learning is to reduce the complexity of learning the solution of a target task by effectively reusing the knowledge retained from solving a set of source tasks. In this paper, we introduce a novel algorithm that transfers samples (i.e., tuples $\langle s, a, s', r \rangle$) from source to target tasks. Under the assumption that tasks have similar transition models and reward functions, we propose a method to select samples from the source tasks that are mostly similar to the target task, and, then, to use them as input for batch reinforcement-learning algorithms. As a result, the number of samples an agent needs to collect from the target task to learn its solution is reduced. We empirically show that, following the proposed approach, the transfer of samples is effective in reducing the learning complexity, even when some source tasks are significantly different from the target task.

1. Introduction

The main objective of transfer in Reinforcement Learning (RL) is to reduce the learning time. In fact, the solution of a set of *source* tasks can provide useful information about how to solve a related *target* task, thus reducing the amount of experience needed to solve it. In order to design an effective transfer algorithm, two aspects must be taken into account: *what* to transfer, that is the knowledge retained from the source tasks, and *when* to transfer, that is the identification of tasks from which transfer is likely to be effective.

There exists a much empirical evidence about the effectiveness of techniques such as *task decomposition*, *options*, *shaping rewards*, *exploration strategies*, in improving the learning speed of RL algorithms in single-task problems. Many studies focus on extending such techniques to the transfer scenario. In particular, hierarchical solutions are often used (Şimşek et al., 2005; Mehta et al., 2005) to augment the action space with policies suitable for the solution of a wide range of tasks sharing the same dynamics, but with different goals. In (Konidaris & Barto, 2007), a set of options is learned in an *agent space* defined by a set of features shared across the tasks, thus making the options reusable even in tasks with different state spaces. The improvement of learning speed can also be obtained through direct transfer of solutions from source to target task. In this scenario, the main issue is to map the solution learned in a source task to the state-action space of the target task, thus initializing the learning algorithm to a convenient solution. Different aspects of a learning algorithm can be initialized, such as value functions, policies, and approximator structure (Taylor et al., 2007, and references therein).

Although these approaches study how the transfer of different elements from source to target tasks can impact on the performance of an RL algorithm, they often rely on the assumption that the tasks are strictly related and they do not address the problem of *negative transfer* (Rosenstein et al., 2005). In fact, transfer may bias the learning process towards solutions that are completely different from the optimal one, thus worsening the learning performance. Some works focus on the definition of measures of relatedness between tasks that can be used to select from which source tasks transfer is actually convenient. An experimental analysis of measures that estimate the expected speed-up on the basis of information such as policy overlapping, Q-values, and reward structure is reported in (Carroll & Seppi, 2005). Unfortunately, it is often difficult to compute these measures before actually solving the target task, and, thus, they can be used only to analyze the effectiveness of a transfer

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

method. In (Ferns et al., 2004), different metrics for the distance between tasks are proposed and theoretical bounds on the difference between the corresponding optimal value functions are derived.

In this paper, we focus on a perspective that received little attention so far, the transfer of samples. We propose a mechanism that selectively transfers samples from source to target tasks on the basis of the similarity of source tasks with the samples collected in the target task. We introduce a criterion to select from which sources transfer should occur, and, within each task, which samples are more likely to speed-up the learning process. As a result, through selective transfer of samples, it is possible to reduce the number of samples needed to solve the target task.

The paper is organized as follows. In Section 2 we introduce notation and we briefly review batch RL. In Section 3 we propose a novel mechanism for transfer of samples in batch RL algorithms. In Section 4 we report the experimental results of sample transfer. In Section 5 we relate our work with other transfer-learning approaches. Finally, in Section 6 we draw conclusions, and we propose directions for future works.

2. Batch Reinforcement Learning

In RL, the interaction between the agent and the environment is modeled as a discrete-time Markov Decision Process (MDP). An MDP is a tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma \rangle$, where $\mathcal{S}$ is the state space, $\mathcal{A}$ is the action space, $\mathcal{P} : \mathcal{S} \times \mathcal{A} \to \Pi(\mathcal{S})$ is the transition model that assigns to each state-action pair a probability distribution over $\mathcal{S}$, $\mathcal{R} : \mathcal{S} \times \mathcal{A} \to \Pi(\mathbb{R})$ is the reward function that assigns to each state-action pair a probability distribution over $\mathbb{R}$, $\gamma \in [0, 1)$ is the discount factor. At each time step, the agent chooses an action according to its current *policy* $\pi : \mathcal{S} \to \Pi(\mathcal{A})$, which maps each state to a probability distribution over actions. The goal of an RL agent is to maximize the expected sum of discounted rewards, that is to learn an optimal policy π^* that leads to the maximization of the value function in each state. The optimal action-value function $Q^*(s, a)$ is defined by the Bellman equations

$$Q^*(s,a) = \sum_{s'} \mathcal{P}(s'|s,a) \left[R(s,a) + \gamma \max_{a'} Q^*(s',a') \right],$$

where $R(s, a) = E[\mathcal{R}(s, a)]$ is the expected reward.

One of the main drawbacks of online RL algorithms (e.g., Q-learning) when applied to real-world problems is the large amount of experience needed to solve a task. In order to overcome this drawback, batch approaches have been proposed. The main idea is to distinguish between the exploration strategy that collects samples of the form $\langle s, a, s', r \rangle$ (*sampling* phase), and the offline learning algorithm that, on the basis of the samples, computes the approximation of the action-value function (*learning* phase). In this paper, we focus on fitted algorithms, although the proposed transfer mechanism can be applied to any batch RL algorithm. The idea underlying fitted solutions (Ernst et al., 2005, and references therein) is to reformulate the learning of the value function as a sequence of regression problems. Given a set of samples, Fitted Q-Iteration (FQI)(Ernst et al., 2005) estimates the optimal action-value function by iteratively extending the optimization horizon. At the first iteration, the algorithm defines a regression problem for a 1-step problem, in which the action-value function is equal to the reward function. An approximation is computed running a chosen regression algorithm on the available samples. Thereafter, at each iteration k, corresponding to a k-step horizon, a new regression problem is stated, in which the training samples are computed exploiting the approximation of the action-value function at the previous iteration.

3. Transfer of Samples in Batch Reinforcement Learning

We formulate the transfer problem as the problem of solving a target task given a set of source tasks drawn according to a given probability distribution defined on a set of tasks which differ in either the transition model or the reward function, or both, but share the same state-action space.

Definition 1 *A* task *T is an MDP defined by the tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{P}_T, \mathcal{R}_T, \gamma \rangle$, in which the transition model $\mathcal{P}_T$ defines the* dynamics*, and the reward function $\mathcal{R}_T$ defines the* goal*.*

Definition 2 *An* environment *E is defined by the tuple $\langle \mathcal{T}, \Omega \rangle$, where $\mathcal{T}$ is the* task space *and Ω is the* task distribution *that provides the probability of a task $T \in \mathcal{T}$ to occur.*

In batch RL algorithms, the element that mainly affects the learning performance is the set of samples used to feed the learning algorithm, the more informative the samples the better the approximation. We focus on the way this set of samples can be augmented by the inclusion of samples drawn from a set of source tasks. The basic intuition underlying this idea is that, since tasks are related through the task distribution Ω, some of the source tasks are likely to contain samples similar to those in the target task. Therefore, we expect the transfer of samples to improve performance of

batch RL algorithms even when a very limited number of samples have been actually collected from the target task. This improvement is particularly important in domains where sampling is slow and expensive (e.g., robotic applications).

More formally, we consider the scenario in which a set of n source tasks $\{S_k\}$, with $S_k \in \mathcal{T}$ and $k \in \mathbb{N}_n$, drawn from Ω are available. From each source task m samples have been collected, while only $t \ll m$ samples are available from the target task T. Let $\{\widehat{S}_k\}$ and $\widehat{T}$ be the sample sets for the source and target tasks respectively. The transfer algorithm selects a set of samples from the source tasks that are used to augment $\widehat{T}$, thus building a new set of samples $\widetilde{T}$. Finally, samples in $\widetilde{T}$ are used as input for the learning algorithm.

3.1. Task Compliance

The main problem of transferring samples across tasks is to avoid negative transfer, that is the transfer of samples from source tasks that are significantly different from the target task. Therefore, we need to identify which source tasks are more likely to have samples similar to those in the target task. Alternatively, this problem can be stated as a *model identification problem*. Let us consider the following scenario: The task space $\mathcal{T}$ contains n tasks, and m samples have been already collected from each task. Let T be a new task drawn according to Ω and $\widehat{T}$ the set of samples collected from it, with $|\widehat{T}| = t \ll m$. Since the transfer of samples from all the tasks in $\mathcal{T}$ may worsen the performance in T, we need to identify which of the previously solved tasks is actually T according to the available samples. Starting from a uniform prior over the tasks in $\mathcal{T}$, we compute the posterior distribution as the probability of a task to be the model from which samples in $\widehat{T}$ are drawn. As the number of samples t increases, the posterior distribution is updated accordingly until the total probability mass concentrates on the task equal to T. Then, the m samples previously collected in the task equal to T can be added to $\widehat{T}$ and used to feed the batch RL algorithm, thus improving its learning performance.

In the general case in which $\mathcal{T}$ is infinite or contains many tasks, the probability to have one source task identical to the target task is negligible. Thus, instead of the probability of a source task to generate *all* the samples collected in the target task, we compute its *compliance* with T as the *average* probability of generating the samples in $\widehat{T}$. Then, we transfer samples from source tasks proportionally to their compliance with the target task.

Let us consider a source task S and the set of target samples $\widehat{T}$. Given a state-action pair $\langle s, a\rangle$, the probability of S to be the model from which the target samples in $\langle s, a\rangle$ are extracted, that is the likelihood of the model in $\langle s, a\rangle$, can be simply computed by applying the Bayes theorem as [1]

$$\begin{aligned} P\left(S|\widehat{T}_{\langle s,a\rangle}\right) &\propto P\left(\widehat{T}_{\langle s,a\rangle}|S\right) P(S) \\ &= \prod_{\tau_i \in \widehat{T}_{\langle s,a\rangle}} P(\tau_i|S)\, P(S) \\ &= \prod_{\tau_i \in \widehat{T}_{\langle s,a\rangle}} \mathcal{P}_S(s'_i|s_i,a_i)\mathcal{R}_S(r_i|s_i,a_i) P(S)\,, \end{aligned} \quad (1)$$

where $\widehat{T}_{\langle s,a\rangle} = \{\tau_i \in \widehat{T} | s_i = s, a_i = a\}$, $P(S)$ is the *prior* on the source task S, and $P(S|\widehat{T}_{\langle s,a\rangle})$ is the *posterior* distribution over the source tasks in $\langle s, a\rangle$.

Unfortunately, the posterior probability cannot be immediately computed without the exact model of S. On the other hand, we have a set of m samples $\widehat{S}$ previously collected in S, from which an approximation of the continuous model can be computed. In the following, with an abuse of notation, with $\widehat{T}$ and $\widehat{S}$ we denote both the sets of samples and the model approximations built on them. Let $\tau_i = \langle s_i, a_i, s'_i, r_i\rangle$ be a sample in $\widehat{T}$, the probability of this sample to be generated by S given the set of source samples $\widehat{S}$ is

$$P(\tau_i|\widehat{S}) = \mathcal{P}_{\widehat{S}}(s'_i|s_i,a_i)\mathcal{R}_{\widehat{S}}(r_i|s_i,a_i),$$

where $\mathcal{P}_{\widehat{S}}$ and $\mathcal{R}_{\widehat{S}}$ are the approximated transition and reward models respectively. Since in continuous spaces the probability to have samples in the same state-action pair is negligible, it is necessary to use an approximation that generalizes over all the samples close to $\langle s_i, a_i\rangle$. In particular, we follow the kernel-based approximation proposed in (Jong & Stone, 2007).

Let $\varphi(\cdot)$ be a kernel function (e.g., a Gaussian kernel $\varphi(x) = \exp(-x^2/\delta)$ with bandwidth δ) applied to a given distance metric d (e.g., Euclidean or Mahalanobis distance). First of all, we define the similarity (*compliance* in the following) between the experience tuple τ_i and the experience tuples $\sigma_j \in \widehat{S}$ in terms of dynamics and reward. We define the compliance of τ_i with respect to σ_j for the transition model as

$$\lambda^{\mathcal{P}}_{ij} = w_{ij} \cdot \varphi\left(\frac{d(s'_i, s_i + (s'_j - s_j))}{\delta_{s'}}\right),$$

where

$$w_{ij} = \frac{\varphi\left(\frac{d(\langle s_i,a_i\rangle,\langle s_j,a_j\rangle)}{\delta_{sa}}\right)}{\sum_{l=1}^{m} \varphi\left(\frac{d(\langle s_i,a_i\rangle,\langle s_l,a_l\rangle)}{\delta_{sa}}\right)}.$$

[1] We assume that samples are mutually independent.

While the first term (w_{ij}) of $\lambda^{\mathcal{P}}_{ij}$ is a weight that takes into consideration the relative closeness of the two samples in the state-action space, the second term measures the similarity of the outcome. In particular, under the assumption that the transition model is continuous in the state-action space, it measures the distance between s'_i and the state obtained by applying the state transition $(s'_j - s_j)$ of σ_j to state s_i (see Jong & Stone, 2007). Therefore, the dynamics of τ_i is highly compliant with that of σ_j when they are close and their state transitions are similar.
Similarly, the compliance of the reward in τ_i with respect to that of σ_j is defined as

$$\lambda^{\mathcal{R}}_{ij} = w_{ij}\varphi\left(\frac{|r_i - r_j|}{\delta_r}\right).$$

The approximated transition and reward models are the average of the compliance between τ_i and all the samples in $\widehat{S}$

$$\mathcal{P}_{\widehat{S}}(s'_i|s_i,a_i) = \frac{1}{Z^{\mathcal{P}}}\sum_{j=1}^{m}\lambda^{\mathcal{P}}_{ij};\ \ \mathcal{R}_{\widehat{S}}(r_i|s_i,a_i) = \frac{1}{Z^{\mathcal{R}}}\sum_{j=1}^{m}\lambda^{\mathcal{R}}_{ij},$$

where $Z^{\mathcal{P}}$ and $Z^{\mathcal{R}}$ are normalization terms. Finally, we define the *compliance* of τ_i to S approximated using samples in $\widehat{S}$ as

$$\lambda_i = P(\tau_i|\widehat{S}) = \frac{1}{Z^{\mathcal{P}}Z^{\mathcal{R}}}\left(\sum_{j=1}^{m}\lambda^{\mathcal{P}}_{ij}\right)\left(\sum_{j=1}^{m}\lambda^{\mathcal{R}}_{ij}\right).$$

Recalling Equation 1, given the compliance of samples in $\langle s,a\rangle$, the probability of the model in $\langle s,a\rangle$ becomes

$$P\left(S|\widehat{T}_{\langle s,a\rangle}\right) \propto \prod_{\tau_i\in\widehat{T}_{\langle s,a\rangle}}\lambda_i P(S). \tag{2}$$

Starting from the probability in each state-action pair, we compute a global measure of the probability for the task to contain samples similar to target samples. We define the compliance of a task S as the average likelihood computed over each state-action pair experienced in the target task.

Definition 3 *Given the target samples $\widehat{T}$ and the source samples $\widehat{S}$, the* task compliance *of S is*

$$\Lambda = \frac{1}{|\widehat{U}|}\sum_{\langle s,a\rangle\in\widehat{U}} P\left(S|\widehat{T}_{\langle s,a\rangle}\right), \tag{3}$$

where $\widehat{U}$ contains all the distinct state-action pairs in the samples of $\widehat{T}$.

Since the probability to have two samples in the very same state-action pair is negligible, it follows that $|\widehat{U}| = |\widehat{T}| = t$ and the previous definition reduces to

$$\Lambda = \frac{1}{t}\sum_{i=1}^{t}\lambda_i P(S), \tag{4}$$

where $P(S)$ is a prior on the source task. When n source tasks with m samples each are available, and t samples are collected from T, the computation of the task compliance has a time complexity of $\Theta(nmt)$.

3.2. Sample Relevance

Although the measure of compliance is effective in identifying which sources, in average, are more convenient to transfer samples from, it does not provide any suggestion about which samples in $\widehat{S}$ are actually better to transfer. In the following, we introduce the concept of *relevance* of each sample $\sigma_j \in \widehat{S}$. The idea is to use the compliance of σ_j with the target task. Unfortunately, in this case, the measure of compliance is often unreliable because of a poor approximation of the target task. In fact, while each source task contains m samples, only $t \ll m$ samples are available for the target task. As a result, it may happen that the compliance of σ_j is computed according to samples τ_i that are significantly far in the state-action space. Therefore, we need a formulation of relevance strictly related to the compliance whenever the number of samples in $\widehat{T}$ close to σ_j is sufficient, while tending to a default value when the compliance is not reliable. Given the definition of compliance $\lambda^{\mathcal{P}}_{ji}$ and $\lambda^{\mathcal{R}}_{ji}$ of σ_j with a sample τ_i, the compliance of σ_j with the approximated model of the target task $\widehat{T}$ is

$$\lambda_j = P(\sigma_j|\widehat{T}) = \frac{1}{Z^{\mathcal{P}}Z^{\mathcal{R}}}\left(\sum_{i=1}^{t}\lambda^{\mathcal{P}}_{ji}\right)\left(\sum_{i=1}^{t}\lambda^{\mathcal{R}}_{ji}\right). \tag{5}$$

Let the samples τ_i be sorted in ascending order according to w_{ji}. We compute the average distance between σ_j and the samples $\tau_i \in \widehat{T}$ as

$$d_j = \frac{1}{h_j}\sum_{i=1}^{h_j} d(\langle s_j,a_j\rangle, \langle s_i,a_i\rangle), \tag{6}$$

where h_j is such that $\sum_{i=1}^{h_j} w_{ji} < \mu$, where $\mu \in (0;1]$ determines the fraction of the total number of samples considered in the computation of the average distance.

Definition 4 *Given the compliance λ_j and the average distance d_j, the* relevance *of σ_j is defined as*

$$\rho_j = \rho(\overline{\lambda}_j, d_j) = e^{-\left(\frac{\overline{\lambda}_j - 1}{d_j}\right)^2}, \tag{7}$$

where $\overline{\lambda}_j$ is the compliance normalized over all the samples in $\widehat{S}$.

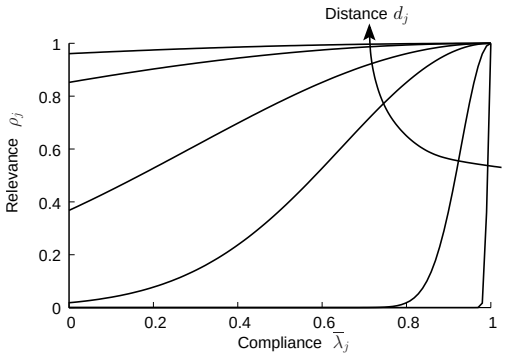

Figure 1. Relevance function for different values of d_j.

Algorithm 1 The sample transfer algorithm

Input: source tasks $\{S_k\}_{k\in\mathbb{N}_n}$, target task T
Parameters: δ_{sa}, $\delta_{s'}$, δ_r, t, m
Output: transferred sample set $\widetilde{T}$
for $k = 1$ to n **do**
  $\widehat{S}_k \leftarrow$ sampling(S_k, m)
end for
$\widehat{T} \leftarrow$ sampling(T, t)
for $k = 1$ to n **do**
  $\Lambda_k \leftarrow$ compliance$(\widehat{S}_k, \widehat{T})$
  for $\sigma_j \in \widehat{S}_k$ **do**
    $\rho_j \leftarrow$ relevance$(\sigma_j, \widehat{T})$
  end for
  Draw $(m-t)\overline{\Lambda}_k$ samples from $\widehat{S}_k$ proportionally to ρ_j
end for
Put the additional samples in $\widehat{T}$ and form the sample set $\widetilde{T}$

The relevance function is shown in Figure 1 for different values of distance d_j. As it can be noticed, sample σ_j may have high relevance in two distinct cases: *(i)* where there is a number of close samples τ_i which it is compliant with, *(ii)* where there are no close samples and, independently from the compliance, we assume a high relevance value. The assumption underlying this definition is that, whenever there is no evidence against the transfer of a sample, it is convenient to transfer it. In fact, in transfer problems the learner often needs to infer knowledge about unexplored regions of the target task. In these regions, the algorithm selects samples from the most compliant source tasks. The assumption is that samples far from target samples, but drawn from highly compliant tasks, are worth transferring, since they provide information in regions that have not been actually experienced.

3.3. Transfer of Samples

The actual transfer process is based on the compliance of the source tasks with the target samples and on the relevance of samples within each source task. For sake of simplicity, we bound the number of samples used by the learning algorithm to m. Since $|\widehat{T}| = t$ samples are already available, $m - t$ samples need to be extracted and transferred from the source tasks. For each source task S_k, the number of samples transferred to the sample set $\widetilde{T}$ of the new target task is proportional to its normalized compliance $\overline{\Lambda}_k = \frac{\Lambda_k}{\sum_{l=1}^{n} \Lambda_l}$. Then, for each source task, samples are drawn according to their relevance, thus avoiding to transfer samples that are quite dissimilar from those in the target task. The whole sample-transfer process is summarized in Algorithm 1.

4. Experiments

In order to evaluate the performance of the sample-transfer algorithm we consider a variant of the boat problem proposed in (Lazaric et al., 2007). The problem is to learn a controller to drive a boat from the left bank to the right-bank quay of a river, in presence of a non-linear current. The boat's bow coordinates, x and y, are defined in the range $[0, 200]$ and the controller sets the desired direction $a \in [-90°, -45°, 0°, 45°, 90°]$. The chosen action is perturbed by a uniform noise in the range $[-5°; 5°]$. The control frequency is set to 1Hz. For the lack of space, we refer the reader to (Lazaric et al., 2007) for the equations of the dynamics. In addition, we introduce sandbanks, i.e., regions of the river in which the speed is reduced by 20%. The reward function is defined as:

$$\mathcal{R}(x,y) = \begin{cases} +10 & x = 200 \text{ and } y \in \mathcal{Z}_s \\ \text{D(x,y)} & x = 200 \text{ and } y \in \mathcal{Z}_v \\ \text{-10} & x = 200 \text{ and } y \in \mathcal{Z}_f \\ \text{-2} & (x,y) \in \text{sandbank} \\ \text{-2} & y \le 0 \text{ or } y \ge 200 \\ 0 & \text{elsewhere} \end{cases} \quad (8)$$

where D is a function that gives a reward decreasing linearly from 10 to -10 relative to the distance from the quay, $\mathcal{Z}_s$ is the quay zone, $\mathcal{Z}_v$ is the viability zone around the quay, and $\mathcal{Z}_f$ is the failure zone in all the other bank points. The dynamics and learning parameters are summarized in Tab. 1. In the following experiments, we use Gaussian kernels and Mahalanobis distance (see Section 3.1). The results are obtained by averaging 100 runs. In FQI, we use extra-randomized trees (Ernst et al., 2005) with 50 trees, 2 random splits, and 2 minimum sample size for each node, trained on 25 iterations. Samples are obtained through random sampling run on independent episodes of maximum 50 steps each. Each episode restarts the boat at the left bank in a random position. Testing is performed on 1,000 episodes with the initial position drawn at random from 20 evenly spaced positions at the left bank.

The first experiment is meant to illustrate the effectiveness of the relevance in identifying which samples are worth transferring. We consider a transfer prob-

lem with three tasks in which S_1 and S_2 are the source tasks and T is the target task. In T the quay is G_1 and there are two sandbanks as illustrated in Figure 2-(*left*). In task S_1 there are two quays G_1 and G_2, and there is only one sandbank corresponding to the region labeled as *sandbank1* in Figure 2-(*left*). Task S_2 has the quay G_2 and the sandbanks illustrated in Figure 2-(*left*). While T and S_1 have the same current force ($f_c = 0.5$), the current in S_2 is in the opposite direction ($f_c = -0.5$). The source task S_2 has a completely different dynamics and reward function from those in T because of different sandbanks and current. Therefore, samples transferred from S_2 are likely to induce negative effects on the learning performance of T. Furthermore, as it can be noticed from the trajectories shown in Figure 2-(*left*), the optimal policy π^*_2 of S_2 obtains very poor performance when tested on T. On the other hand, S_1 has the same dynamics as T in large regions of the state-action space and shares one goal with T. Although its optimal policy π^*_1 is significantly different from π^*, it is possible to choose samples from $\widehat{S}_1$ to improve the performance in T.

Figure 3-(*left*) shows the performance obtained by FQI with four different configurations: *No Transfer*, *Random*, *Compliance*, and *Relevance Transfer*. In the first configuration FQI is run with samples directly collected from T. The other three configurations are run on the sample set $\widetilde{T}$ obtained by transferring samples chosen at random, according to the compliance, and according to the relevance respectively. Furthermore, we also report the performance obtained by transferring policies π^*_1 and π^*_2 as baselines. The augmentation of $\widehat{T}$ with samples drawn from S_1 and S_2 at random does not lead to any significant improvement of the performance with respect to learning directly on samples in $\widehat{T}$. In fact, the only advantage achieved with the transferred samples is that the agent avoids to go outside of the boundaries, but she learns neither to avoid sandbanks nor to achieve the goal. The main reason for this poor performance is that samples drawn from S_2 do not provide any information about the actual dynamics and rewards of T and, thus, may lead to learning very bad policies. On the other hand, the compliance-based transfer successfully excludes samples of S_2 from the transfer process (the normalized compliance of S_1 for $t = 200$ is $\overline{\Lambda}_1 = 0.93 \pm 0.09$), thus augmenting $\widehat{T}$ with samples mainly coming from S_1. Since S_1 shares with T the dynamics and the rewards in all the state space but at *sandbank2* and in the quay G_2, the transfer is positive and leads to a significant improvement in the performance of the learning process. Nonetheless, there are still many trajectories leading to the quay G_2 and crossing the sandbank because of the negative effect of transferring samples from regions with dynamics and reward different from T. In Figure 3-(*right*) we report the relevance of the samples in $\widehat{S}_1$ (averaged on all the actions). As it can be noticed, the relevance identifies the regions where samples are actually similar in source and target tasks, excluding samples coming from *sandbank2* and the lower quay G_2. As a result, the performance of the relevance-based transfer is further improved.

In order to evaluate the relative improvement of transfer, we compute the area ratio (Taylor et al., 2007) of the three transfer configurations, defined as the difference between the accumulated reward with and without transfer divided by the reward accumulated without transfer. Figure 3-(*center*) shows the area ratio for the three transfer configurations. As it can be noticed, random transfer does not lead to any significant improvement, while relevance-based transfer improves the performance by $75.3\% \pm 13.2$. All the differences are statistically significant ($p < 0.01$).

In the previous experiment, source and target tasks have been designed to show how the algorithm works. Now, we consider the general case in which tasks are

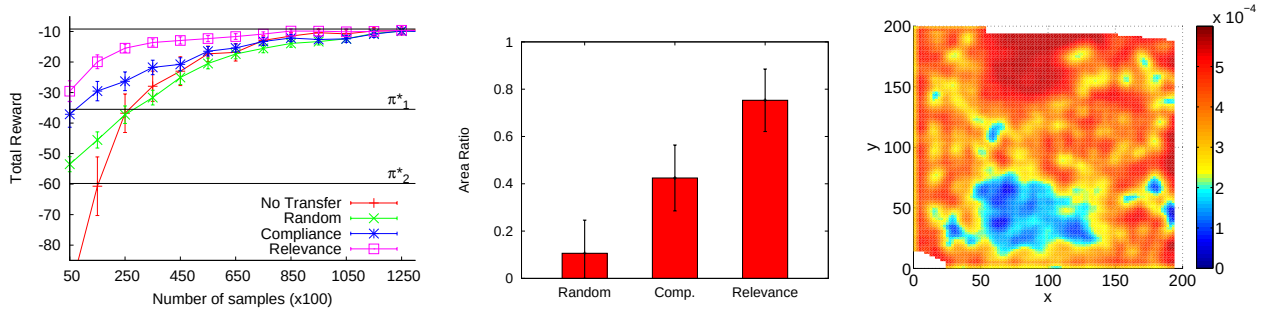

Figure 3. (*left-center*) Total reward and area ratio. (*right*) Relevance of samples in $\widehat{S}_1$ at convergence.

drawn from an infinite task space $\mathcal{T}$. For sake of simplicity, we consider the same target task of the previous experiment, while source tasks have current f_c=0.5 and one sandbank. Source tasks are drawn from a distribution Ω such that the coordinates of the center, height, and width of the sandbank are uniformly drawn from the space $[20.0; 180.0] \times [20.0; 180.0] \times [40.0; 100.0] \times [40.0; 100.0]$, while the quay position is drawn uniformly in $[20.0; 180.0]$. In Figure 4, we report the results of relevance-based transfer obtained by averaging the result with 10 different sets of five source tasks. Although the source tasks are different from the target in large regions, the transfer algorithm is able to identify which samples are worth transferring from the source tasks and it successfully improves the learning performance with an area ratio of $59.5\% \pm 15.4$.

Since the algorithms of transfer in RL proposed so far rely on temporal-difference or model-based learning algorithms, an empirical comparison with the performance of sample transfer would not be fair. Nonetheless, in the next section, we discuss its similarities and differences with other transfer approaches.

5. Related Works

In (Sunmola & Wyatt, 2006) a Bayesian approach is used for transfer of MDPs, where source task models are pre-posteriors for the distributions of the parameters of the target model and model-based RL is used to compute the solution. Although we similarly adopt a Bayesian argument in the compliance, we directly transfer samples and we use a model-free learning algorithm. Furthermore, instead of a parametric approximation of the model of the source tasks, we follow a non-parametric solution.

The task compliance can be interpreted as a sort of distance metric between tasks. In (Ferns et al., 2004), distance metrics for MDP similarity are introduced in the context of bisimulation to aggregate states with similar dynamics and reward. Under a transfer perspective, these metrics can be used to measure the difference between states in distinct tasks and to bound the performance loss of using the optimal policy of a source task in the target task. Unfortunately, this technique cannot be directly applied to our scenario for different reasons. The computation of the Kantorovich distance between different states is very expensive, because it requires the solution of a complex optimization problem. Furthermore, the proposed algorithm needs either the exact models of tasks or accurate approximations. On the other hand, we adopt a solution with low computational complexity, linearly depending on the number of samples of the source tasks. Finally, empirical analysis (Phillips, 2006) showed that the theoretical bounds on the performance loss are too loose and they do not provide useful directions about the actual performance of the transferred policy.

The transfer of samples is also related to works about transfer of solutions in the RL context (Taylor et al., 2007). Although the transfer of samples or solutions (e.g., policies) from only one source task obtains similar results, there are situations in which sample transfer can obtain better results than solution transfer. Even when the difference between source and target tasks is limited to few state-action pairs, the optimal policies of the two tasks can be significantly different and the transfer may achieve very poor performance. On the other hand, the transfer of samples can still be effective. In fact, since most of the samples in the two tasks are identical, the learning algorithm can benefit from samples coming from the source task independently from the actual difference of their optimal policies. Furthermore, the transfer of samples does not require to actually solve the source tasks, and it can be used even when the samples are not enough to solve source tasks. In (Mehta et al., 2005) a solution in which the model-based hierarchical task decomposition allows for transfer at multiple levels of the hierarchy is proposed. This approach relies on the assumption that rewards are a linear combination of *basis* re-

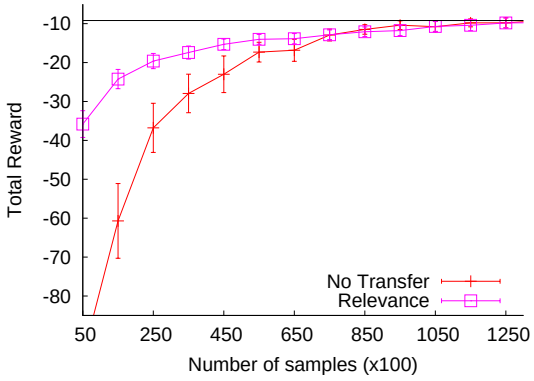

Figure 4. Performance with five random source tasks.

ward functions and it can be applied only to problems of goal transfer, with a fixed transition model. On the other hand, sample transfer can be applied to any transfer scenario. Finally, a method for mapping samples from a source to a target task with different state-action space is proposed in (Taylor et al., 2008).

6. Conclusions

In this paper, we introduced a mechanism for the transfer of samples with the aim of improving the learning performance. The main advantages of the proposed solution are: *(i)* it is independent from the similarity of the policies and action-value functions of the tasks at hand and, thus, can be applied to a wide range of problems, *(ii)* it is independent from the batch RL algorithm, *(iii)* it can be applied to any transfer problem in which either reward or transition or both models change. Experimental results show the effectiveness of the method in improving the learning performance and in avoiding negative transfer when the source tasks are significantly different from the target.

Some aspects of the algorithm can be improved in future works. In case of tasks that either share exactly the same transition or reward model, it is possible to transfer only the part of the samples common to all the tasks. For instance, if two tasks share the same transition model, but have different goals, it is possible to transfer the $\langle s, a, s' \rangle$ part of the samples and to "complete" the sample using an approximation of the reward function of the target task (e.g., using the first iteration of FQI). Furthermore, the sample-transfer algorithm could be integrated with the model proposed in (Taylor et al., 2008) in order to deal with problems with tasks defined on different state-action spaces.

Local Likelihood Modeling of Temporal Text Streams

Guy Lebanon LEBANON@STAT.PURDUE.EDU
Yang Zhao ZHAO18@STAT.PURDUE.EDU
Department of Statistics, Purdue University – West Lafayette, IN 47907

Abstract

Temporal text data is often generated by a time-changing process or distribution. Such a drift in the underlying distribution cannot be captured by stationary likelihood techniques. We consider the application of local likelihood methods to generative and conditional modeling of temporal document sequences. We examine the asymptotic bias and variance and present an experimental study using the RCV1 dataset containing a temporal sequence of Reuters news stories.

1. Introduction

Time stamped documents such as news stories often cannot be accurately modeled by a single time invariant distribution. An alternative is to assume that the concepts underlying the distribution generating the data drift with time. In other words, the data is generated by a time dependent process $z^{(t)} \sim p_t(z), t \in I \subset \mathbb{R}$ whose approximation $\{\hat{p}_t : t \in I\}$ becomes the main objective of the learning task. We assume that the time t is a continuous quantity, even in cases where the realized time points form a discrete sample. For example, assuming that the time stamps represent the days of the year when the documents were authored, we assume that the set $\{1, \ldots, 365\}$ is a discrete sample from a underlying continuous interval $[1, 365]$. We further assume that the data samples $z^{(t)}$, sampled from p_t, correspond to pairs $z^{(t)} = (x, y)$ constituting a document x and a categorial-valued label y. Such pairs (x, y) appear often in practice, for example with y corresponding to the document topic (Lewis et al., 2004), sentiment (Pang & Lee, 2005), author (Mosteller & Wallace, 1964) or Email spam/no-spam (Mulligan, 1999).

Assuming that our data is a set of time stamped documents and labels $(t, (x, y))$, the drift $p_t(x, y)$ can be characterized by considering the temporal transition of the joint distribution $p_t(x, y)$, the conditionals $p_t(y|x)$, $p_t(x|y)$, or the marginals $p_t(x), p_t(y)$. The choice of which of the distributions above to model depends on the application at hand. For example, modeling $p_t(y|x)$ is usually sufficient for document classification purposes while modeling $p_t(x|y)$ is necessary for language modeling which is an important component in speech recognition, machine translation, and IR.

We demonstrate the presence of concept drift in practice by considering the Reuters RCV1 dataset (Lewis et al., 2004) which contains over 800,000 news stories gathered in a period spanning 365 consecutive days and categorized according to topic. Figure 1 displays the temporal change in the relative frequency (number of appearance in a document divided by document length) of three words: `million`, `common`, and `Handelsgesellschaft` (German trade unions) for documents in the most popular RCV1 category titled `CCAT`. It is obvious from these plots that the relative frequency of these words vary substantially in time. For example, the word `Handelsgesellschaft` appear in 8 distinct time regions, representing time points in which German trade unions were featured in the Reuters news archive.

The temporal variation in relative frequencies illustrated by Figure 1 corresponds to a drift in the distribution generating the data. Since the drift is rather pronounced, standard estimation methods based on maximum likelihood are not likely to accurately model the data. In this paper, we consider instead estimating $\{p_t(x, y) : t \in I\}$ based on the the local likelihood principle. Local likelihood is a locally weighted version of the loglikelihood with the weights determined by the difference between the time points associated with the sampled data and a the time at which the inference takes place.

After presenting a more formal discussion of concept drift in Section 3 and the definition of local likelihood in Section 4 we turn to examine in detail the case of

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

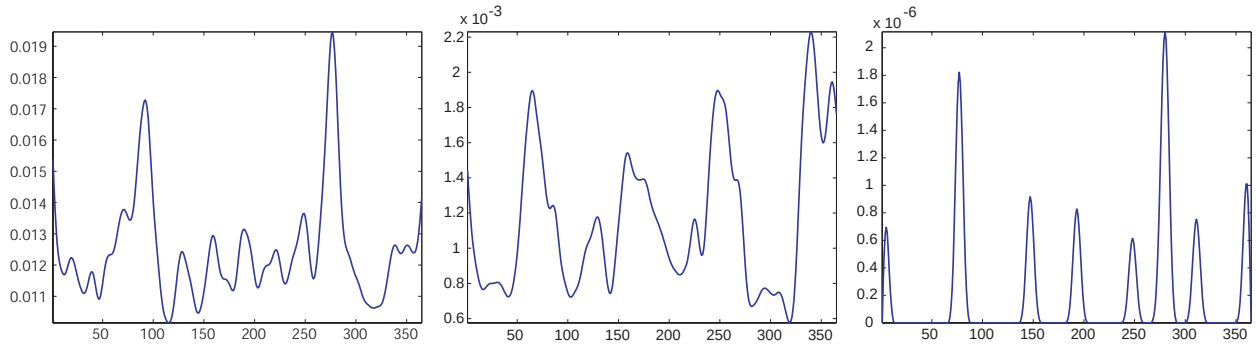

Figure 1. Estimated relative frequency (number of appearances in a document divided by document length) of three words from the most popular category in RCV1 as a function of time. The three panels correspond to the words `million`, `common`, and `Handelsgesellschaft` (German trade unions). The displayed curves were smoothed to remove sampling noise.

modeling $p_t(x|y)$ with local likelihood for n-grams and modeling $p_t(y|x)$ with local likelihood for logistic regression. In the case of 1-grams or the naive Bayes model, we provide a precise as well as asymptotic description of the bias and variance which illuminates certain facts concerning the selection of weights and the difference between the online and offline scenarios. Experiments conducted on the RCV1 dataset demonstrates the local likelihood estimation in practice and contrasts it with more standard non-local alternatives.

2. Related Work

Concept drift or similar phenomena under different names have been studied in a number of communities. It has recently gained interest primarily due to an increase in the need to model large scale temporal data streams.

Early machine learning literature on the concept drift problem involved mostly computational learning theory tools (Helmbold & Long, 1994; Kuh et al., 1990). Hulten et al. (2001) studied the problem in the context of datamining large scale streams whose distribution change in time. More recently, Forman (2006) studied the concept drift phenomenon in the context of information retrieval in large textual databases. Sharan and Neville (2007) consider the modeling of temporal changes in relational databases and its application to text classification.

Overall, the prevailing techniques have been to train standard methods on examples obtained by filtering the data through a sliding window. Tibshirani and Hastie (1987) developed the local likelihood idea in the statistics community within the context of non-parametric smoothing and regression. More details on local likelihood can be found in (Loader, 1999).

3. The Concept Drift Phenomenon and its Estimation

Formally, the concept drift phenomenon may be thought of as a smooth flow or transition of the joint distribution of a random vector. We will focus on the case of a joint distribution of a random vector X and a random variable Y representing predictor and response variables. We will also restrict our attention to temporal or one dimensional drifts.

Definition 1. *Let X and Y be two discrete random vectors taking values in $\mathcal{X}$ and $\mathcal{Y}$. A smooth temporal drift of X, Y is a smooth mapping from $I \subset \mathbb{R}$ to a family of joint distributions*

$$t \mapsto p_t(x, y) \stackrel{\text{def}}{=} p_t(X = x, Y = y).$$

By restricting ourselves to discrete random variables we can obtain a simple geometrical interpretation of concept drift. Denoting the simplex of all distributions over the set S by

$$\mathbb{P}_S \stackrel{\text{def}}{=} \left\{ r \in \mathbb{R}^{|S|} \;:\; \forall i \, r_i \geq 0, \; \sum_{i=1}^{|S|} r_i = 1 \right\} \quad (1)$$

we have that Definition 1 is equivalent to a smooth parameterized curve in the simplex $\mathbb{P}_{\mathcal{X} \times \mathcal{Y}}$.

The drift in the joint distribution can be decomposed in several ways. The first decomposition $p_t(x, y) = p_t(x|y)p_t(y)$ is useful for generative modeling and the second decomposition $p_t(x, y) = p_t(y|x)p_t(x)$ is useful for conditional modeling. In the generative case we will focus on modeling $p_t(x|y)$ since modeling $p_t(y)$ is typically an easier problem due to its lower dimensionality (in most cases involving text documents $|\mathcal{Y}| \ll |\mathcal{X}|$). In the case of conditional modeling, we focus on modeling $p_t(y|x)$ and we ignore the drift in the marginal $p_t(x)$ since it is irrelevant for discriminative tasks.

In both cases we assume that our data is a set of time-stamped labeled documents sampled from $p_t(x, y)$ where the time points t are sampled from a distribution $g(t)$. If g is a continuous density, the number of samples at time t, denoted by N_t, is no greater than 1 with probability 1. In practice, however, we allow N_t to be larger than 1 in order to account for the discretization of time. We thus have the data

$$D = \{(x_{tj}, y_{tj}) : t \in I \subset \mathbb{R}, j = 1, \ldots, N_t\} \quad (2)$$

where the time points are sampled from $g(t)$ and $(x_{tj}, y_{tj}) \sim p_t(x, y)$.

To illustrate these concepts in the context of the RCV1 dataset, we display in Figure 2 the total number of words per day (left) and the total number of documents per day (right) corresponding to the most popular category in RCV1. As is evident from the right panel, $g(t)$ is a highly non-uniform density corresponding to varying amount of news content in different dates.

It is easy to come up with two simple solutions to the problem of concept drift modeling. The first solution, called the extreme global model, is to simply ignore the temporal drift and use all of the samples in D regardless of their time stamp. This approach results in a single global model $\hat{p}$ which serves as an estimate for the entire flow $\{p_t, t \in I\}$ effectively modeling the concept drift as a degenerate curve equivalent to a stationary point in the simplex. The second simple alternative, called the extreme local model, is to model p_t using only data sampled from time t i.e. $\{(x_{tj}, y_{tj}) : j = 1, \ldots, N_t\}$. This alternative decomposes the concept drift estimation into a sequence of disconnected estimation problems.

The extreme local model has the benefit that if the individual estimation problems are unbiased, the estimation of the concept drift is unbiased as well. The main drawback of this method is the high estimation variance resulting from the relatively small number of daily samples N_t used to estimate the individual models. Furthermore, assuming D is finite we can only estimate the drift in the finite number of time points appearing in the dataset D (since we have no training data for the remaining time points). On the other hand, the extreme global model enjoys low variance since it uses all data points to estimate p_t. Its main drawback is that it is almost always heavily biased due to the fact that samples from one distribution p_{t_1} are used to estimate a different distribution p_{t_2}.

It is a well known fact that the optimal solution in terms of minimizing the mean squared estimation error usually lies between the extreme local and extreme global models. An intermediate solution can trade-off increased bias for reduced variance and can significantly improve the estimation accuracy. Motivated by this principle, we employ local smoothing in forming a local version of the maximum likelihood principle which includes as special cases the two extreme models mentioned above. The intuition behind local smoothing in the present context is that due to the similarity between p_t and $p_{t+\epsilon}$, it makes sense to estimate p_t using samples from neighboring time points $t + \epsilon$. However, in contrast to the global model the contribution of points sampled from $p_{t+\epsilon}$ towards estimating p_t should decrease as ϵ increases.

4. Local Likelihood and Concept Drift

The local likelihood principle extends the ideas of non-parametric regression smoothing and density estimation to likelihood-based inference. We concentrate on using the local likelihood principle for estimating $p_t(x|y)$ and $p_t(y|x)$ which are described next.

4.1. Local Likelihood for n-Gram Estimation

We apply local likelihood to the problem of estimating $p_t(x|y)$ by assuming the naive Bayes assumption i.e. that $x|y$ is generated by a multinomial distribution or its n-gram extensions. Assuming documents contain words belonging to a finite dictionary of size V, the naive Bayes assumption may be stated as

$$p_t(x|y) \propto \prod_{w \in V} \theta_w^{c(w,x)}, \qquad \theta \in \mathbb{P}_V \quad (3)$$

where $c(w, x)$ represents the number of times word w appears in document x. Similarly, the n-gram model extends naive Bayes (3) by considering n-order Markov dependency. The naive Bayes and n-gram are a mainstay of statistical text processing (Manning & Schutze, 1999) and usually lead to accurate language modeling, especially when appropriate smoothing is used (Chen & Goodman, 1998). For notational simplicity we consider the problem of estimating $p_t(x)$ rather than the equivalent $p_t(x|y)$ and we concentrate on naive Bayes i.e. 1-gram. Extending the discussion to n-grams with $n > 1$ is relatively straightforward and is omitted due to lack of space.

Applied to the concept drift problem, the local log-likelihood at time t is a smoothed or weighted version of the loglikelihood of the data D in (2) with the amount of smoothing determined by a non-negative smoothing kernel $K_h : \mathbb{R} \to \mathbb{R}$

$$\ell_t(\eta|D) \stackrel{\text{def}}{=} \sum_{\tau \in I'} K_h(t - \tau) \sum_{j=1}^{N_\tau} \log p(x_{\tau j}\,; \eta). \quad (4)$$

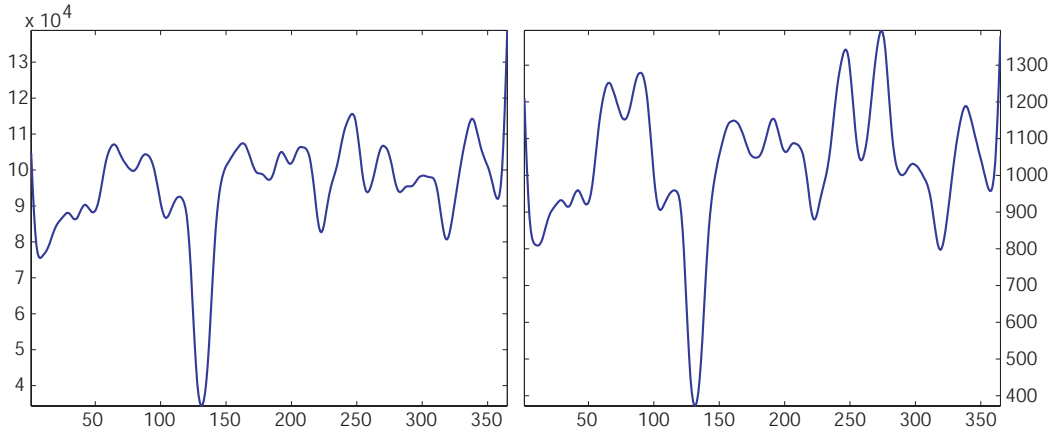

Figure 2. Total number of words per day (left) and documents per day (right) for the most popular category in RCV1. The displayed curves were smoothed to remove sampling noise.

We assume that the kernel function is a normalized density concentrated around 0 and parameterized by a scale parameter $h > 0$ reflecting its spread and satisfying the relation $K_h(r) = h^{-1}K(r/h)$ for some $K : \mathbb{R} \to \mathbb{R}$ referred to as the base kernel form. We further assume that K has bounded support and $\int u^r K(u)\, du < \infty$ for $r \leq 2$. Wand and Jones (1995) provide more details on the formal requirements of a smoothing kernel.

Three popular kernel choices are the tricube, triangular and uniform kernels, defined as $K_h(r) = h^{-1}K(r/h)$ where the $K(\cdot)$ functions are respectively

$$K(r) = (1 - |r|^3)^3 \cdot 1_{\{|r|<1\}} \quad (5)$$

$$K(r) = (1 - |r|) \cdot 1_{\{|r|<1\}} \quad (6)$$

$$K(r) = 2^{-1} \cdot 1_{\{|r|<1\}}. \quad (7)$$

The uniform kernel is the simplest choice and leads to a local likelihood (4) equivalent to filtering the data by a sliding window i.e. $\hat{\theta}_t$ is computed based on data from adjacent time points with uniform weights. Unfortunately, it can be shown that the uniform kernel is suboptimal in terms of its statistical efficiency or rate of convergence to the underlying distribution (Wand & Jones, 1995). Surprisingly, the triangular kernel has a higher statistical efficiency than the Gaussian kernel and is the focus of our experiments in this subsection. We use the tricube kernel in the next subsection.

The scale parameter h is central to the bias-variance tradeoff. Large h represents more uniform kernels achieving higher bias and lower variance. Small h represents a higher degree of locality or lower bias but higher variance. Since $\lim_{h\to 0} K_h$ approaches Dirac's delta function and $\lim_{h\to\infty} K_h$ approaches a constant function the local log-likelihood (4) interpolates between the loglikelihoods of the extreme local model and the extreme global model mentioned in Section 3 as h ranges from 0 to $+\infty$.

Solving the maximum local likelihood problem for each t provides an estimation of the entire drift $\{\hat{\theta}_t : t \in \mathbb{R}\}$ with $\hat{\theta}_t = \arg\max_{\eta\in\Theta} \ell_t(\eta|D)$. In the case of the naive Bayes or n-gram model we obtain a closed form expression for the local likelihood maximizer $\hat{\theta}_t$ as well as convenient expressions for its bias and variance. In general, however, there is no closed form maximizer and iterative optimization algorithms are needed in order to obtain $\hat{\theta}_t = \arg\max_{\eta\in\Theta} \ell_t(\eta|D)$ for all t.

We denote the length of a document in (2) by $|x_{tj}| \stackrel{\text{def}}{=} \sum_{v\in V} c(x_{tj}, v)$ and the total number of words in day t in (2) by $|x_t| \stackrel{\text{def}}{=} \sum_{j=1}^{N_t} |x_{tj}| = \sum_{v\in V}\sum_{j=1}^{N_t} c(v, x_{tj})$. We assume that the length of documents x_{tj} is independent of t and is drawn from a distribution with expectation λ.

Under the above assumptions, the local likelihood (4) of the naive Bayes model becomes

$$\ell_t(\eta|D) = \sum_{\tau\in I'} K_h(t-\tau) \sum_{j=1}^{N_\tau} \sum_{w\in V} c(w, x_{\tau j}) \log \eta_w$$

where $\eta \in \mathbb{P}_V$. The local likelihood has a single global maximum whose closed form is obtained by setting to 0 the gradient of the Lagrangian

$$0 = \frac{1}{[\hat{\theta}_t]_w} \sum_{\tau\in I} K_h(t-\tau) \sum_{j=1}^{N_\tau} c(w, x_{\tau j}) + \lambda_w$$

to obtain

$$[\hat{\theta}_t]_w = \frac{\sum_{\tau \in I} K_h(t-\tau) \sum_{j=1}^{N_\tau} c(w, x_{\tau j})}{\sum_{\tau \in I} K_h(t-\tau)|x_\tau|}. \quad (8)$$

The estimator $\hat{\theta}_t$ is a normalized linear combination of word counts where the combination coefficients are determined by the kernel function and normalized by the number of words in different days. We note that $\hat{\theta}_t$ in (8) is different from a weighted averaging of the relative frequencies $c(w, x_{\tau j}) / \sum_{w'} c(w', x_{\tau j})$.

We distinguish between two fundamental scenarios for predicting the drift θ_t.

Offline scenario: The goal is to estimate the drift $\{\theta_t : t \in \mathbb{R}\}$ given the entire dataset D. In this case we will consider symmetric kernels $K(r) = K(-r)$ which will achieve an increased convergence rate of $\hat{\theta}_t \to \theta_t$ as indicated by Proposition 2.

Online scenario: The goal is estimate a model for the present distribution θ_t using training data from the past i.e. a dataset whose time stamps are strictly smaller than t. This corresponds to situations where the data arrives sequentially as a temporal stream and at each time point a model for the present is estimated using the available stream at that time. We realize this restriction by constraining K to satisfy $K(r) = 0, r \leq 0$.

As with other statistical estimators, the accuracy of $\hat{\theta}_t$ may be measured in terms of its mean squared error $\mathsf{E}\,(\hat{\theta}_t - \theta_t)^2$ which decomposes as the sum of the squared bias and variance of $\hat{\theta}_t$. Examining these quantities allow us to study the convergence rate of $\hat{\theta}_t \to \theta$ and its leading coefficient .

Proposition 1. *The bias vector* $\mathsf{bias}(\hat{\theta}_t) \stackrel{\text{def}}{=} \mathsf{E}\hat{\theta}_t - \theta_t$ *and variance matrix of* $\hat{\theta}_t$ *in* (8) *are*

$$\mathsf{bias}(\hat{\theta}_t) = \frac{\sum_{\tau \in I} K_h(t-\tau)|x_\tau|\,(\theta_\tau - \theta_t)}{\sum_{\tau \in I} K_h(t-\tau)|x_\tau|} \quad (9)$$

$$\mathsf{Var}(\hat{\theta}_t) = \frac{\sum_{\tau \in I} K_h^2(t-\tau)|x_\tau|\,(diag(\theta_\tau) - \theta_\tau \theta_\tau^\top)}{\left(\sum_{\tau \in I} K_h(t-\tau)|x_\tau|\right)^2} \quad (10)$$

where $diag(z)$ *is the diagonal matrix* $[diag(z)]_{ij} = \delta_{ij} z_i$.

Proof. The random variable (RV) $c(w, x_{\tau j})$ is distributed as a sum of multivariate Bernoulli RVs, or single draws from multinomial distribution. The expectation and variance of the estimator are that of a linear combination of iid multinomial RVs. To conclude the proof we note that for $Y \sim \mathrm{Mult}(1, \theta)$, $\mathsf{E}\,Y = \theta$, $\mathsf{Var}(\theta) = \mathrm{diag}(\theta) - \theta\theta^\top$. □

Examining Equations (9)-(10) reveals the expected dependency of the bias on h and θ_t. The contribution to the bias of the terms $(\theta_\tau - \theta_t)$, for large $|\tau - t|$, will decrease as h decreases since the kernel becomes more localized and will reduce to 0 as $h \to 0$. Similarly, for slower drifts, $\|\theta_\tau - \theta_t\|, t \approx \tau$ will decrease and reduce the bias.

Despite the relative simplicity of Equations (9)-(10), it is difficult to quantitatively capture the relationship between the bias and variance, the sample size, h, λ, and the smoothness of θ_t, g. Towards this goal we derive the following asymptotic expansions.

Proposition 2. *Assuming (i)* θ, g *are smooth in* t, *(ii)* $h \to 0, hn \to \infty$, *(iii)* $g > 0$ *in a neighborhood of* t, *and (iv) document lengths do not depend on* t *and have expectation* λ, *we have in the offline case*

$$\mathsf{bias}(\hat{\theta}_t|I) = h^2 \mu_{21}(K) \left(\dot{\theta}_t \frac{g'(t)}{g(t)} + \frac{1}{2}\ddot{\theta}_t \right) + o_P(h^2) \quad (11)$$

$$\mathsf{Var}(\hat{\theta}_t|I) = \frac{\mu_{02}(K)}{(nh)g(t)\lambda}(diag(\theta_t) - \theta_t\theta_t^\top) + o_P((nh)^{-1})$$

and in the online case

$$\mathsf{bias}(\hat{\theta}_t|I) = h\mu_{11}(K)\dot{\theta}_t + o_P(h) \quad (12)$$

$$\mathsf{Var}(\hat{\theta}_t|I) = \left(\frac{\mu_{02}(K)}{nhg(t)\lambda} + \frac{\mu_{12}(K)g'(t)}{ng^2(t)\lambda} \right)(diag(\theta_t) - \theta_t\theta_t^\top) + \frac{\mu_{12}(K)}{n\lambda g(t)}(diag(\dot{\theta}_t) - \dot{\theta}_t\theta_t^\top - \theta_t\dot{\theta}^\top) + o_P((nh)^{-1})$$

where $\mu_{kl}(K) \stackrel{\text{def}}{=} \int u^k K^l(u)\,du$ *is assumed to be finite and* $\dot{\theta}_t$ *is the vector* $[\dot{\theta}_t]_i = \frac{d}{dt}[\theta_t]_i$.

The proof is somewhat similar to the derivation of the asymptotic bias and variance of the Nadaraya-Watson local regression (Wand & Jones, 1995) and is omitted due to space limitations. The notation $g_n \xrightarrow{p} f$ represents convergence in probability of g_n to f i.e. $\forall \epsilon > 0, P(|g_n - f| > \epsilon) \to 0$, and $g_n = o_P(f_n)$ represents $g_n / f_n \xrightarrow{p} 0$.

Corollary 1. *Under the assumptions in Proposition 2, and in particular* $h \to 0, nh \to \infty$, *the estimator* $\hat{\theta}_t$ *is consistent i.e.* $\hat{\theta}_t \xrightarrow{p} \theta_t$ *in both the offline and online settings.*

Proposition 2 specifies the conditions for consistency as well as the rate of convergence. In particular, the bias of online kernels converges at a linear rather than quadratic rate. In either cases, the estimator is biased and inconsistent unless $h \to 0, n \to \infty$ and $nh^{-1} \to$

∞. Expressions (11)-(12) reveal the performance gain associated with a slower drift and sampling density g indicated by $\dot{\theta}_t$ and $g'(t)$ and with more (represented by n) and longer (represented by λ) documents.

Figure 3 displays the RCV1 per-word test set loglikelihood for the online and offline scenarios as a function of the (triangular) kernel's bandwidth. As expected, offline kernels performs better than online kernels with both achieving the best performance for a bandwidth approximately 25 which corresponds to a support of 25 days in the online scenario and 50 days in the offline scenario. Note that in addition to obtaining higher accuracy than the global model corresponding to $h \to \infty$, the local model enjoys computational efficiency as it ignores a large portion of the training data.

A central issue in local likelihood modeling is selecting the appropriate bandwidth h. A practical solution is to use cross validation or some other automatic bandwidth selection mechanism. On RCV1 data, the performance of such cross validation schemes is very good and the estimated bandwidth possesses test set loglikelihood that is almost identical to the optimal bandwidth (see Figure 4, left).

Allowing the kernel scale to vary over time results in a higher modeling accuracy than using fixed bandwidth for all dates (see Figure 4, right). A time-dependent cross validation procedure may be used to approximate the time-dependent optimal bandwidth which performs slightly better than the fixed-date cross validation estimator. Note that the accuracy with which the cross validation estimator approximates the optimal bandwidth is lower in the time-dependent or varying bandwidth situation due the fact that much less data is available in each of the daily cross validation problems.

From a theoretical perspective, the asymptotic bias and variance can be used to characterize the optimal bandwidth and study its properties. Minimizing the (offline) leading term of sum of component-wise MSE with respect to h we obtain the bandwidth estimator

$$\hat{h}_t^5 = \frac{\mu_{02}(K)\mathrm{tr}(\mathrm{diag}(\theta_t) - \theta_t\theta_t^\top)}{4n\lambda\mu_{21}^2(K)\sum_j \left([\dot{\theta}_t]_j\, g'(t)/\sqrt{g(t)} + \sqrt{g(t)}[\ddot{\theta}_t]_j\,/2\right)^2}. \quad (13)$$

As expected, the optimal bandwidth decreases as $n, \lambda, \|\dot{\theta}_t\|, \|\ddot{\theta}\|$ increases. Intuitively this makes sense since in these cases the variance decreases and bias either increases or stays constant. In practice, $\dot{\theta}_t, \ddot{\theta}_t$ may vary significantly with time which leads to the conclusion that a single bandwidth selection for all t may not perform adequately. These changes are illustrated in Figure 5 (left) which demonstrates the temporal change in the gradient norm.

Perhaps more interesting than the dependency of the optimal bandwidth on $n, \lambda, \dot{\theta}_t, \ddot{\theta}_t$ is its dependency on the time sampling distribution $g(t)$. Equation (13) reveals an un-expected non-monotonic dependency of the optimal bandwidth in $g(t)$. The dependency, expressed by $\hat{h}_t \propto (\sum_{j=1}^V (c_{1j}/\sqrt{g(t)} + c_{2j}\sqrt{g(t)})^2)^{-1/5}$ is illustrated in Figure 6 (left) where we assume for simplicity that c_{1j}, c_{2j} do not change with j resulting in $(\hat{h}_t)^{-1} \propto (c_1/\sqrt{g(t)} + c_2\sqrt{g(t)})^{2/5}$. The key to understanding this relationship is the increased asymptotic bias due to the presence of the term $g'(t)/g(t)$ in Equation (11). Intuitively, the variations in $g(t)$ expressed by $g'(t)$ introduce a bias component which alters the otherwise monotonic role of the optimal bandwidth and bias-variance tradeoff. Since $g(t)$ is highly non-uniform (as illustrated in Figure 2), this dependency of $\hat{h}_t$ on $g(t)$ is likely to play a significant role.

We finally point out that different words w have different parameters $[\theta_t]_w$ and parameter derivatives $[\dot{\theta}_t]_w$ which indicates that it is unlikely that a single bandwidth will work best for all words. Frequent words are likely to benefit more from narrow kernel smoothing than rare words which almost never appear. As a result, a lower bandwidth should be used for frequent words while a high bandwidth should be used for rare words. A systematic investigation of these topics is beyond the scope of this paper.

4.2. Local Likelihood for Logistic Regression

Often, the primary goal behind modeling the drift is conditional modeling i.e. predicting the value of y given x. In this case, drift modeling should focus on estimating the conditional $p_t(y|x)$ since modeling the marginal $p_t(x)$ becomes irrelevant. In contrast to the modeling of the conditional by Bayes rule $p_t(y|x) \propto p_t(x|y)p_t(y)$ described in the previous section, we explore here direct modeling of $\{p_t(y|x) : t \in I\}$ using local likelihood for logistic regression.

By direct analogy to Equation (4) the conditional local likelihood estimator $p_t(y|x)$ is the maximizer of the locally weighted conditional loglikelihood

$$\ell_t(\eta|D) = \sum_{\tau\in I}^{n} K_h(t-\tau) \sum_{j=1}^{N_\tau} \log p(y_{\tau j}|x_{\tau j};\eta) \quad \eta \in \Theta.$$

As in the generative case, the kernel parameter h balances the degree of the kernel's locality and controls the bias-variance tradeoff.

Denoting by $f(x)$ the vector of relative frequencies in the document x, the logistic regression model

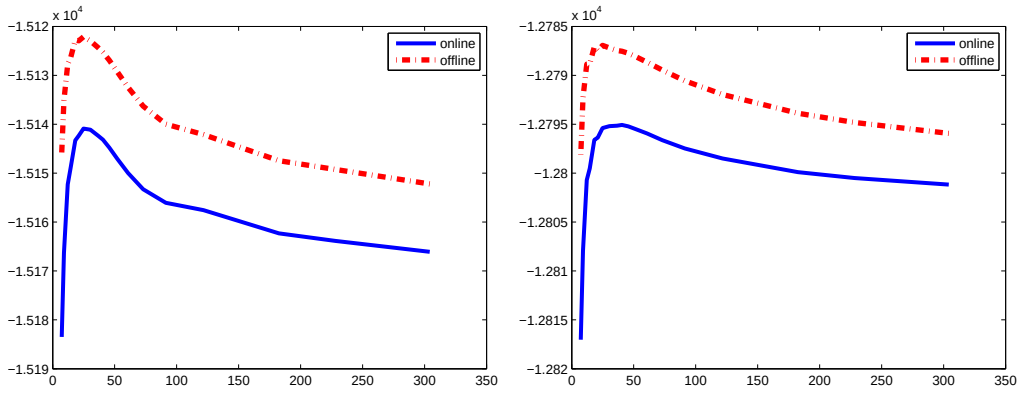

Figure 3. Per-word log-likelihood of held out test set as a function of the triangular kernel's bandwidth for the two largest RCV1 categories (CCAT (left) and GCAT (right)). In all four cases, the optimal bandwidth seems to be approximately 25 which indicates a support of 25 days for the online kernels and 50 days for the offline kernels.

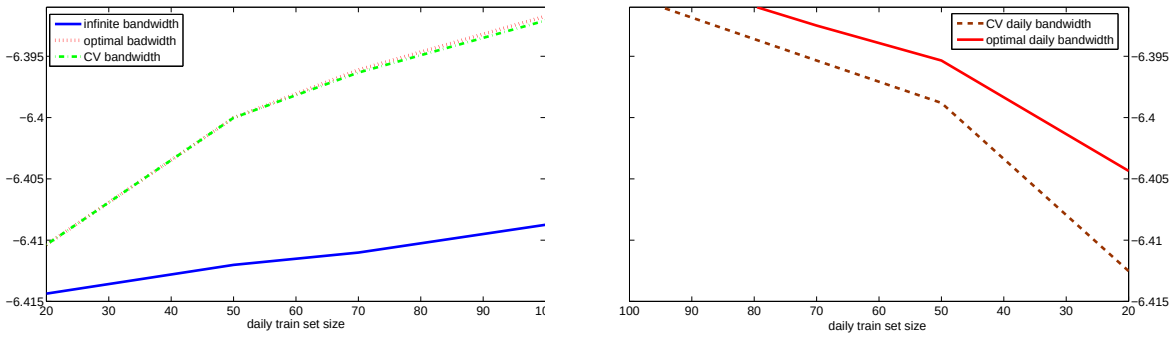

Figure 4. Per-word log-likelihood over held-out test set for various bandwidths as a function of the daily training set size. Left: The extreme global model corresponding to $h \to \infty$ performs worst. Selecting the bandwidth by cross validation results in an accurate estimate and test-set loglikelihood almost identical to that of the optimal slope. Right: Allowing the kernel scale to vary over time results in a higher modeling accuracy than using fixed bandwidth for all dates.

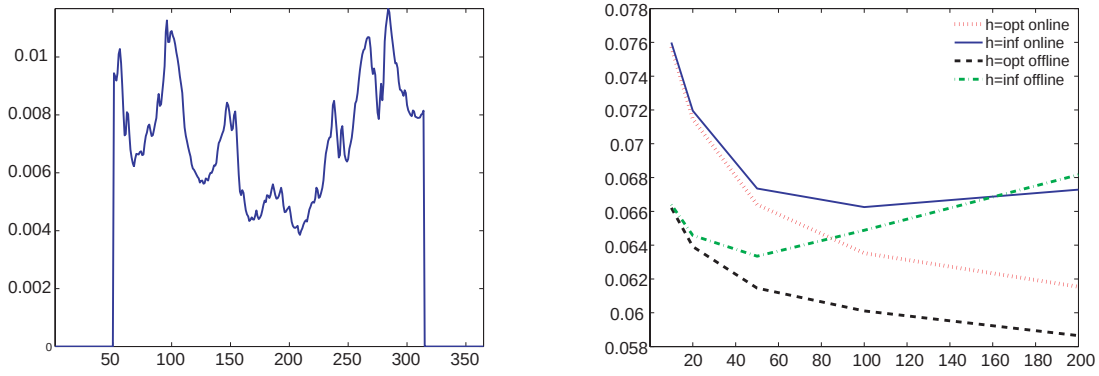

Figure 5. Left: Estimated gradient norm for the most popular category in RCV1 as a function of t. The derivatives were estimated using local smoothing. To avoid running into boundary effects we ignore the first and last 50 days. Right: Classification error rate over a held-out test set for the local logistic regression model as a function of the train set size.

$\log \frac{p(1|x;\theta_t)}{1-p(1|x;\theta_t)} = \langle \theta_t, f(x) \rangle$, $\theta \in \mathbb{R}^V$ leads to the following local conditional likelihood

$$\ell_t(\eta|D) = -\sum_{\tau \in I}^{n} K_h(t-\tau) \sum_{j=1}^{N_\tau} \log\left(1 + e^{-y_{\tau j}\langle x_{\tau j}, \eta \rangle}\right).$$

In contrast to the naive Bayes model in the previous section, the local likelihood does not have a close form maximizer. However, it can be shown that under mild conditions it is a concave problem exhibiting a single global maximum (for each t) (Loader, 1999). Most of the standard iterative algorithms for training logistic regression can be modified to account for the local weighting introduced by the smoothing kernel. Moreover, recently popularized regularization techniques such as the penalty $c\|\eta\|^q, q = 1, 2$ may be added to the local likelihood to obtain a local regularized version equivalent to maximum posterior estimation.

Figure 5 (right) displays classification error rate over a held-out test set for local logistic regression as a function of the train set size. The classification task was predicting the most popular class vs the second most popular class in RCV1. The plots in the figure contrast the performance of the online and offline tricube kernels with optimal and infinite bandwidths, using L_2 regularization. The local model achieved a relative reduction of error rate over the global model by about 8%. As expected, the online kernel generally achieve worse error rates than the offline kernels. In all the experiments mentioned above we averaged over multiple random samplings of the training set to remove sampling noise.

5. Discussion

A large number of textual datasets such as emails, webpages, news stories, etc. contain time stamped documents. For such datasets, considering a drifting rather than a stationary distribution is often appropriate. The local likelihood framework provides a natural extension for many standard likelihood models to the concept drift scenario. As the drift becomes more noticeable and the data size increases the potential benefits of local likelihood methods over their extreme global or local counterparts increase.

In this paper we illustrate the drift phenomenon and examine the properties of the local likelihood estimator including the asymptotic bias and variance tradeoff and optimal bandwidth. Experiments conducted on the RCV1 dataset demonstrate the validity of the local likelihood estimators in practice and contrast them with more standard non-local alternatives.

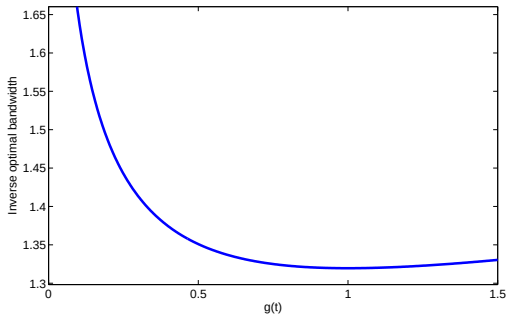

Figure 6. Inverse of the optimal bandwidth derived from Equation (13) as a function of $g(t)$: $(\hat{h}_t)^{-1} \propto (c_1/\sqrt{g(t)} + c_2\sqrt{g(t)})^{2/5}$ (we take $c_1 = c_2 = 1$). The graph show the non-monotonic dependency between $\hat{h}^{\text{opt}}$ and $g(t)$.

A Worst-Case Comparison between Temporal Difference and Residual Gradient with Linear Function Approximation

Lihong Li LIHONG@CS.RUTGERS.EDU
Department of Computer Science, Rutgers University, 110 Frelinghuysen Road, Piscataway, NJ, USA 08854

Abstract

Residual gradient (RG) was proposed as an alternative to TD(0) for policy evaluation when function approximation is used, but there exists little formal analysis comparing them except in very limited cases. This paper employs techniques from online learning of linear functions and provides a worst-case (non-probabilistic) analysis to compare these two types of algorithms when linear function approximation is used. No statistical assumptions are made on the sequence of observations, so the analysis applies to non-Markovian and even adversarial domains as well. In particular, our results suggest that RG may result in smaller temporal differences, while TD(0) is more likely to yield smaller prediction errors. These phenomena can be observed even in two simple Markov chain examples that are non-adversarial.

1. Introduction

Reinforcement learning (RL) is a learning paradigm for optimal sequential decision making (Bertsekas & Tsitsiklis, 1996; Sutton & Barto, 1998) and has been successfully applied to a number of challenging problems. In the RL framework, the *agent* interacts with the *environment* in discrete timesteps by repeatedly observing its current state, taking an action, receiving a real-valued reward, and transitioning to a next state. A *policy* is a function that maps states to actions; semantically, it specifies what action to take given the current state. The goal of an agent is to optimize its policy in order to maximize the expected long-term return, namely, the discounted sum of rewards it receives by following the policy.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

An important step in this optimization process is *policy evaluation*—the problem of evaluating expected returns of a *fixed* policy. This problem is often the most challenging step in approximate policy-iteration algorithms (Bertsekas & Tsitsiklis, 1996; Lagoudakis & Parr, 2003). *Temporal difference* (TD) is a family of algorithms for policy evaluation (Sutton, 1988) and has received a lot of attention from the community. Unfortunately, it is observed (*e.g.*, Baird (1995)) that TD methods may diverge when they are combined with *function approximation*. An alternative algorithm known as *residual gradient* (RG) was proposed by Baird (1995) and enjoys guaranteed convergence to a local optimum. Since RG is similar to TD(0), a particular instance of the TD family, we will focus on RG, TD(0), and a variant of TD(0) in this paper.

Despite convergence issues, little is known that compares RG and TD(0). Building on previous work on *online learning of linear functions* (Cesa-Bianchi et al., 1996) and a similar analysis by Schapire and Warmuth (1996), we provide a worst-case (non-probabilistic) analysis of these algorithms and focus on two evaluation metrics: (i) total squared prediction error, and (ii) total squared temporal difference. The former measures *accuracy* of the predictions, while the latter measures *consistency* and is closely related to the *Bellman error* (Sutton & Barto, 1998).

Either metric may be preferred over the other in different situations. For instance, Lagoudakis and Parr (2003) argue that TD solutions tend to preserve the shape of the value function and is more suitable for approximate policy iteration, while there is evidence that minimizing squared Bellman errors is more robust in general (Munos, 2003). Our analysis suggests that TD can make more accurate predictions, while RG can result in smaller temporal differences. All terms will be made precise in the next section. Although our theory focuses on worst-case upper bounds, we also provide numerical evidence and expect the resulting insights to give useful guidance to RL practitioners in deciding which algorithm best suits their purposes.

2. Preliminaries

Fully observable environments in RL are often modelled as *Markov decision processes* (Puterman, 1994), which are equivalent to induced *Markov chains* when controlled by a fixed policy. Here, however, we consider a different model that is suitable for worst-case analysis, as introduced in the next subsection. This model makes no statistical assumption about the observations, and thus our results apply to much more general situations including *partially* observable or adversarial environments that subsume Markov chains.

Some notation is in order. We use bold-face, lower-case letters to denote real-valued column vectors such as $\mathbf{v}$. Their components are denoted by the corresponding letter with subscripts such as v_t. We use $\|\cdot\|$ to denote the Euclidean, or ℓ_2-norm: $\|\mathbf{v}\| = \sqrt{\mathbf{v}^\top \mathbf{v}}$ where $\mathbf{v}^\top$ is the transpose of $\mathbf{v}$. For a square matrix M, the set of eigenvalues of M, known as the *spectrum* of M, is denoted $\sigma(M)$. If M is symmetric, its eigenvalues must be real, and its largest eigenvalue is denoted $\rho(M)$.

2.1. The Sequential Online Learning Model

Our learning model is adopted from Schapire and Warmuth (1996) and is an extension of the online-learning model to sequential prediction problems. Let k be the dimension of input vectors. The agent maintains a weight vector of the same dimension and uses it to make predictions. In RL, input vectors are often feature vectors of states or state–action pairs, and are used to approximate value functions (Sutton & Barto, 1998). Learning proceeds in discrete timesteps and terminates after T steps. The agent starts with an initial input vector $\mathbf{x}_1 \in \mathbb{R}^k$ and an initial weight vector $\mathbf{w}_1 \in \mathbb{R}^k$. At timestep $t \in \{1, 2, 3, \cdots, T\}$:

- The agent makes a prediction $\hat{y}_t = \mathbf{w}_t^\top \mathbf{x}_t \in \mathbb{R}$, where $\mathbf{w}_t$ is the weight vector at time t. Throughout the paper, assume $\|\mathbf{x}_t\| \le X$ for some known constant $X > 0$.
- The agent then observes an *immediate reward* $r_t \in \mathbb{R}$ and the next input vector $\mathbf{x}_{t+1}$. Based on this information, it updates its weight vector whose new value is denoted $\mathbf{w}_{t+1}$. The change in weight is $\Delta\mathbf{w}_t = \mathbf{w}_{t+1} - \mathbf{w}_t$.

By convention, $r_t = 0$ and $\mathbf{x}_t = \mathbf{0}$ for $t > T$. Define the *return* at time t by $y_t = \sum_{\tau=t}^{\infty} \gamma^{\tau-t} r_\tau$, where $\gamma \in [0, 1)$ is the *discount factor*. Since $\gamma < 1$, it effectively diminishes future rewards exponentially fast. A quick observation is that $y_t = r_t + \gamma y_{t+1}$, which is analogous to the Bellman equation for Markov chains (Sutton & Barto, 1998). The agent attempts to mimic y_t by its prediction $\hat{y}_t$, and the *prediction error* is $e_t = y_t - \hat{y}_t$. Our first evaluation metric is the *total squared prediction error*: $\ell_{\mathcal{P}} = \sum_{t=1}^{T} e_t^2 = \|\mathbf{e}\|^2$.

Another useful metric in RL is the *temporal differences* (also known as *TD errors*), which measures how consistent the predictions are. In particular, the temporal difference at time t is $d_t = r_t + \gamma \mathbf{w}_t^\top \mathbf{x}_{t+1} - \mathbf{w}_t^\top \mathbf{x}_t$, and the *total squared temporal difference* is $\ell_{\mathcal{TD}} = \sum_{t=1}^{T} d_t^2 = \|\mathbf{d}\|^2$.

2.2. Previous Work

Previous convergence results of TD and RG often rely heavily on certain stochastic assumptions of the environment such as the assumption that the sequence of observations, $[(\mathbf{x}_t, r_t)]_{t\in\mathbb{N}}$, are generated by an irreducible and aperiodic Markov chain. Tsitsiklis and Van Roy (1997) first proved convergence of TD with linear function approximation, while they also pointed out the potential divergence risk when nonlinear approximation is used.

To resolve the instability issue of TD(0), Baird (1995) proposed the RG algorithm, but also noted that RG may converge more slowly than TD(0) in some problems. Such an observation was later proved by Schoknecht and Merke (2003), who used spectral analysis to compare the asymptotic convergence rates of the two algorithms. Although their results are interesting, they only apply to quite limited cases where, for example, a certain matrix associated with TD updates has real eigenvalues only (which does not hold in general). More importantly, they study *synchronous* updates while TD and RG are often applied *asynchronously* in practice. Furthermore, their results assume that the value function is represented by a lookup table, but the initial motivation of studying RG was to develop a provably convergent algorithm when function approximation is used.

Schapire and Warmuth (1996) were also concerned with similar worst-case behavior of TD-like algorithms within the model described in Subsection 2.1. They defined a new class of algorithms called TD$^*(\lambda)$, which is very similar to the TD(λ) algorithms of Sutton (1988). They developed worst-case bounds for the total squared prediction error of TD$^*(\lambda)$, but not the total squared temporal difference.

2.3. Algorithms

The algorithms we consider all update the weight vector incrementally and differ only in the update rules. TD(0) uses the following rule:

$$\Delta\mathbf{w}_t = \eta d_t \mathbf{x}_t, \tag{1}$$

where $\eta \in (0,1)$ is the *step-size* parameter controlling aggressiveness of the update. Although TD(0) is widely used in practice, analysis turns out to be easier with a close relative of it, TD*(0). This algorithm differs from TD(0) in that it adapts the step-size based on the input vectors (Schapire and Warmuth (1996) defined TD*(0) in a different, but equivalent, form):

$$\Delta \mathbf{w}_t = \frac{\eta d_t \mathbf{x}_t}{1 - \gamma\eta \mathbf{x}_t^\top \mathbf{x}_{t+1}}. \tag{2}$$

Due to space limitation, we only provide results for TD*(0), but similar results hold for TD(0). It is expected, and also supported by the numerical evidence in Section 4, that TD(0) and TD*(0) have similar behavior and performance in practice. For this reason, we refer to both algorithms as TD in the rest of the paper if there is no risk of confusion. In contrast, RG uses the following update rule:

$$\Delta \mathbf{w}_t = \eta d_t \left(\mathbf{x}_t - \gamma \mathbf{x}_{t+1}\right). \tag{3}$$

3. Main Results

This section contains the main theoretical results. We will first describe how to evaluate an algorithm in the worst-case scenario. For completeness, we also summarize the squared prediction error bounds for TD*(0) due to Schapire and Warmuth (1996). Then, we analyze total squared temporal difference bounds and RG.

Our analysis makes a few uses of matrix theory (see, *e.g.*, Horn and Johnson (1986)), and several technical lemmas are found in the appendix. Two basic facts about $\rho(M)$ will be used repeatedly: (i) if M is negative-definite, then $\rho(M) < 0$; and (ii) the Rayleigh-Ritz theorem (Horn & Johnson, 1986, Theorem 4.2.2) states that $\rho(M) = \max_{\mathbf{v}\neq\mathbf{0}} \frac{\mathbf{v}^\top M \mathbf{v}}{\mathbf{v}^\top \mathbf{v}}$.

3.1. Evaluation Criterion

Analogous to other online-learning analysis, we treat $\ell_{\mathcal{P}}$ and $\ell_{\mathcal{TD}}$ as *total losses*, and compare the total loss of an algorithm to that of an arbitrary weight vector, $\mathbf{u}$. We wish to prove that this difference is small for *all* $\mathbf{u}$, including the *optimal* (in any well-defined sense) but unknown vector $\mathbf{u}^*$.

The prediction using vector $\mathbf{u}$ at time t is $y_t^{\mathbf{u}} = \mathbf{u}^\top \mathbf{x}_t$. Accordingly, the prediction error and temporal difference at time t are $e_t^{\mathbf{u}} = y_t - y_t^{\mathbf{u}}$ and $d_t^{\mathbf{u}} = r_t + \gamma \mathbf{u}^\top \mathbf{x}_{t+1} - \mathbf{u}^\top \mathbf{x}_t$, respectively. The total squared prediction error and total squared temporal difference of $\mathbf{u}$ are $\ell_{\mathcal{P}}^{\mathbf{u}} = \|\mathbf{e}^{\mathbf{u}}\|^2 = \sum_{t=1}^T \left(y_t - \mathbf{u}^\top \mathbf{x}_t\right)^2$ and $\ell_{\mathcal{TD}}^{\mathbf{u}} = \|\mathbf{d}^{\mathbf{u}}\|^2 = \sum_{t=1}^T \left(r_t + \gamma \mathbf{u}^\top \mathbf{x}_{t+1} - \mathbf{u}^\top \mathbf{x}_t\right)^2$, respectively.

3.2. Squared Prediction Errors of TD*(0)

Using step-size $\eta = \frac{1}{X^2+1}$, Schapire and Warmuth (1996) showed a worst-case upper bound:

$$\ell_{\mathcal{P}} \leq \frac{\left(1+X^2\right)\left(\ell_{\mathcal{P}}^{\mathbf{u}} + \|\mathbf{w}_1 - \mathbf{u}\|_2^2\right)}{1-\gamma^2}.$$

Furthermore, if E and W are known beforehand such that $\ell_{\mathcal{P}}^{\mathbf{u}} \leq E$ and $\|\mathbf{w}_1 - \mathbf{u}\| \leq W$, then the step-size η can be optimized by $\eta = \frac{W}{X\sqrt{E}+X^2 W}$ to yield an asymptotically better bound:

$$\ell_{\mathcal{P}} \leq \frac{\ell_{\mathcal{P}}^{\mathbf{u}} + 2WX\sqrt{E} + X^2W^2}{1-\gamma^2}. \tag{4}$$

3.3. Squared Temporal Differences of TD*(0)

We will extend the analysis of Schapire and Warmuth (1996) to the new loss function $\ell_{\mathcal{TD}}$ by examining how the potential function, $\|\mathbf{w}_t - \mathbf{u}\|^2$, evolves when a single update is made at time t. It can be shown (Schapire & Warmuth, 1996, Eqn 8) that $-\|\mathbf{w}_1 - \mathbf{u}\|^2 \leq \eta^2 X^2 \mathbf{e}^\top D^\top D \mathbf{e} + 2\eta \mathbf{e}^\top D^\top (\mathbf{e}^{\mathbf{u}} - \mathbf{e})$, where

$$D = \begin{pmatrix} 1 & -\gamma & 0 & \cdots & 0 & 0 \\ 0 & 1 & -\gamma & \cdots & 0 & 0 \\ & & \ddots & & & \\ 0 & 0 & \cdots & 1 & -\gamma & 0 \\ 0 & 0 & \cdots & 0 & 1 & -\gamma \\ 0 & 0 & \cdots & 0 & 0 & 1 \end{pmatrix}. \tag{5}$$

Define $\mathbf{f} = D\mathbf{e}$. According to Lemma A.1(1), $\mathbf{d}^{\mathbf{u}} = D\mathbf{e}^{\mathbf{u}}$, and hence the inequality above is rewritten as:

$$-\|\mathbf{w}_1 - \mathbf{u}\|^2 \leq \eta^2 X^2 \mathbf{f}^\top \mathbf{f} - 2\eta \mathbf{f}^\top D^{-1} \mathbf{f} + 2\eta \mathbf{f}^\top D^{-1} \mathbf{d}^{\mathbf{u}}.$$

Using the fact that $2\mathbf{p}^\top \mathbf{q} \leq \|\mathbf{p}\|^2 + \|\mathbf{q}\|^2$ for $\mathbf{p} = \frac{\eta}{\sqrt{b}} D^{-\top}\mathbf{f}$, $\mathbf{q} = \sqrt{b}\mathbf{d}^{\mathbf{u}}$, and arbitrary $b > 0$, the inequality becomes $-\|\mathbf{w}_1 - \mathbf{u}\|^2 \leq \mathbf{f}^\top M_1 \mathbf{f} + b\ell_{\mathcal{TD}}^{\mathbf{u}}$, where

$$M_1 = \eta^2 X^2 I + \frac{\eta^2}{b} D^{-1} D^{-\top} - \eta(D^{-1} + D^{-\top}) \tag{6}$$

is a symmetric matrix. Since $\rho(M_1)$ is the largest eigenvalue of M_1, we have $\mathbf{f}^\top M_1 \mathbf{f} \leq \rho(M_1)\|\mathbf{f}\|^2$, and hence, $-\|\mathbf{w}_1 - \mathbf{u}\|^2 \leq \|\mathbf{f}\|^2 \rho(M_1) + b\ell_{\mathcal{TD}}^{\mathbf{u}}$. Combining this with Lemma A.4, we have that $\|\mathbf{f}\|^2$ is at most

$$(1+\gamma)^2 \left(X^2 + \frac{1}{b(1-\gamma)^2}\right)\left(b\ell_{\mathcal{TD}}^{\mathbf{u}} + \|\mathbf{w}_1 - \mathbf{b}\|^2\right),$$

when the step-size is

$$\eta = \frac{1}{(1+\gamma)\left(X^2 + \frac{1}{b(1-\gamma)^2}\right)}. \tag{7}$$

Due to Lemma A.1 (2), we have

$$\begin{aligned} d_t^2 &= \left(1-\gamma\eta\mathbf{x}_t^\top\mathbf{x}_{t+1}\right)^2 f_t^2 \\ &\le \left(1+\gamma\eta X^2\right)^2 f_t^2 \;\le\; \frac{(1+2\gamma)^2}{(1+\gamma)^2} f_t^2. \end{aligned}$$

Therefore, $\ell_{\mathcal{TD}}$ is at most

$$(1+2\gamma)^2\left(X^2+\frac{1}{b(1-\gamma)^2}\right)\left(b\ell_{\mathcal{TD}}^{\mathbf{u}}+\|\mathbf{w}_1-\mathbf{u}\|^2\right).$$

Using $b=1$, we have thus proved the first main result.

Theorem 3.1. *Let η be given by Eqn 7 using $b=1$, then the following holds for TD*(0):*

$$\ell_{\mathcal{TD}} \le (1+2\gamma)^2\left(X^2+\frac{1}{(1-\gamma)^2}\right)\left(\ell_{\mathcal{TD}}^{\mathbf{u}}+\|\mathbf{w}_1-\mathbf{u}\|^2\right).$$

Theorem 3.2. *If E and W are known beforehand such that $\ell_{\mathcal{TD}}^{\mathbf{u}} \le E$ and $\|\mathbf{w}_1-\mathbf{u}\| \le W$, then η can be optimized in TD*(0) so that*

$$\ell_{\mathcal{TD}} \le (1+2\gamma)^2 \left(\frac{\ell_{\mathcal{TD}}^{\mathbf{u}}}{(1-\gamma)^2}+\frac{2XW\sqrt{E}}{1-\gamma}+X^2\|\mathbf{w}_1-\mathbf{u}\|^2\right). \quad (8)$$

Proof. Previous analysis for Theorem 3.1 yields

$$\begin{aligned} \ell_{\mathcal{TD}} &\le (1+2\gamma)^2\left(\left(bX^2\ell_{\mathcal{TD}}^{\mathbf{u}}+\frac{\|\mathbf{w}_1-\mathbf{u}\|^2}{b(1-\gamma)^2}\right)+\left(\frac{\ell_{\mathcal{TD}}^{\mathbf{u}}}{(1-\gamma)^2}+X^2\|\mathbf{w}_1-\mathbf{u}\|^2\right)\right) \\ &\le (1+2\gamma)^2\left(\left(bX^2E+\frac{W^2}{b(1-\gamma)^2}\right)+\left(\frac{\ell_{\mathcal{TD}}^{\mathbf{u}}}{(1-\gamma)^2}+X^2\|\mathbf{w}_1-\mathbf{u}\|^2\right)\right) \end{aligned}$$

for any $b>0$. We may simply choose $b=\frac{W}{X(1-\gamma)\sqrt{E}}$, and the step-size in Eqn 7 becomes

$$\eta=\frac{1}{(1+\gamma)\left(X^2+\frac{X\sqrt{E}}{W(1-\gamma)}\right)}. \quad \square$$

3.4. Squared Prediction Errors of RG

By the update rule in Eqn 3 and simple algebra,

$$\begin{aligned} \Delta\mathbf{w}_t^\top(\mathbf{w}_t-\mathbf{u}) &= \eta d_t(\mathbf{x}_t-\gamma\mathbf{x}_{t+1})^\top(\mathbf{w}_t-\mathbf{u}) \\ &= \eta d_t\left(\left(\mathbf{w}_t^\top\mathbf{x}_t-\gamma\mathbf{w}_t^\top\mathbf{x}_{t+1}-r_t\right)-\left(\mathbf{u}^\top\mathbf{x}_t-\gamma\mathbf{u}^\top\mathbf{x}_{t+1}-r_t\right)\right) \\ &= \eta d_t(d_t^{\mathbf{u}}-d_t), \\ \|\Delta\mathbf{w}_t\|^2 &= \eta^2 d_t^2\|\mathbf{x}_t-\gamma\mathbf{x}_{t+1}\|_2^2 \\ &\le \eta^2 d_t^2 X^2(1+\gamma)^2. \end{aligned}$$

Similar to the previous section, we use the potential function $\|\mathbf{w}_t-\mathbf{u}\|^2$ to measure progress of learning:

$$\begin{aligned} -\|\mathbf{w}_1-\mathbf{u}\|^2 &\le \sum_{t=1}^T\left(\|\mathbf{w}_{t+1}-\mathbf{u}\|^2-\|\mathbf{w}_t-\mathbf{u}\|^2\right) \\ &= \sum_{t=1}^T\left(2\Delta\mathbf{w}_t^\top(\mathbf{w}_t-\mathbf{u})+\Delta\mathbf{w}_t^\top\Delta\mathbf{w}_t\right) \\ &\le \sum_{t=1}^T\left(2\eta d_t(d_t^{\mathbf{u}}-d_t)+\eta^2 d_t^2X^2(1+\gamma)^2\right) \\ &= 2\eta\mathbf{d}^\top\mathbf{d}^{\mathbf{u}}-2\eta\mathbf{d}^\top\mathbf{d}+\eta^2X^2(1+\gamma)^2\mathbf{d}^\top\mathbf{d}. \end{aligned}$$

According to Lemma A.1 (1) and using the fact that $2\mathbf{p}^\top\mathbf{q}\le\|\mathbf{p}\|^2+\|\mathbf{q}\|^2$ for $\mathbf{p}=\frac{\eta}{\sqrt{b}}D^\top\mathbf{d}$, $\mathbf{q}=\sqrt{b}\mathbf{e}^{\mathbf{u}}$, and arbitrary $b>0$, the inequality above is written as:

$$-\|\mathbf{w}_1-\mathbf{u}\|^2 \le b\|\mathbf{e}^{\mathbf{u}}\|^2+\frac{\eta^2}{b}\mathbf{d}^\top DD^\top\mathbf{d}+\left(\eta^2X^2(1+\gamma)^2-2\eta\right)\|\mathbf{d}\|^2$$

Due to Lemma A.1 (3), $\mathbf{d}=\Sigma D\mathbf{e}$, where

$$\Sigma = \operatorname{diag}\left(\frac{1}{1+\gamma\eta(\mathbf{x}_1-\gamma\mathbf{x}_2)^\top\mathbf{x}_2}, \frac{1}{1+\gamma\eta(\mathbf{x}_2-\gamma\mathbf{x}_3)^\top\mathbf{x}_3},\cdots, \frac{1}{1+\gamma\eta(\mathbf{x}_{T-1}-\gamma\mathbf{x}_T)^\top\mathbf{x}_T},1\right). \quad (9)$$

Then, the inequality above becomes:

$$-\|\mathbf{w}_1-\mathbf{u}\|^2 \le b\|\mathbf{e}^{\mathbf{u}}\|^2+\mathbf{e}^\top M_2\mathbf{e},$$

where

$$M_2=D^\top\Sigma\left(\frac{\eta^2}{b}DD^\top+\left(\eta^2X^2(1+\gamma)^2-2\eta\right)I\right)\Sigma D. \quad (10)$$

Since $\mathbf{e}^\top M_2\mathbf{e}\le\rho(M_2)\|\mathbf{e}\|^2$, Lemma A.5 implies the following theorems when the step-size is

$$\eta=\frac{1}{(1+\gamma)^2\left(X^2+\frac{1}{b}\right)}. \quad (11)$$

Theorem 3.3. *Let η be given by Eqn 11 using $b=1$, then the following holds for RG:*

$$\ell_{\mathcal{P}} \le \frac{(1+2\gamma)^2\left(X^2+1\right)}{(1-\gamma)^2}\left(\ell_{\mathcal{P}}^{\mathbf{u}}+\|\mathbf{w}_1-\mathbf{u}\|^2\right).$$

Theorem 3.4. *If E and W are known beforehand such that $\ell_{\mathcal{P}}^{\mathbf{u}} \le E$ and $\|\mathbf{w}_1-\mathbf{u}\| \le W$, then η can be optimized in RG so that*

$$\ell_{\mathcal{P}} \le \frac{(1+2\gamma)^2}{(1-\gamma)^2}\left(\ell_{\mathcal{P}}^{\mathbf{u}}+2XW\sqrt{E}+X^2\|\mathbf{w}_1-\mathbf{u}\|^2\right). \quad (12)$$

Proof. Previous analysis in this subsection yields

$$\begin{aligned}\ell_{\mathcal{P}} &\leq \frac{(1+2\gamma)^2}{(1-\gamma)^2}\left(\left(\ell^{\mathbf{u}}_{\mathcal{P}} + X^2\left\|\mathbf{w}_1-\mathbf{u}\right\|^2\right) + \left(X^2 b\ell^{\mathbf{u}}_{\mathcal{P}} + \frac{\left\|\mathbf{w}_1-\mathbf{u}\right\|^2}{b}\right)\right)\\ &\leq \frac{(1+2\gamma)^2}{(1-\gamma)^2}\left(\left(\ell^{\mathbf{u}}_{\mathcal{P}} + X^2\left\|\mathbf{w}_1-\mathbf{u}\right\|^2\right) + \left(X^2 bE + \frac{W^2}{b}\right)\right).\end{aligned}$$

We simply choose $b = \frac{W}{X\sqrt{E}}$ and accordingly the step-size in Eqn 11 becomes

$$\eta = \frac{1}{(1+\gamma)^2\left(X^2 + \frac{X\sqrt{E}}{W}\right)}. \quad \square$$

3.5. Squared Temporal Differences of RG

It is most convenient to turn this problem into one of analyzing the total squared prediction error in the original online-learning-of-linear-function framework (Cesa-Bianchi et al., 1996). In particular, define $\mathbf{z}_t = \mathbf{x}_t - \gamma\mathbf{x}_{t+1}$ and thus $\|\mathbf{z}_t\| \leq (1+\gamma)X$. Now, RG can be viewed as a gradient descent algorithm operating over the sequence of data $[(\mathbf{z}_t, r_t)]_{t\in\{1,2,\cdots,T\}}$. Due to Theorem IV.1 of Cesa-Bianchi et al. (1996), we immediately have

$$\ell_{\mathcal{TD}} \leq 2.25\left(\ell^{\mathbf{u}}_{\mathcal{TD}} + X^2(1+\gamma)^2\left\|\mathbf{u}\right\|^2\right),$$

for any $\mathbf{u}$ when the step-size is $\eta = \frac{2}{3X^2(1+\gamma)^2}$. If E and W are known beforehand so that $\ell^{\mathbf{u}}_{\mathcal{TD}} \leq E$ and $\|\mathbf{u}\| \leq W$, then η can be optimized (Theorem IV.3 of Cesa-Bianchi et al. (1996)) by $\eta = \frac{W}{X(1+\gamma)(WX(1+\gamma)+\sqrt{E})}$ to obtain the following improved bound:

$$\ell_{\mathcal{TD}} \leq \ell^{\mathbf{u}}_{\mathcal{TD}} + 2WX(1+\gamma)\sqrt{E} + (1+\gamma)^2W^2X^2. \quad (13)$$

3.6. Discussions

Based on Eqns 4, 8, 12, and 13, Table 1 summarizes the asymptotic upper bounds (when $T \to \infty$) assuming E and W are known beforehand to optimize η.[1] Although our bounds are all upper bounds, results in the table *suggest* that, in worst cases, TD*(0) (and also TD(0)) tend to make smaller prediction errors, while RG tends to make smaller temporal differences. The gaps between corresponding bounds increase as $\gamma \to 1$. On the other extreme where $\gamma = 0$, all these asymptotic bounds coincide, which is not surprising as TD(0), TD*(0), and RG are all identical when $\gamma = 0$.

[1] Strictly speaking, the validity of these asymptotic results relies on the assumptions that (i) $\sqrt{E} = o(\ell^{\mathbf{u}}_{\mathcal{P}})$, and (ii) W and X remain constant as $T \to \infty$. Both assumptions are reasonable in practice.

Table 1. Asymptotic upper bounds for total squared prediction error and total squared temporal difference of TD*(0) and RG.

	$\ell_{\mathcal{P}}/\ell^{\mathbf{u}}_{\mathcal{P}}$	$\ell_{\mathcal{TD}}/\ell^{\mathbf{u}}_{\mathcal{TD}}$
TD*(0)	$\frac{1}{1-\gamma^2} + o(1)$	$\frac{(1+2\gamma)^2}{(1-\gamma)^2} + o(1)$
RG	$\frac{(1+2\gamma)^2}{(1-\gamma)^2} + o(1)$	$1 + o(1)$

Since it is unknown whether the leading constants in Table 1 are optimal, the next section will provide numerical evidence to support our claims about the relative strengths of these algorithms.

It is worth mentioning that in sequential prediction or decision problems, the factor $\frac{1}{1-\gamma}$ often plays a role similar to the *decision horizon* (Puterman, 1994). Therefore, in some sense, our bounds also characterize how prediction errors and temporal differences may scale with decision horizon, in the worst-case sense.

When $\ell_{\mathcal{P}}$ or $\ell_{\mathcal{TD}}$ are relatively small, the asymptotic bounds in Table 1 are less useful as the $\|\mathbf{w}_1-\mathbf{u}\|^2$ in the bounds dominate $\ell_{\mathcal{P}}$ or $\ell_{\mathcal{TD}}$. However, we still get similar qualitative results by comparing the constant factors of the term $\|\mathbf{w}_1-\mathbf{u}\|^2$ in the bounds.

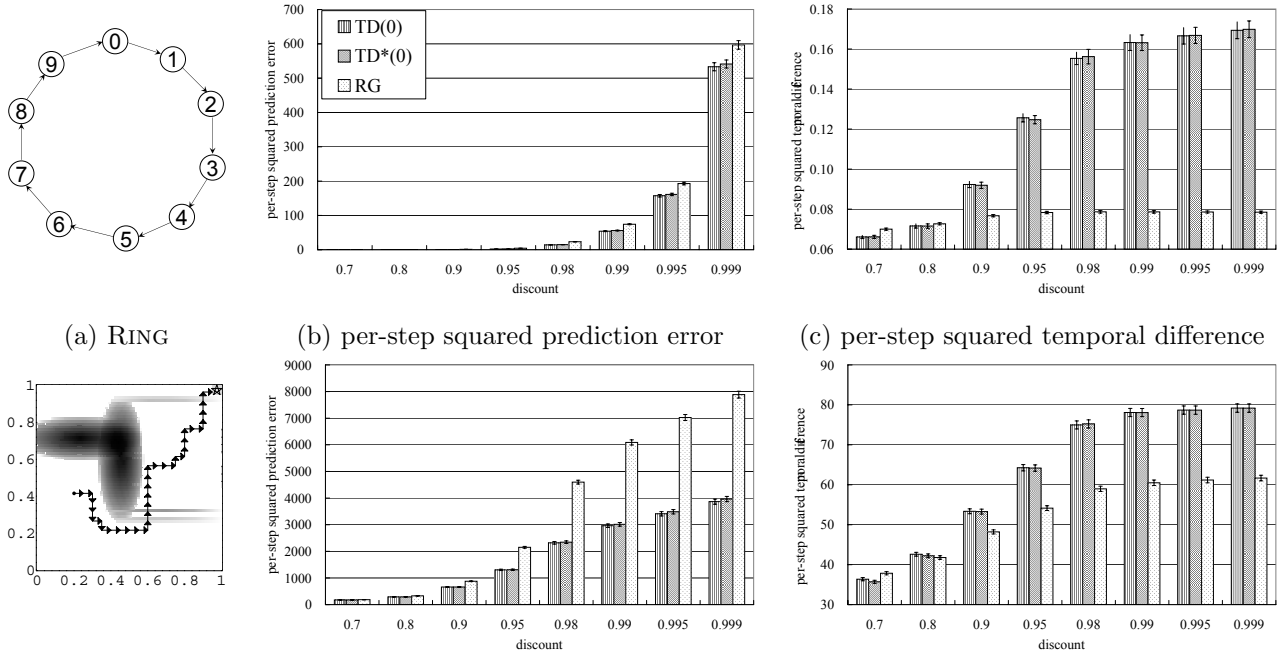
Since our setting is quite different from that of Schoknecht and Merke (2003), our results are not comparable to theirs.

4. Experiments

This section presents empirical evidence in two Markov chains that supports our claims in Section 3.6.

The first is the RING Markov chain (Figure 1 (a)), a variant of the HALL problem introduced by Baird (1995) in which RG was observed to converge to the optimal weights more slowly than TD(0). The state space is a ring consisting of 10 states numbered from 0 through 9. Each state is associated with a randomly selected feature vector of dimension $k = 5$: $\mathbf{x}^{(0)}, \cdots, \mathbf{x}^{(9)} \in \mathbb{R}^k$. Transitions are deterministic and are indicated by arrows. The reward in every state is stochastic and is distributed uniformly in $[-0.1, 0.1]$. As in HALL , the value of every state is exactly 0.

The second problem is a benchmark problem known as PUDDLEWORLD (Boyan & Moore, 1995). The state space is a unit square (Figure 1 (d)), and a start state of an episode is randomly selected in $[0, 0.2] \times [0, 0.2]$.



(a) RING (b) per-step squared prediction error (c) per-step squared temporal difference

(d) PUDDLEWORLD (e) per-step squared prediction error (f) per-step squared temporal difference

Figure 1. Two Markov chains we used: (a) RING and (d) PUDDLEWORLD (Boyan & Moore, 1995). All results are averaged over 500 runs, with 99% confidence intervals plotted. RING and PUDDLEWORLD results are in (b,c) and (e,f), respectively.

The agent adopts a fixed policy that goes north or east with probability 0.5 each. Every episode takes about 40 steps to terminate. The reward is -1 unless the agent steps into the puddles and receives penalty for that; the smallest possible reward is -41. We used 16 RBF features of width 0.3, whose centers were evenly distributed in the state space. We also tried a degree-two polynomial feature: for a state $\mathbf{s} = (s_1, s_2)^\top$, the feature vector had six components: $\mathbf{x_s} = \left(1, s_1, s_2, s_1 s_2, s_1^2, s_2^2\right)^\top$. Since the results are similar to those for RBF features, they are not included.

We ran three algorithms in the experiments: TD(0), TD*(0), and RG. For a fair comparison, all algorithms started with the all-one weight vector and were given the same sequence of $(\mathbf{x}_t, r_t)$ for learning. The procedure was repeated 500 times. For RING , each run used a different realization of feature $\mathbf{x}^{(s)}$ and $T = 500$; for PUDDLEWORLD , each run consisted of 50 episodes (yielding slightly less than 2000 steps in total). A wide range of step-sizes were tried, and the best choices for each discount-factor–algorithm combination were used to evaluate $\ell_{\mathcal{P}}$ and $\ell_{\mathcal{TD}}$, respectively. Figure 1 (b,c,e,f) gives the average per-step squared prediction errors and squared temporal differences for these two problems, with 99% confidence intervals plotted.

These results are consistent with our analysis: TD(0) and TD*(0) tended to make more accurate predictions, while RG did a better job at minimizing temporal differences; the differences between these algorithms were even larger as the discount factor γ approached 1.[2] Finally, as a side effect, it is verified that TD(0) and TD*(0) had essentially identical performance, although their best learning rates might differ.

5. Conclusion

We have carried out a worst-case analysis to compare two policy-evaluation algorithms, TD and RG, when linear function approximation is used. Together with previously known results due to Schapire and Warmuth (1996) and Cesa-Bianchi et al. (1996), our results suggest that, although the TD algorithms may make more accurate predictions, RG may be a better choice when small temporal differences are desired. This claim is supported by empirical evidence in two simple Markov chains. Although the analysis is purely mathematical, we expect the implications to deepen the understanding of these two types of algorithms and can provide useful insights to RL practitioners.

[2]This effect was less obvious when γ got too close to 1. This was because the trajectories in our experiments were not long enough for such γ to have full impacts.

There has been relatively little attention to this sort of online-learning analysis within the RL community. Our analysis shows that this kind of analysis may be helpful and provide useful insights. A few directions are worth pursuing. First, we have focused on worst-case upper bounds, but it remains open whether matching lower bounds can be found. More extensive empirical studies are also necessary to see if such worst-case behavior can be observed in realistic problems. Second, we wish to generalize the analysis of total squared temporal difference from TD(0) and TD*(0) to TD(λ) and TD*(λ), respectively. Finally, we would like to mention that, in their original forms, both TD and RG use *additive* updates. Another class of updates known as *multiplicative* updates (Kivinen & Warmuth, 1997) has been useful when the number of features (*i.e.*, the k in Subsection 2.1) is large but only a few of them are relevant for making predictions. Such learning rules have potential uses in RL (Precup & Sutton, 1997), but it remains open whether these algorithms converge or whether worst-case error bounds similar to the ones given in this paper can be obtained.

A. Lemmas and Proofs

Lemma A.1. *This lemma collects a few basic facts useful in our analysis (D is given in Eqn 5):*

1. *In all three algorithms,* $\mathbf{d^u} = D\mathbf{e^u}$.
2. *In TD*(0),* $d_t = (1 - \gamma\eta\mathbf{x}_t^\top\mathbf{x}_{t+1})(e_t - \gamma e_{t+1})$.
3. *In RG,* $d_t = \frac{e_t - \gamma e_{t+1}}{1+\gamma\eta(\mathbf{x}_t - \gamma\mathbf{x}_{t+1})^\top\mathbf{x}_{t+1}}$.

Proof. 1. Since $y_t = r_t + \gamma y_{t+1}$, we have

$$\begin{aligned} d_t^{\mathbf{u}} &= r_t + \gamma\mathbf{u}^\top\mathbf{x}_{t+1} - \mathbf{u}^\top\mathbf{x}_t \\ &= \left(y_t - \mathbf{u}^\top\mathbf{x}_t\right) - \left(y_t - r_t - \gamma\mathbf{u}^\top\mathbf{x}_{t+1}\right) \\ &= \left(y_t - \mathbf{u}^\top\mathbf{x}_t\right) - \gamma\left(y_{t+1} - \mathbf{u}^\top\mathbf{x}_{t+1}\right) \\ &= e_t^{\mathbf{u}} - \gamma e_{t+1}^{\mathbf{u}}. \end{aligned}$$

In matrix form, this is $\mathbf{d^u} = D\mathbf{e^u}$.

2. Since $\mathbf{w}_t = \mathbf{w}_{t+1} - \Delta\mathbf{w}_t$ and $y_t = r_t + \gamma y_{t+1}$,

$$\begin{aligned} d_t &= r_t + \gamma\mathbf{w}_t^\top\mathbf{x}_{t+1} - \mathbf{w}_t^\top\mathbf{x}_t \\ &= r_t + \gamma(\mathbf{w}_{t+1} - \Delta\mathbf{w}_t)^\top\mathbf{x}_{t+1} - \mathbf{w}_t^\top\mathbf{x}_t + \\ &\quad (y_t - r_t - \gamma y_{t+1}) \\ &= (y_t - \mathbf{w}_t^\top\mathbf{x}_t) - \gamma(y_{t+1} - \mathbf{w}_{t+1}^\top\mathbf{x}_{t+1}) - \\ &\quad \gamma\Delta\mathbf{w}_t^\top\mathbf{x}_{t+1} \\ &= e_t - \gamma e_{t+1} - \frac{\gamma\eta d_t\mathbf{x}_t^\top\mathbf{x}_{t+1}}{1 - \gamma\eta\mathbf{x}_t^\top\mathbf{x}_{t+1}}. \end{aligned}$$

Reorganizing terms will complete the proof.

3. Similar to the proof for part (2) except that $\Delta\mathbf{w}_t$ is computed by Eqn 3. □

Two technical lemmas are useful to prove Lemma A.4. It should be noted that the bounds they give are tight.

Lemma A.2. *For D given in Eqn 5, let A be $D^\top D$ or $DD^\top$, and B be $D^{-1}D^{-\top}$ or $D^{-\top}D^{-1}$. Then, $\sigma(A) \subseteq \left[(1-\gamma)^2, (1+\gamma)^2\right]$ and $\sigma(B) \subseteq \left[(1+\gamma)^{-2}, (1-\gamma)^{-2}\right]$.*

Proof. It can be verified that $D^\top D$ equals

$$\begin{pmatrix} 1 & -\gamma & 0 & \cdots & 0 \\ -\gamma & 1+\gamma^2 & -\gamma & \cdots & 0 \\ & & \ddots & & \\ 0 & 0 & \cdots & 1+\gamma^2 & -\gamma \\ 0 & 0 & \cdots & -\gamma & 1+\gamma^2 \end{pmatrix}.$$

Since $D^\top D$ is symmetric, $\sigma\left(D^\top D\right) \subset \mathbb{R}$. It follows from Geršgorin's theorem (Horn & Johnson, 1986, Theorem 6.1.1) that $\sigma\left(D^\top D\right) \subseteq \left[(1-\gamma)^2, (1+\gamma)^2\right]$. The same holds for $\sigma\left(DD^\top\right)$. The second part follows immediately by observing that $D^{-1}D^{-\top} = \left(D^\top D\right)^{-1}$ and $D^{-\top}D^{-1} = \left(DD^\top\right)^{-1}$. □

Lemma A.3. *Let D be given by Eqn 5, then*

$$\sigma(D^{-1} + D^{-\top}) \subseteq \left[\frac{2}{1+\gamma}, \frac{2}{1-\gamma}\right].$$

Proof. It can be verified that $D^{-1} + D^{-\top}$ equals

$$G = \begin{pmatrix} 2 & \gamma & \gamma^2 & \cdots & \gamma^{T-2} & \gamma^{T-1} \\ \gamma & 2 & \gamma & \cdots & \gamma^{T-3} & \gamma^{T-2} \\ & & \ddots & & & \\ \gamma^{T-3} & \gamma^{T-4} & \cdots & 2 & \gamma & \gamma^2 \\ \gamma^{T-2} & \gamma^{T-3} & \cdots & \gamma & 2 & \gamma \\ \gamma^{T-1} & \gamma^{T-2} & \cdots & \gamma^2 & \gamma & 2 \end{pmatrix},$$

and that $(G-I)^{-1}$ equals

$$\begin{pmatrix} \frac{1}{1-\gamma^2} & \frac{-\gamma}{1-\gamma^2} & 0 & \cdots & 0 & 0 \\ \frac{-\gamma}{1-\gamma^2} & \frac{1+\gamma^2}{1-\gamma^2} & \frac{-\gamma}{1-\gamma^2} & \cdots & 0 & 0 \\ & & \ddots & & & \\ 0 & 0 & \cdots & \frac{1+\gamma^2}{1-\gamma^2} & \frac{-\gamma}{1-\gamma^2} & 0 \\ 0 & 0 & \cdots & \frac{-\gamma}{1-\gamma^2} & \frac{1+\gamma^2}{1-\gamma^2} & \frac{-\gamma}{1-\gamma^2} \\ 0 & 0 & \cdots & 0 & \frac{-\gamma}{1-\gamma^2} & \frac{1}{1-\gamma^2} \end{pmatrix}.$$

Clearly, $(G-I)^{-1}$ is symmetric, and it follows from Geršgorin's theorem that

$$\sigma\left((G-I)^{-1}\right) \subseteq \left[\frac{1-\gamma}{1+\gamma}, \frac{1+\gamma}{1-\gamma}\right].$$

Therefore,

$$\begin{aligned} \sigma(G-I) &\subseteq \left[\left(\frac{1+\gamma}{1-\gamma}\right)^{-1}, \left(\frac{1-\gamma}{1+\gamma}\right)^{-1}\right] \\ &= \left[\frac{1-\gamma}{1+\gamma}, \frac{1+\gamma}{1-\gamma}\right]. \end{aligned}$$

Consequently,

$$\sigma(G) \subseteq \left[1 + \frac{1-\gamma}{1+\gamma}, 1 + \frac{1+\gamma}{1-\gamma}\right] = \left[\frac{2}{1+\gamma}, \frac{2}{1-\gamma}\right]. \quad \square$$

We are now ready to prove the following lemma.

Lemma A.4. *$\rho(M_1) \leq -\frac{2\eta}{1+\gamma} + \eta^2\left(X^2 + \frac{1}{b(1-\gamma)^2}\right)$ where M_1 is given in Eqn 6.*

Proof. By Weyl's theorem (Horn & Johnson, 1986, Theorem 4.3.1),

$$\begin{aligned}\rho(M_1) \quad &\leq \quad \rho\left(\eta^2 X^2 I\right) + \rho\left(\frac{\eta^2}{b} D^{-1} D^{-\top}\right) + \\ &\qquad \rho\left(-\eta\left(D^{-1} + D^{-\top}\right)\right).\end{aligned}$$

The lemma then follows immediately from Lemmas A.2 and A.3. $\square$

Lemma A.5. *Let M_2 be defined by Eqn 10 and suppose the step-size is given by Eqn 11, then*

$$\rho(M_2) \leq -\frac{(1-\gamma)^2}{(1+2\gamma)^2\left(X^2 + \frac{1}{b}\right)}.$$

Proof. Let $\alpha = \frac{\eta^2}{b}$ and $\beta = \eta^2 X^2 (1+\gamma)^2 - 2\eta$, then $M_2 = D^\top \Sigma \left(\alpha D D^\top + \beta I\right) \Sigma D$. It is known that

$$\rho(M_2) = \max_{\mathbf{v}_1 \neq \mathbf{0}} \frac{\mathbf{v}_1^\top M_2 \mathbf{v}_1}{\mathbf{v}_1^\top \mathbf{v}_1}.$$

Define $\mathbf{v}_2 = D\mathbf{v}_1$ and we have:

$$\begin{aligned}\rho(M_2) \quad &= \quad \max_{\mathbf{v}_2 \neq \mathbf{0}} \frac{\mathbf{v}_2 \Sigma \left(\alpha D D^\top + \beta I\right) \Sigma \mathbf{v}_2}{\mathbf{v}_2^\top D^{-\top} D^{-1} \mathbf{v}_2} \\ &\leq \quad \max_{\mathbf{v}_2 \neq \mathbf{0}} \frac{(1-\gamma)^2 \mathbf{v}_2 \Sigma \left(\alpha D D^\top + \beta I\right) \Sigma \mathbf{v}_2}{\mathbf{v}_2^\top \mathbf{v}_2},\end{aligned}$$

where the last step is due to Lemma A.2 and the fact that M_2 is negative-definite for $\eta \ll 1$. Similarly, we define $\mathbf{v}_3 = \Sigma \mathbf{v}_2$ and use the fact that

$$0 \leq \mathbf{v}_2^\top \mathbf{v}_2 = \mathbf{v}_3^\top \Sigma^{-2} \mathbf{v}_3 \leq \left(1 + \gamma(1+\gamma)\eta X^2\right)^2 \|\mathbf{v}_3\|^2$$

to obtain:

$$\begin{aligned}\rho(M_2) \quad &\leq \quad \max_{\mathbf{v}_3 \neq \mathbf{0}} \frac{(1-\gamma)^2 \mathbf{v}_3^\top \left(\alpha D D^\top + \beta I\right) \mathbf{v}_3^\top}{\left(1 + \gamma(1+\gamma)\eta X^2\right)^2 \mathbf{v}_3^\top \mathbf{v}_3} \\ &= \quad \frac{(1-\gamma)^2 \rho\left(\alpha D D^\top + \beta I\right)}{\left(1 + \gamma(1+\gamma)\eta X^2\right)^2} \\ &\leq \quad \frac{(1-\gamma)^2\left(\alpha(1+\gamma)^2 + \beta\right)}{\left(1 + \gamma(1+\gamma)\eta X^2\right)^2}.\end{aligned}$$

If we choose η as in Eqn 11, then the lemma follows immediately from the fact that

$$1 + \frac{\gamma X^2}{(1+\gamma)\left(X^2 + \frac{1}{b}\right)} \leq 1 + \frac{\gamma}{1+\gamma} = \frac{1+2\gamma}{1+\gamma}. \quad \square$$

Acknowledgment

Abstract

We introduce a learning framework that combines elements of the well-known PAC and mistake-bound models. The KWIK (knows what it knows) framework was designed particularly for its utility in learning settings where active exploration can impact the training examples the learner is exposed to, as is true in reinforcement-learning and active-learning problems. We catalog several KWIK-learnable classes and open problems.

1. Motivation

At the core of recent reinforcement-learning algorithms that have polynomial sample complexity guarantees (Kearns & Singh, 2002; Kearns & Koller, 1999; Kakade et al., 2003; Strehl et al., 2007) lies the idea of distinguishing between instances that have been learned with sufficient accuracy and those whose outputs are still unknown.

The Rmax algorithm (Brafman & Tennenholtz, 2002), for example, estimates transition probabilities for each state–action–next-state triple of a Markov decision process (MDP). The estimates are made separately, as licensed by the Markov property, and the accuracy of the estimate is bounded using Hoeffding bounds. The algorithm explicitly distinguishes between probabilities that have been estimated accurately (known) and those for which more experience will be needed (unknown). By encouraging the agent to gather more experience in the unknown states, Rmax can guarantee a polynomial bound on the number of timesteps in which it has a non-near-optimal policy (Kakade, 2003).

In this paper, we make explicit the properties that are sufficient for a learning algorithm to be used in efficient exploration algorithms like Rmax. Roughly, the learning algorithm needs to make only accurate predictions, although it can opt out of predictions by saying "I don't know" ($\perp$). However, there must be a (polynomial) bound on the number of times the algorithm can respond $\perp$. We call such a learning algorithm KWIK ("know what it knows").

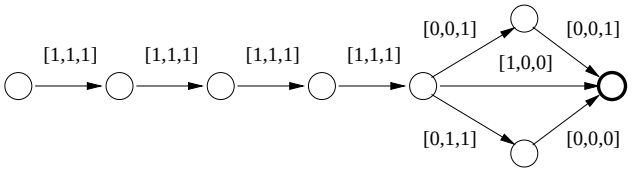

Figure 1. A cost-vector navigation graph.

Section 2 provides a motivating example and sketches possible uses for KWIK algorithms. Section 3 defines the KWIK conditions more precisely and relates them to established models from learning theory. Sections 4 and 5 survey a set of hypothesis classes for which KWIK algorithms can be created.

2. A KWIK Example

Consider the simple navigation task in Figure 1. There is a set of nodes connected by edges, with the node on the left as the source and the dark one on the right as the sink. Each edge in the graph is associated with a binary *cost vector* of dimension $d = 3$, indicated in the figure. The cost of traversing an edge is the dot product of its cost vector with a fixed weight vector $w = [1, 2, 0]$. Assume that w is not known to the agent, but the graph topology and all cost vectors are. In each episode, the agent starts from the source and moves along some path to the sink. Each time it crosses an edge, the agent observes its true cost. Once the sink is reached, the next episode begins. The learning task is to take a non-cheapest path in as few episodes as possible. There are 3 distinct paths in this example. Given the w above, the top has a cost of 12, the middle

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

13, and the bottom 15.

A simple approach for this task is for the agent to assume edge costs are uniform and walk the shortest (middle) path to collect data. It would gather 4 examples of $[1,1,1] \rightarrow 3$ and one of $[1,0,0] \rightarrow 1$. Standard regression algorithms could use this dataset to find a $\hat{w}$ that fits this data. Here, $\hat{w} = [1,1,1]$ is a natural choice. The learned weight vector could then be used to estimate costs for the three paths: 14 for the top, 13 for the middle, 14 for the bottom. Using these estimates, an agent would continue to take the middle path forever, never realizing it is not optimal.

In contrast, consider a learning algorithm that "knows what it knows". Instead of creating an approximate weight vector $\hat{w}$, it reasons about whether the costs for each edge can be obtained from the available data. The middle path, since we've seen all its edge costs, is definitely 13. The last edge of the bottom path has cost vector $[0,0,0]$, so its cost must be zero, but the penultimate edge of this path has cost vector $[0,1,1]$. This vector is a linear combination of the two observed cost vectors, so, regardless of w,

$$w{\cdot}[0,1,1] = w{\cdot}([1,1,1]-[1,0,0]) = w{\cdot}[1,1,1]-w{\cdot}[1,0,0],$$

which is just $3 - 1 = 2$. Thus, we know the bottom path's cost is 14—worse than the middle path.

The vector $[0,0,1]$ on the top path is linearly independent of the cost vectors we've seen, so its cost is unconstrained. We know we don't know. A safe thing to assume provisionally is that it's zero, encouraging the agent to try the top path in the second episode. Now, it observes $[0,0,1] \rightarrow 0$, allowing it to solve for w and accurately predict the cost for any vector (the training data spans $\Re^d$). It now knows that it knows all the costs, and can confidently take the optimal (top) path.

In general, any algorithm that guesses a weight vector may never find the optimal path. An algorithm that uses linear algebra to distinguish known from unknown costs will either take an optimal route *or* discover the cost of a linearly independent cost vector on each episode. Thus, it can never choose suboptimal paths more than d times.

The motivation for studying KWIK learning grew out of its use in multi-state sequential decision making problems like this one. However, other machine-learning problems could benefit from this perspective and from the development of efficient algorithms. For instance, action selection in bandit problems (Fong, 1995) and associative bandit problems (Strehl et al., 2006) (bandit problems with inputs) can both be addressed in the KWIK setting by choosing the better arm when both payoffs are known and an unknown arm otherwise.

KWIK could also be a useful framework for studying active learning (Cohn et al., 1994) and anomaly detection (Lane & Brodley, 2003), both of which are machine-learning problems that require some degree of reasoning about whether a recently presented input is predictable from previous examples. When mistakes are costly, as in utility-based data mining (Weiss & Tian, 2006) or learning robust control (Bagnell et al., 2001), having explicit predictions of certainty can be very useful for decision making.

3. Formal Definition

This section provides a formal definition of KWIK learning and its relationship to existing frameworks.

3.1. KWIK Definition

KWIK is an objective for supervised learning algorithms. In particular, we begin with an *input set* X and *output set* Y. The *hypothesis class* H consists of a set of functions from X to Y: $H \subseteq (X \rightarrow Y)$. The *target function* $h^* \in H$ is the source of training examples and is unknown to the learner. Note that the setting is "realizable", meaning we assume the target function is in the hypothesis class.

The protocol for a "run" is:

- The hypothesis class H and accuracy parameters ϵ and δ are known to both the learner and environment.
- The environment selects a target function $h^* \in H$ adversarially.
- Repeat:
  - The environment selects an input $x \in X$ adversarially and informs the learner.
  - The learner predicts an output $\hat{y} \in Y \cup \{\perp\}$.
  - If $\hat{y} \neq \perp$, it should be accurate: $|\hat{y} - y| \leq \epsilon$, where $y = h^*(x)$. Otherwise, the entire run is considered a failure. The probability of a failed run must be bounded by δ.
  - Over a run, the total number of steps on which $\hat{y} = \perp$ must be bounded by $B(\epsilon, \delta)$, ideally polynomial in $1/\epsilon$, $1/\delta$, and parameters defining H. Note that this bound should hold even if $h^* \notin H$, although, obviously, outputs need not be accurate in this case.
  - If $\hat{y} = \perp$, the learner makes an observation $z \in Z$ of the output, where $z = y$ in the deterministic case, $z = 1$ with probability y and

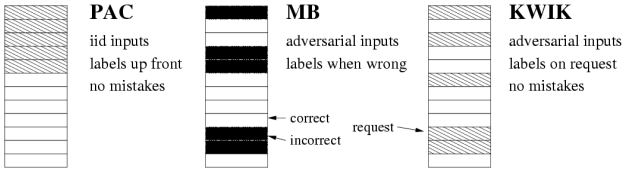

Figure 2. Relationship of KWIK to existing PAC and MB (mistake bound) frameworks in terms of how labels are provided for inputs.

0 with probability $1-y$ in the Bernoulli case, or $z = y + \eta$ for zero-mean random variable η in the additive noise case.

3.2. Connection to PAC and MB

Figure 2 illustrates the relationship of KWIK to the similar PAC (probably approximately correct) (Valiant, 1984) and MB (mistake bound) (Littlestone, 1987) frameworks. In all three cases, a series of inputs (instances) is presented to the learner. Each input is depicted in the figure by a rectangular box.

In the PAC model, the learner is provided with labels (correct outputs) for an initial sequence of inputs, depicted by cross-hatched boxes. After that point, the learner is responsible for producing accurate outputs (empty boxes) for all new inputs. Inputs are drawn from a fixed distribution.

In the MB model, the learner is expected to produce an output for every input. Labels are provided to the learner whenever it makes a mistake (filled boxes). Inputs are selected adversarially, so there is no bound on when the last mistake might be made. However, MB algorithms guarantee that the *total* number of mistakes is small, so the ratio of incorrect to correct outputs must go to zero asymptotically. Any MB algorithm for a hypothesis class can be used to provide a PAC algorithm for the same class, but not necessarily vice versa (Blum, 1994).

The KWIK model has elements of both PAC and MB. Like PAC, a KWIK algorithm is not allowed to make mistakes. Like MB, inputs to a KWIK algorithm are selected adversarially. Instead of bounding mistakes, a KWIK algorithm must have a bound on the number of label requests ($\perp$) it can make. By requiring performance to be independent of the distribution, a KWIK algorithm can be used in cases in which the input distribution is dependent in complex ways on the KWIK algorithm's behavior, as can happen in on-line or active learning settings. And, like PAC and MB, the definition of KWIK algorithms can be naturally extended to enforce low computational complexity.

Note that any KWIK algorithm can be turned into a MB algorithm with the same bound by simply having the algorithm guess an output each time it is not certain. However, some hypothesis classes are exponentially harder to learn in the KWIK setting than in the MB setting. An example is conjunctions of n Boolean variables, in which MB algorithms can guess "false" when uncertain and learn with $n+1$ mistakes, but a KWIK algorithm may need $\Omega(2^{n/2})$ $\perp$s to acquire the negative examples required to capture the target hypothesis.

3.3. Other Online Learning Models

The notion of allowing the learner to opt out of some inputs by returning $\perp$ is not unique to KWIK. Several other authors have considered related models. For instance, sleeping experts (Freund et al., 1997) can respond $\perp$ for some inputs, although they need not learn from these experiences. Learners in the settings of Selective Sampling (SS) (Cesa-Bianchi et al., 2006) and Label Efficient Prediction (Cesa-Bianchi et al., 2005) request labels randomly with a changing probability and achieve bounds on the expected number of mistakes and the expected number of label requests for a finite number of interactions. These algorithms cannot be used unmodified in the KWIK setting because, with high probability, KWIK algorithms must not make mistakes at any time. In the MB-like Apple-Tasting setting (Helmbold et al., 2000), the learner receives feedback asymmetrically only when it predicts a particular label (a positive example, say), which conflates the request for a sample with the prediction of a particular outcome.

Open Problem 1 *Is there a way of modifying SS algorithms to satisfy the KWIK criteria?*

4. Some KWIK Learnable Classes

This section describes some hypothesis classes for which KWIK algorithms are available. It is not meant to be an exhaustive survey, but simply to provide a flavor for the properties of hypothesis classes KWIK algorithms can exploit. The complexity of many learning problems has been characterized by defining the *dimensionality* of hypothesis classes (Angluin, 2004). No such definition has been found for the KWIK model, so we resort to enumerating examples of learnable classes.

Open Problem 2 *Is there a way of characterizing the "dimension" of a hypothesis class in a way that can be used to derive KWIK bounds?*

4.1. Memorization and Enumeration

We begin by describing the simplest and most general KWIK algorithms.

Algorithm 1 *The* memorization algorithm *can learn any hypothesis class with input space X with a KWIK bound of $|X|$. This algorithm can be used when the input space X is finite and observations are noise free.*

To achieve this bound, the algorithm simply keeps a mapping $\hat{h}$ initialized to $\hat{h}(x) = \perp$ for all $x \in X$. When the environment chooses an input x, the algorithm reports $\hat{h}(x)$. If $\hat{h}(x) = \perp$, the environment will provide a label y and the algorithm will assign $\hat{h}(x) := y$. It will only report $\perp$ once for each input, so the KWIK bound is $|X|$.

Algorithm 2 *The* enumeration algorithm *can learn any hypothesis class H with a KWIK bound of $|H|-1$. This algorithm can be used when the hypothesis class H is finite and observations are noise free.*

The algorithm keeps track of $\hat{H}$, the version space, and initially $\hat{H} = H$. Each time the environment provides input $x \in X$, the algorithm computes $\hat{L} = \{h(x) | h \in \hat{H}\}$. That is, it builds the set of all outputs for x for all hypotheses that have not yet been ruled out. If $|\hat{L}| = 0$, the version space has been exhausted and the target hypothesis is not in the hypothesis class ($h^* \notin H$).

If $|\hat{L}| = 1$, it means that all hypotheses left in $\hat{H}$ agree on the output for this input, and therefore the algorithm knows what the proper output must be. It returns $\hat{y} \in \hat{L}$. On the other hand, if $|\hat{L}| > 1$, two hypotheses in the version space disagree. In this case, the algorithm returns $\perp$ and receives the true label y. It then computes an updated version space

$$\hat{H}' = \{h | h \in \hat{H} \wedge h(x) = y\}.$$

Because $|\hat{L}| > 1$, there must be some $h \in \hat{H}$ such that $h(x) \neq y$. Therefore, the new version space must be smaller $|\hat{H}'| \leq |\hat{H}| - 1$. Before the next input is received, the version space is updated $\hat{H} := \hat{H}'$.

If $|\hat{H}| = 1$ at any point, $|\hat{L}| = 1$, and the algorithm will no longer return $\perp$. Therefore, $|H|-1$ is the maximum number of $\perp$s the algorithm can return.

Example 1 *You own a bar that is frequented by a group of n patrons P. There is one patron $\mathbf{f} \in P$ who is an instigator—whenever a group of patrons is in the bar $G \subseteq P$, if $\mathbf{f} \in G$, a fight will break out. However, there is another patron $\mathbf{p} \in P$, who is a peacemaker. If $\mathbf{p}$ is in the group, it will prevent a fight, even if $\mathbf{f}$ is present.*

You want to predict whether a fight will break out among a subset of patrons, initially without knowing the identities of $\mathbf{f}$ and $\mathbf{p}$. The input space is $X = 2^P$ and the output space is $Y = \{$fight, no fight$\}$.

The memorization algorithm achieves a KWIK bound of 2^n for this problem, since it may have to see each possible subset of patrons. However, the enumeration algorithm can KWIK learn this hypothesis class with a bound of $n(n-1)$ since there is one hypothesis for each possible assignment of a patron to $\mathbf{f}$ and $\mathbf{p}$. Each time it reports $\perp$, it is able to rule out at least one possible instigator–peacemaker combination.

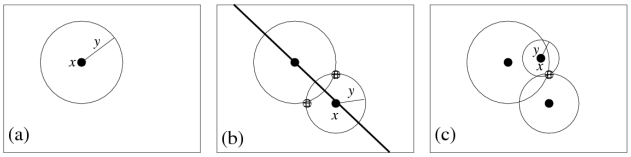

Figure 3. Schematic of behavior of the planar-distance algorithm after the first (a), second (b), and third (c) time it returns $\perp$.

4.2. Real-valued Functions

The previous two examples exploited the finiteness of the hypothesis class and input space. KWIK bounds can also be achieved when these sets are infinite.

Algorithm 3 *Define $X = \Re^2$, $Y = \Re$, and*

$$H = \{f | f : X \to Y, c \in \Re^2, f(x) = \|x - c\|_2\}.$$

This is, there is an unknown point and the target function maps input points to the distance from the unknown point. The planar-distance algorithm *can learn in this hypothesis class with a KWIK bound of 3.*

The algorithm proceeds as follows, illustrated in Figure 3. First, given initial input x, the algorithm says $\perp$ and receives output y. Since y is the distance between x and some unknown point c, we know c must lie on the circle illustrated in Figure 3(a). (If $y = 0$, then $c = x$.) Let's call this input–output pair x_1, y_1. The algorithm will return y_1 for any future input that matches x_1. Otherwise, it will need to return $\perp$ and will obtain a new input–output pair x, y, as shown in Figure 3(b). They become x_2 and y_2.

Now, the algorithm can narrow down the location of c to the two hatch-marked points. In spite of this ambiguity, for any input on the dark diagonal line the algorithm will be able to return the correct distance—all

these points are equidistant from the two possibilities. The two circles must intersect, assuming the target hypothesis is in H[1].

Once an input x is received that is not co-linear with x_1 and x_2, the algorithm returns $\perp$ and obtains another x, y pair, as illustrated in Figure 3(c). Finally, since three circles will intersect at at most one point, the algorithm can identify the location of c and use it to correctly answer any future query. Thus, three $\perp$s suffice for KWIK learning in this setting. The algorithm generalizes to d-dimensional versions of the setting with a KWIK bound of $d + 1$.

Algorithm 3 illustrates a number of important points. First, since learners have no control over their inputs in the KWIK setting, they must be robust to degenerate inputs such as inputs that lie precisely on a line. Second, they can often return valid answers for some inputs even before they have learned the target function over the entire input space.

4.3. Noisy Observations

Up to this point, observations have been noise free. Next, we consider the simplest noisy KWIK learning problem in the Bernoulli case.

Algorithm 4 *The* coin-learning algorithm *can accurately predict the probability that a biased coin will come up heads given Bernoulli observations with a KWIK bound of* $B(\epsilon, \delta) = \frac{1}{2\epsilon^2} \ln \frac{2}{\delta} = O\left(\frac{1}{\epsilon^2} \ln \frac{1}{\delta}\right)$.

We have a biased coin whose unknown probability of heads is p. In the notation of this paper, $|X| = 1$, $Y = [0, 1]$, and $Z = \{0, 1\}$. We want to learn an estimate $\hat{p}$ that is accurate ($|\hat{p} - p| \leq \epsilon$) with high probability $(1 - \delta)$.

If we could observe p, then this problem would be trivial: Say $\perp$ once, observe p, and let $\hat{p} = p$. The KWIK bound is thus 1. Now, however, observations are noisy. Instead of observing p, we see either 1 (with probability p) or 0 (with probability $1 - p$).

Each time the algorithm says $\perp$, it gets an independent trial that it can use to compute $\hat{p} = \frac{1}{T} \sum_{t=1}^{T} z_t$, where $z_t \in Z$ is the tth observation in T trials. The number of trials needed before we are $1-\delta$ certain our estimate is within ϵ can be computed using a Hoeffding bound:

$$T \geq \frac{1}{2\epsilon^2} \ln \frac{2}{\delta} = O\left(\frac{1}{\epsilon^2} \ln \frac{1}{\delta}\right).$$

[1]They can also intersect at one point, if the circles are tangent, in which case the algorithm can identify c unambiguously.

Algorithm 5 *Define* $X = \Re^d$, $Y = \Re$, *and*

$$H = \{f | f : X \to Y, w \in \Re^d, f(x) = w \cdot x\}.$$

That is, H is the linear functions on d variables. Given additive noise, the noisy linear-regression algorithm *can learn in H with a KWIK bound of* $B(\epsilon, \delta) = \tilde{O}(d^3/\epsilon^4)$, *where* $\tilde{O}(\cdot)$ *suppresses log factors.*

The deterministic case was described in Section 2 with a bound of d. Here, the algorithm must be cautious to average over the noisy samples to make predictions accurately. This problem was solved by Strehl and Littman (2008). The algorithm uses the least squares estimate of the weight vector for inputs with high certainty. Certainty is measured by two terms representing (1) the number and proximity of previous samples to the current point and (2) the appropriateness of the previous samples for making a least squares estimate. When certainty is low for either measure, the algorithm reports $\perp$ and observes a noisy sample of the linear function.

Here, solving a noisy version of a problem resulted in an increased KWIK bound (from d to essentially d^3). Note that the deterministic Algorithm 3 also has a bound of d, but no bound has been found for the stochastic case.

Open Problem 3 *Is there a general scheme for taking a KWIK algorithm for a deterministic class and updating it to work in the presence of noise?*

5. Combining KWIK Learners

This section provides examples of how KWIK learners can be combined to provide learning guarantees for more complex hypothesis classes.

Algorithm 6 *Let* $F : X \to Y$ *be the set of functions mapping input set X to output set Y. Let* $H_1, \ldots, H_k$ *be a set of KWIK learnable hypothesis classes with bounds of* $B_1(\epsilon, \delta), \ldots, B_k(\epsilon, \delta)$ *where* $H_i \subseteq F$ *for all* $1 \leq i \leq k$. *That is, all the hypothesis classes share the same input/output sets. The* union algorithm *can learn the joint hypothesis class* $H = \bigcup_i H_i$ *with a KWIK bound of* $B(\epsilon, \delta) = (1 - k) + \sum_i B_i(\epsilon, \delta)$.

The union algorithm is like a higher-level version of the enumeration algorithm (Algorithm 2) and applies in the deterministic setting. It maintains a set of active algorithms $\hat{A}$, one for each hypothesis class: $\hat{A} = \{1, \ldots, k\}$. Given an input x, the union algorithm queries each algorithm $i \in \hat{A}$ to obtain a prediction $\hat{y}_i$ from each active algorithm. Let $\hat{L} = \{\hat{y}_i | i \in \hat{A}\}$.

If $\perp \in \hat{L}$, the union algorithm reports $\perp$ and obtains the correct output y. Any algorithm i for which $\hat{y} = \perp$ is then sent the correct output y to allow it to learn. If $|\hat{L}| > 1$, then there is disagreement among the subalgorithms. The union algorithm reports $\perp$ in this case because at least one of the algorithms has learned the wrong hypothesis and it needs to know which.

Any algorithm that made a prediction other than y or $\perp$ is "killed"—removed from consideration. That is,

$$\hat{A}' = \{i | i \in \hat{A} \wedge (\hat{y}_i = \perp \vee \hat{y}_i = y)\}.$$

On each input for which the union algorithm reports $\perp$, either one of the subalgorithms reported $\perp$ (at most $\sum_i B_i(\epsilon, \delta)$ times) or two algorithms disagreed and at least one was removed from $\hat{A}$ (at most $k - 1$ times). The KWIK bound follows from these facts.

Example 2 *Let $X = Y = \Re$. Now, define $H_1 = \{f | f(x) = |x - c|, c \in \Re\}$. That is, each function in H_1 maps x to its distance from some unknown point c. We can learn H_1 with a KWIK bound of 2 using a 1-dimensional version of Algorithm 3. Next, define $H_2 = \{f | f(x) = yx + b, m \in \Re, b \in \Re\}$. That is, H_2 is the set of lines. We can learn H_2 with a KWIK bound of 2 using the regression algorithm in Section 2. Finally, define $H = H_1 \cup H_2$, the union of these two classes. We can use Algorithm 6 to KWIK learn H.*

Assume the first input is $x_1 = 2$. The union algorithm asks the learners for H_1 and H_2 the output for x_1 and neither has any idea, so it returns $\perp$ and receives the feedback $y_1 = 2$, which it passes to the subalgorithms. The next input is $x_2 = 8$. The learners for H_1 and H_2 still don't have enough information, so it returns $\perp$ and sees $y_2 = 4$, which it passes to the subalgorithms. Next, $x_3 = 1$. Now, the learner for H_1 unambiguously computes $c = 4$, because that's the only interpretation consistent with the first two examples ($|2 - 4| = 2$, $|8 - 4| = 4$), so it returns $|1 - 4| = 3$. On the other hand, the learner for H_2 unambiguously computes $m = 1/3$ and $b = 4/3$, because that's the only interpretation consistent with the first two examples ($2 \times 1/3 + 4/3 = 2$, $8 \times 1/3 + 4/3 = 4$), so it returns $1 \times 1/3 + 4/3 = 5/3$. Since the two subalgorithms disagree, the union algorithm returns $\perp$ one last time and finds out that $y_3 = 3$. It makes all future predictions (accurately) using the algorithm for H_1.

Next, we consider a variant of Algorithm 1 that combines learners across disjoint input spaces.

Algorithm 7 *Let $X_1, \ldots, X_k$ be a set of disjoint input spaces ($X_i \cap X_j = \emptyset$ if $i \neq j$) and Y be an output space. Let $H_1, \ldots, H_k$ be a set of KWIK learnable hypothesis classes with bounds of $B_1(\epsilon, \delta), \ldots, B_k(\epsilon, \delta)$ where $H_i \in (X_i \to Y)$. The* input-partition algorithm *can learn the hypothesis class $H \in (X_1 \cup \cdots \cup X_k \to Y)$ with a KWIK bound of $B(\epsilon, \delta) = \sum_i B_i(\epsilon, \delta/k)$.*

The input-partition algorithm runs the learning algorithm for each subclass H_i. When it receives an input $x \in X_i$, it queries the learning algorithm for class H_i and returns its response, which is ϵ accurate, by request. To achieve $1 - \delta$ certainty, it insists on $1 - \delta/k$ certainty from each of the subalgorithms. By the union bound, the overall failure probability must be less than the sum of the failure probabilities for the subalgorithms.

Example 3 *An MDP consists of n states and m actions. For each combination of state and action and next state, the transition function returns a probability. As the reinforcement-learning agent moves around in the state space, it observes state–action–state transitions and must predict the probabilities for transitions it has not yet observed. In the model-based setting, an algorithm learns a mapping from the size n^2m input space of state–action–state combinations to probabilities via Bernoulli observations. Thus, the problem can be solved via the input-partition algorithm (Algorithm 7) over a set of individual probabilities learned via Algorithm 4. The resulting KWIK bound is $B(\epsilon, \delta) = O\left(\frac{n^2 m}{\epsilon^2} \ln \frac{nm}{\delta}\right)$.*

Note that this approach is precisely what is found in most efficient RL algorithms in the literature (Kearns & Singh, 2002; Brafman & Tennenholtz, 2002).

Algorithm 7 combines hypotheses by partitioning the input space. In contrast, the next example concerns combinations in input and output space.

Algorithm 8 *Let $X_1, \ldots, X_k$ and $Y_1, \ldots, Y_k$ be a set of input and output spaces and $H_1, \ldots, H_k$ be a set of KWIK learnable hypothesis classes with bounds of $B_1(\epsilon, \delta), \ldots, B_k(\epsilon, \delta)$ on these spaces. That is, $H_i \in (X_i \to Y_i)$. The* cross-product algorithm *can learn the hypothesis class $H \in ((X_1 \times \cdots \times X_k) \to (Y_1 \times \cdots \times Y_k))$ with a KWIK bound of $B(\epsilon, \delta) = \sum_i B_i(\epsilon, \delta/k)$.*

Here, each input consists of a vector of inputs from each of the spaces $X_1, \ldots, X_k$ and outputs are vectors of outputs from $Y_1, \ldots, Y_k$. Like Algorithm 7, each component of this vector can be learned independently via the corresponding algorithm. Each is learned to within an accuracy of ϵ and confidence $1 - \delta/k$. Any time any component returns $\perp$, the cross-product algorithm returns $\perp$. Since each $\perp$ returned can be traced to one of the subalgorithms, the total is bounded as

described above. By the union bound, total failure probability is no more than $k \times \delta/k = \delta$.

Example 4 *Transitions in factored-state MDP can be thought of as mappings from vectors to vectors. Given known dependencies, the cross-product algorithm can be used to learn each component of the transition function. Each component is, itself, an instance of Algorithm 7 applied to the coin-learning algorithm. This three-level KWIK algorithm provides an approach to learn the transition function of a factored-state MDP with a polynomial KWIK bound. This insight can be used to derive the factored-state-MDP learning algorithm used by Kearns and Koller (1999).*

The previous two algorithms apply to both deterministic and noisy observations. We next provide a powerful algorithm that generalizes the union algorithm (Algorithm 6) to work with noisy observations as well.

Algorithm 9 *Let $F : X \to Y$ be the set of functions mapping input set X to output set $Y = [0, 1]$. Let $Z = \{0, 1\}$ be a binary observation set. Let $H_1, \ldots, H_k$ be a set of KWIK learnable hypothesis classes with bounds of $B_1(\epsilon, \delta), \ldots, B_k(\epsilon, \delta)$ where $H_i \subseteq F$ for all $1 \leq i \leq k$. That is, all the hypothesis classes share the same input/output sets. The* noisy union algorithm *can learn the joint hypothesis class $H = \bigcup_i H_i$ with a KWIK bound of $B(\epsilon, \delta) = O\left(\frac{k}{\epsilon^2} \ln \frac{k}{\delta}\right) + \sum_{i=1}^{k} B_i(\frac{\epsilon}{4}, \frac{\delta}{k+1})$.*

For simplicity, we sketch the special case of $k = 2$. The general case will be briefly discussed at the end. The noisy union algorithm is similar to the union algorithm (Algorithm 6), except that it has to deal with noisy observations. The algorithm proceeds by running the KWIK algorithms, using parameters (ϵ_0, δ_0), as subalgorithms for each of the H_i hypothesis classes, where $\epsilon_0 = \frac{\epsilon}{4}$ and $\delta_0 = \frac{\delta}{3}$. Given an input x_t in trial t, it queries each algorithm i to obtain a prediction $\hat{y}_{ti}$. Let $\hat{L}_t$ be the set of responses.

If $\perp \in \hat{L}_t$, the noisy union algorithm reports $\perp$, obtains an observation $z_t \in Z$, and sends it to all subalgorithms i with $\hat{y}_{ti} = \perp$ to allow them to learn. In the following, we focus on the other case where $\perp \notin \hat{L}_t$.

If $|\hat{y}_{t1} - \hat{y}_{t2}| \leq 4\epsilon_0$, then these two predictions are sufficiently consistent, and we claim that, with high probability, the prediction $\hat{p}_t = (\hat{y}_{t1} + \hat{y}_{t2})/2$ is ϵ-close to $y_t = \Pr(z_t = 1)$. This claim follows because, by assumption, one of the predictions, say $\hat{y}_{t1}$, deviates from y_t by at most ϵ_0 with probability at least $1 - \delta/3$, and hence $|\hat{p}_t - y_t| = |\hat{p}_t - \hat{y}_{t1} + \hat{y}_{t1} - y_t| \leq |\hat{p}_t - \hat{y}_{t1}| + |\hat{y}_{t1} - \hat{y}_t| = |\hat{y}_{t1} - \hat{y}_{t2}|/2 + |\hat{y}_{t1} - \hat{y}_t| \leq 2\epsilon_0 + \epsilon_0 < \epsilon$.

If $|\hat{y}_{t1} - \hat{y}_{t2}| > 4\epsilon_0$, then the individual predictions are not consistent enough for the noisy union algorithm to make an ϵ-accurate prediction. Thus, the noisy union algorithm reports $\perp$ and needs to know which subalgorithm provided an inaccurate response. But, since the observations are noisy in this problem, it cannot eliminate h_i on the basis of a single observation. Instead, it maintains the total squared prediction error for every subalgorithm i: $\ell_i = \sum_{t \in I} (\hat{y}_{ti} - z_t)^2$, where $I = \{t \,|\, |\hat{y}_{t1} - \hat{y}_{t2}| > 4\epsilon_0\}$ is the set of trials in which the subalgorithms gave inconsistent predictions. We observe that $|I|$ is the number of $\perp$s returned by the noisy union algorithm alone (not counting those returned by the subalgorithms). Our last step is to show ℓ_i provides a robust measure for eliminating invalid predictors when $|I|$ is sufficiently large.

Applying the Hoeffding bound and some algebra, we find $\Pr(\ell_1 > \ell_2) \leq$

$$\exp\left(-\frac{\sum_{t \in I} |\hat{y}_{t1} - \hat{y}_{t2}|^2}{8}\right) \leq \exp\left(-2\epsilon_0^2 |I|\right).$$

Setting the righthand side to be $\delta/3$ and solving for $|I|$, we have $|I| = \frac{1}{2\epsilon_0^2} \ln \frac{3}{\delta} = O\left(\frac{1}{\epsilon^2} \ln \frac{1}{\delta}\right)$.

Since each h_i succeeds with probability $1 - \frac{\delta}{3}$, and the comparison of ℓ_1 and ℓ_2 also succeeds with probability $1 - \frac{\delta}{3}$, a union bound implies that the noisy union algorithm succeeds with probability at least $1 - \delta$. All $\perp$s are either from a subalgorithm (at most $\sum_i B_i(\epsilon_0, \delta_0)$) or from the noisy union algorithm ($O\left(\frac{1}{\epsilon^2} \ln \frac{1}{\delta}\right)$).

The general case where $k > 2$ can be reduced to the $k = 2$ case by pairing the k learners and running the noisy union algorithm described above on each pair. Here, each subalgorithm is run with parameter $\frac{\epsilon}{4}$ and $\frac{\delta}{k+1}$. Although there are $\binom{k}{2} = O(k^2)$ pairs, a slightly improved reduction and analysis can reduce the dependence of $|I|$ on k from quadratic to linearithmic, leading to the bound given in the statement.

Example 5 *Without known dependencies, learning a factored-state MDP is more challenging. Strehl et al. (2007) showed that each possible dependence structure can be viewed as a separate hypothesis and provided an algorithm for learning the dependencies in a factored-state MDP while learning the transition probabilities. The algorithm can be viewed as a four-level KWIK algorithm with a noisy union algorithm at the top (to discover the dependence structure), a cross-product algorithm beneath it (to decompose the transitions for the separate components of the factored-state representation), an input-partition algorithm below that (to handle the different combinations of state component and action), and a coin-learning algorithm*

at the very bottom (to learn the transition probabilities themselves). Note that Algorithm 9 is conceptually simpler, significantly more efficient ($k \log k$ vs. k^2 dependence on k), and more generally applicable than the one due to Strehl et al. (2007).

6. Conclusion and Future Work

We described the KWIK ("knows what it knows") model of supervised learning, which identifies and generalizes a key step common to a class of algorithms for efficient exploration. We provided algorithms for a set of basic hypothesis classes given deterministic and noisy observations as well as methods for composing hypothesis classes to create more complex algorithms. One example algorithm consisted of a four-level decomposition of an existing learning algorithm from the reinforcement-learning literature.

By providing a set of example algorithms and composition rules, we hope to encourage the use of KWIK algorithms as a component in machine-learning applications as well as spur the development of novel algorithms. One concern of particular interest in applying the KWIK framework to real-life data we leave as an open problem.

Open Problem 4 *How can KWIK be adapted to apply in the unrealizable setting in which the target hypothesis can be chosen from outside the hypothesis class H?*

Pairwise Constraint Propagation by Semidefinite Programming for Semi-Supervised Classification

Abstract

We consider the general problem of learning from both pairwise constraints and unlabeled data. The pairwise constraints specify whether two objects belong to the same class or not, known as the must-link constraints and the cannot-link constraints. We propose to learn a mapping that is smooth over the data graph and maps the data onto a unit hypersphere, where two must-link objects are mapped to the same point while two cannot-link objects are mapped to be orthogonal. We show that such a mapping can be achieved by formulating a semidefinite programming problem, which is convex and can be solved globally. Our approach can effectively propagate pairwise constraints to the whole data set. It can be directly applied to multi-class classification and can handle data labels, pairwise constraints, or a mixture of them in a unified framework. Promising experimental results are presented for classification tasks on a variety of synthetic and real data sets.

1. Introduction

Learning from both labeled and unlabeled data, known as semi-supervised learning, has attracted considerable interest in recent years (Chapelle et al., 2006), (Zhu, 2005). The key to the success of semi-supervised learning is the cluster assumption (Zhou et al., 2004), stating that nearby objects and objects on the same manifold structure are likely to be in the same class. Different algorithms actually implement the cluster assumption from different viewpoints (Zhu et al.,), (Zhou et al., 2004), (Belkin et al., 2006), (Chapelle & Zien, 2005), (Zhang & Ando, 2006), (Szummer et al., 2002). When the cluster assumption is appropriate, we can properly classify the whole data set with only one labeled object for each class.

However, the distributions of real-world data are often more complex than expected, where there are circumstances that a class may consist of multiple separate groups or manifolds, and different classes may be close to or even overlap with each other. For example, a common experience is that face images of the same person under different poses and illuminations can be drastically different, while those with similar appearances may originate from two different persons. To handle the classification problems of such practical data, additional assumptions should be made and more supervisory information should be exploited when available.

Class labels of data are the most widely used supervisory information. In addition, pairwise constraints are also often seen, which specify whether two objects belong to the same class or not, known as the must-link constraints and the cannot-link constraints. Such pairwise constraints may arise from domain knowledge automatically or with a little human effort (Wagstaff & Cardie, 2000), (Klein et al., 2002), (Kulis et al., 2005), (Chapelle et al., 2006). They can also be obtained from data labels where objects with the same label are must-link while objects with different labels are cannot-link. Generally, we cannot infer data labels from only pairwise constraints, especially for multi-class data. In this sense, pairwise constraints are inherently weaker and thus more general than labels of data. Pairwise constrains have been widely used in the contexts of clustering with side information (Wagstaff et al., 2001), (Klein et al., 2002), (Xing et al., 2003), (Kulis et al., 2005), (Kamvar et al., 2003), (Globerson & Roweis, 2006), (Basu et al., 2004), (Bilenko

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

et al., 2004), (Bar-Hillel et al., 2003), (Hoi et al., 2007), where it has been shown that the presence of appropriate pairwise constraints can often improve the clustering performance.

In this paper, we consider a more general problem of semi-supervised classification from pairwise constraints and unlabeled data, which includes the traditional semi-supervised classification as a subproblem that considers labeled and unlabeled data. Note that the label propagation techniques, which are often used in the traditional semi-supervised classification (Zhou et al., 2004), (Zhu et al.,), (Belkin et al., 2006), cannot be readily generalized to propagate pairwise constraints. Recently, two methods (Goldberg et al., 2007), (Tong & Jin, 2007) are proposed to incorporate dissimilarity information in semi-supervised classification, which is similar to the cannot-link constraints. It is important to notice that the similarities between objects are not identical to the must-link constraints imposed on them. The former reflects their distances in the input space while the latter is often obtained using domain knowledge or specified by the user.

We propose an approach, called *pairwise constraint propagation* (PCP), that can effectively propagate pairwise constraints to the whole data set. PCP intends to learn a mapping that is smooth over the data graph and maps the data onto a unit hypersphere, where two must-link objects are mapped to the same point while two cannot-link objects are mapped to be orthogonal. Such a mapping can be implicitly achieved using the kernel trick via semidefinite programming, which is convex and can be solved globally. Our approach can be directly applied to multi-class classification and can handle data labels, pairwise constraints, or a mixture of them in a unified framework.

2. Motivation

Given a data set of n objects $\mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n\}$ and two sets of pairwise must-link and cannot-link constraints, denoted respectively by $\mathcal{M} = \{(\mathbf{x}_i, \mathbf{x}_j)\}$ where $\mathbf{x}_i$ and $\mathbf{x}_j$ should be in the same class and $\mathcal{C} = \{(\mathbf{x}_i, \mathbf{x}_j)\}$ where $\mathbf{x}_i$ and $\mathbf{x}_j$ should be in different classes, our goal is to classify $\mathcal{X}$ into k classes such that not only the constraints are satisfied, but also those unlabeled objects similar to two must-link objects respectively are classified into the same class and those similar to two cannot-link objects respectively are classified into different classes.

To better illustrate our purpose, let us consider the classification task on a toy data set shown in Fig. 1(a). Although this data set consists of three separate

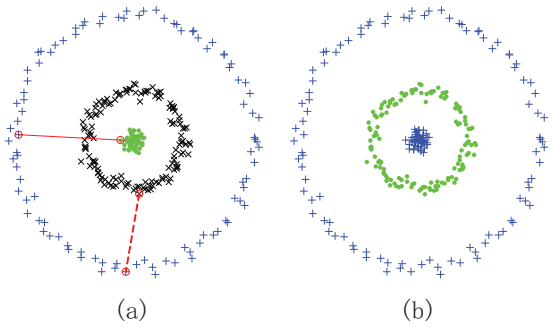

Figure 1. Classification on Three-Circle. (a) A data set with one must-link constraint and one cannot-link constraint, denoted by the solid and the dashed red lines, respectively. (b) Ideal classification (two classes) we hope to obtain where different classes are denoted by different colors and symbols.

groups (denoted by different colors and symbols in Fig. 1(a)), it has only two classes (Fig. 1(b)). We argue that the must-link constraint asks merging the outer circle and the inner circle into one class, instead of just merging the two must-link objects; and the cannot-link constraint asks for keeping the middle circle and the outer circles into different classes, not just keeping the two cannot-link objects into different classes. Consequently, the desired classification result is the one shown in Fig. 1(b). It is such a global implication that we interpret the pairwise constraints.

From this simple example, we can see that the cluster assumption is still valid, i.e., nearby objects tend to be in the same class and objects on the same manifold structure also tend to be in the same class. However, this assumption does not concern those objects that are not close to each other and do not share the same manifold structure. We argue that the classification for such objects should accord with the input pairwise constraints. For example, any two objects on the outer and inner circles in Fig. 1(a) should be in the same class because they respectively share the same manifold structures with the two must-link objects, and any two objects on the outer and middle circles should be in different classes because they respectively share the same manifold structures with the two cannot-link objects. We refer to this assumption as the *pairwise constraint assumption*.

In this paper, we seek to implement both the cluster assumption and the pairwise constraint assumption in a unified framework. A dilemma is that one may specify nearby objects or objects sharing the same manifold structure to be cannot-link. In this case, we choose to respect the pairwise constraint assumption first and then the cluster assumption, considering that the prior pairwise constraints are from reliable knowledge. This

is true in most practical applications.

3. Pairwise Constraint Propagation

3.1. A General Framework

As mentioned in the last section, our goal is to propagate the given pairwise constraints to the whole data set in a global implication for classification. Intuitively, it is hard to implement our idea in the input space. Therefore, we seek a mapping (usually non-linear) to map the objects to a new and possibly higher-dimensional space such that the objects are reshaped in this way: two must-link objects become close while two cannot-link objects become far apart; objects respectively similar to two must-link objects also become close while objects respectively similar to two cannot-link objects become far apart.

Let $\boldsymbol{\phi}$ be a mapping from $\mathcal{X}$ to some space $\mathcal{F}$,

$$\mathbf{x}_i \in \mathcal{X} \mapsto \boldsymbol{\phi}(\mathbf{x}_i) \in \mathcal{F}. \tag{1}$$

The above analysis motivates us to consider the following optimization framework:

$$\min_{\boldsymbol{\phi}} : \ \mathcal{S}(\boldsymbol{\phi}) \tag{2}$$

$$\text{s.t.} : \ \|\boldsymbol{\phi}(\mathbf{x}_i) - \boldsymbol{\phi}(\mathbf{x}_j)\|_{\mathcal{F}} < \varepsilon, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{M}, \tag{3}$$

$$\|\boldsymbol{\phi}(\mathbf{x}_i) - \boldsymbol{\phi}(\mathbf{x}_j)\|_{\mathcal{F}} > \delta, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{C}, \tag{4}$$

where $\mathcal{S}(\boldsymbol{\phi})$ is a smoothness measure for $\boldsymbol{\phi}$ such that the smaller is $\mathcal{S}(\boldsymbol{\phi})$, the smoother is $\boldsymbol{\phi}$; ε is a small positive number; δ is a large positive number; $\|\cdot\|_{\mathcal{F}}$ is a distance metric in $\mathcal{F}$; $\mathcal{M}$ is the set of the must-link constraints; $\mathcal{C}$ is the set of cannot-link constraints. The inequality constraints (3) and (4) require $\boldsymbol{\phi}$ to map two must-link objects to be close and two cannot-link objects far apart. By enforcing the smoothness on $\boldsymbol{\phi}$ (minimizing the objective (2)), we actually require $\boldsymbol{\phi}$ to map any two objects respectively similar to two must-link objects to be close and map any two objects respectively similar to two cannot-link objects far apart. Hopefully, after the mapping, each class becomes relatively compact and different classes become far apart. Once such a mapping is derived, the classification task can be done much easier.

This optimization framework is quite general and the details have to be developed. We propose a unit hypersphere model to substantialize it in Section 3.2, and then solve the resulting optimization problem in Section 3.3.

3.2. The Unit Hypersphere Model

Recall that our goal is to find a smooth mapping that maps two must-link objects close and two cannot-link objects far apart. To this end, we consider it better to put the images of all the objects under a uniform scale. The unit hypersphere in $\mathcal{F}$ is a good choice because there is a natural way to impose the pairwise constraints on it. Our key idea is to map all the objects onto the unit hypersphere in $\mathcal{F}$, where two must-link objects are mapped to the same point and two cannot-link objects to be orthogonal. Mathematically, we require $\boldsymbol{\phi}$ to satisfy

$$< \boldsymbol{\phi}(\mathbf{x}_i), \boldsymbol{\phi}(\mathbf{x}_i) >_{\mathcal{F}} = 1, \ i = 1, 2, ..., n, \tag{5}$$

$$< \boldsymbol{\phi}(\mathbf{x}_i), \boldsymbol{\phi}(\mathbf{x}_j) >_{\mathcal{F}} = 1, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{M}, \tag{6}$$

$$< \boldsymbol{\phi}(\mathbf{x}_i), \boldsymbol{\phi}(\mathbf{x}_j) >_{\mathcal{F}} = 0, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{C}, \tag{7}$$

where $< \cdot, \cdot >_{\mathcal{F}}$ denotes the dot product in $\mathcal{F}$.

Next we impose smoothness on $\boldsymbol{\phi}$ using the spectral graph theory where the graph Laplacian plays an essential role (Chung, 1997). Let $G = (V, W)$ be an undirected, weighted graph with the node set $V = \mathcal{X}$ and the weight matrix $W = [w_{ij}]_{n \times n}$, where w_{ij} is the weight on the edge connecting nodes $\mathbf{x}_i$ and $\mathbf{x}_j$, denoting how similar they are. W is commonly assumed to be symmetric and non-negative. The graph Laplacian L of G is defined as $L = D - W$, where $D = [d_{ij}]_{n \times n}$ is a diagonal matrix with $d_{ii} = \sum_j w_{ij}$. The normalized graph Laplacian $\bar{L}$ of G is defined as

$$\bar{L} = D^{-1/2} L D^{-1/2} = I - D^{-1/2} W D^{-1/2}, \tag{8}$$

where I is the identity matrix. W is also called the affinity matrix, and $\bar{W} = D^{-1/2} W D^{-1/2}$ the normalized affinity matrix. $\bar{L}$ is symmetric and positive semidefinite, with eigenvalues in the interval $[0, 2]$ (Chung, 1997).

Following the idea of regularization in spectral graph theory (e.g., see (Zhou et al., 2004)), we define the smoothness measure $\mathcal{S}(\cdot)$ by

$$\mathcal{S}(\boldsymbol{\phi}) = \frac{1}{2} \sum_{i,j=1}^{n} w_{ij} \| \frac{\boldsymbol{\phi}(\mathbf{x}_i)}{\sqrt{d_{ii}}} - \frac{\boldsymbol{\phi}(\mathbf{x}_j)}{\sqrt{d_{jj}}} \|_{\mathcal{F}}^2, \tag{9}$$

where $\boldsymbol{\phi}(\mathbf{x}_i) \in \mathcal{F}$, and $\|\cdot\|_{\mathcal{F}}$ is a distance metric in $\mathcal{F}$. Note that $\mathcal{F}$ is possibly an infinite-dimensional space. By this definition, we can see that $\mathcal{S}(\boldsymbol{\phi}) \geq 0$ since W is non-negative, and the value $\mathcal{S}(\boldsymbol{\phi})$ penalizes the large change of the mapping $\boldsymbol{\phi}$ between two nodes linked with a large weight. In other words, minimizing $\mathcal{S}(\cdot)$ encourages the smoothness of a mapping over the data graph. Next we rewrite $\mathcal{S}(\boldsymbol{\phi})$ in matrix form.

Let $k_{ij} =< \boldsymbol{\phi}(\mathbf{x}_i), \boldsymbol{\phi}(\mathbf{x}_j) >_{\mathcal{F}}$. Then the matrix $K = [k_{ij}]_{n \times n}$ is symmetric and positive semidefinite, denoted by $K \succeq 0$, and thus can be thought as a kernel

over $\mathcal{X}$ (Smola & Kondor, 2003). From (9), we have

$$\begin{aligned}\mathcal{S}(\boldsymbol{\phi}) &= \frac{1}{2}\sum_{i,j=1}^{n} w_{ij}\left(\frac{1}{d_{ii}}k_{ii} + \frac{1}{d_{jj}}k_{jj} - 2\frac{1}{\sqrt{d_{ii}d_{jj}}}k_{ij}\right) \\ &= \sum_{i=1}^{n} k_{ii} - \sum_{i,j=1}^{n}\frac{w_{ij}}{\sqrt{d_{ii}d_{jj}}}k_{ij} \quad (10) \\ &= I \bullet K - (D^{-1/2}WD^{-1/2}) \bullet K \quad (11) \\ &= (I - D^{-1/2}WD^{-1/2}) \bullet K = \bar{L} \bullet K, \quad (12)\end{aligned}$$

where $\bullet$ denotes the dot product between two matrices, defined as $A \bullet B = \sum_{i=1}^{n}\sum_{j=1}^{m} a_{ij}b_{ij}$, for $A = [a_{ij}]_{n\times m}$ and $B = [b_{ij}]_{n\times m}$.

3.3. Learning a Kernel Matrix

With the above analysis (5)–(7), and (12), we have arrived at the following optimization problem:

$$\begin{aligned}\min_{K}: \ & \bar{L} \bullet K \quad (13) \\ \text{s.t.}: \ & k_{ii} = 1, \ i = 1, 2, ..., n, \quad (14) \\ & k_{ij} = 1, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{M}, \quad (15) \\ & k_{ij} = 0, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{C}, \quad (16) \\ & K \succeq 0, \quad (17)\end{aligned}$$

which can be recognized as a semidefinite programming (SDP) problem (Boyd & Vandenberghe, 2004). This problem is convex and thus the global optimal solution is guaranteed. To solve this problem, we can use the highly optimized software packages, such as SeDuMi (Sturm, 1999) and CSDP (Borchers, 1999).

We can also express the above SDP problem in a more familiar matrix form. Let E_{ij} be a $n \times n$ matrix consisting of all 0's except the $(i, j)^{th}$ entry being 1. Then the above SDP problem becomes

$$\begin{aligned}\min_{K}: \ & \bar{L} \bullet K \quad (18) \\ \text{s.t.}: \ & E_{ii} \bullet K = 1, \ i = 1, 2, ..., n, \quad (19) \\ & E_{ij} \bullet K = 1, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{M}, \quad (20) \\ & E_{ij} \bullet K = 0, \ \forall(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{C}, \quad (21) \\ & K \succeq 0. \quad (22)\end{aligned}$$

It should be noted that we have transformed the problem of learning a mapping $\boldsymbol{\phi}$ stated in (2)–(4) into the problem of learning a kernel matrix K such that $\boldsymbol{\phi}$ is the feature mapping induced by K. The kernel trick (Schölkopf & Smola, 2002) indicates that we can implicitly derive $\boldsymbol{\phi}$ by explicitly pursuing K. Note that the kernel matrix K captures the distribution of the point set $\{\boldsymbol{\phi}(\mathbf{x}_i)\}_{i=1}^{n}$ in the feature space. The equality constraints (14) constrain $\boldsymbol{\phi}(\mathbf{x}_i)$'s to be on the unit hypersphere, the inequality constraints (15) and (16) force $\boldsymbol{\phi}(\mathbf{x}_i) = \boldsymbol{\phi}(\mathbf{x}_j)$ if $\mathbf{x}_i$ and $\mathbf{x}_j$ are must-link and $\boldsymbol{\phi}(\mathbf{x}_i)$ and $\boldsymbol{\phi}(\mathbf{x}_j)$ to be orthogonal if $\mathbf{x}_i$ and $\mathbf{x}_j$ are cannot-link. By minimizing the objective function (13), which is equivalent to enforcing smoothness on $\boldsymbol{\phi}$, $\boldsymbol{\phi}(\mathbf{x}_i)$ and $\boldsymbol{\phi}(\mathbf{x}_j)$ will move close to each other if $\mathbf{x}_i$ and $\mathbf{x}_j$ are similar (lie on the same group or manifold). This process will continue until a global stable state is achieved (the objective function is minimized and the constraints are satisfied). We call this process the *pairwise constraint propagation*. It is expected that after the propagation, each class becomes compact and different classes become far apart (being nearly orthogonal on the unit hypersphere). This phenomenon is also observed by our experiments (see Section 5.2). The idea of reshaping the data in a high-dimensional space by propagating the spatial information among objects is previously appeared in our recent work (Li et al., 2007) where the problem of clustering highly noisy data is addressed.

3.4. Classification

Let K^* be the kernel matrix obtained by solving the SDP problem stated in (18)–(22). The final step of our approach is to obtain k classes from K^*. We apply the kernel K-means algorithm (Shawe-Taylor & Cristianini, 2004) to K^* to form k classes.

4. The Algorithm

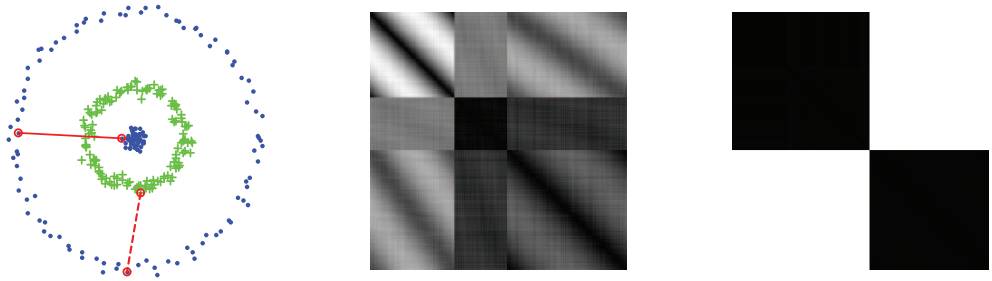
Based on the previous analysis, we develop a semi-supervised classification algorithm listed in Algorithm 1, which we called the *Pairwise Constraint Propagation* (PCP). The scale factor σ in Step 1 needs to be tuned, which is discussed in Section 5.1.

Algorithm 1 Pairwise Constraint Propagation

Input: A data set of n objects $\mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n\}$, the set of must-link constraints $\mathcal{M} = \{(\mathbf{x}_i, \mathbf{x}_j)\}$, the set of cannot-link constraints $\mathcal{C} = \{(\mathbf{x}_i, \mathbf{x}_j)\}$, and the number of classes k.

Output: The class labels of the objects in $\mathcal{X}$.

1. Form the affinity matrix $W = [w_{ij}]_{n\times n}$ with $w_{ij} = \exp(-d^2(\mathbf{x}_i, \mathbf{x}_j)/2\sigma^2)$ if $i \neq j$ and $w_{ii} = 0$.
2. Form the normalized graph Laplacian $\bar{L} = I - D^{-1/2}WD^{-1/2}$, where $D = \text{diag}(d_{ii})$ is the diagonal matrix with $d_{ii} = \sum_{j=1}^{n} w_{ij}$.
3. Obtain the kernel matrix K^* by solving the SDP problem stated in (18)–(22).
4. Form k classes by applying the kernel K-means to K^*.



(a) (b) (c)

Figure 2. (a) Three-Circle with classes denoted by different colors and symbols. The solid red line denotes a must-link constraint and the dashed red line denotes a cannot-link constraint. (b) & (c) Distance matrices for Three-Circle in the input space and in the feature space, respectively, where, for illustration purpose, the data are arranged such that points within a class appear consecutively. The darker is a pixel, the smaller is the distance the pixel represents.

5. Experimental Results

In this section, we evaluate the proposed algorithm PCP on a number of synthetic and real data sets. By comparison, the results of two notable and most related algorithms, Kamvar et al.'s spectral learning algorithm (SL) (Kamvar et al., 2003) and Kulis et al's semi-supervised kernel K-means algorithm (SSKK) (Kulis et al., 2005), are also presented. Note that most semi-supervised classification algorithms cannot be directly applied to the tasks of classification from pairwise constraints we consider here, because they perform classification from labeled and unlabeled data and cannot be readily generalized to address classification from pairwise constraints and unlabeled data.

In order to evaluate these algorithms, we compare the results with available ground-truth data labels, and employ the *Normalized Mutual Information* (NMI) as the performance measure (Strehl & Ghosh, 2003). For two random variables $\mathbf{X}$ and $\mathbf{Y}$, the NMI is defined as:

$$\mathrm{NMI}(\mathbf{X},\mathbf{Y}) = \frac{I(\mathbf{X},\mathbf{Y})}{\sqrt{H(\mathbf{X})H(\mathbf{Y})}}, \tag{23}$$

where $I(\mathbf{X},\mathbf{Y})$ is the mutual information between $\mathbf{X}$ and $\mathbf{Y}$, and $H(\mathbf{X})$ and $H(\mathbf{Y})$ are the entropies of $\mathbf{X}$ and $\mathbf{Y}$, respectively. Note that $0 \le \mathrm{NMI} \le 1$, and $\mathrm{NMI} = 1$ when a result is the same as the ground-truth. The larger is the NMI, the better is a result.

To evaluate the algorithms under different settings of pairwise constraints, we generate a varying number of pairwise constraints randomly for each data set. For a data set of k classes, we randomly generate j must-link constraints for each class, and j cannot-link constraints for every two classes, giving total $j \times (k + k(k-1)/2)$ constraints for each j, where j ranges from 1 to 10. The averaged NMI is reported for each number of pairwise constraints over 20 different realizations. Since all the three algorithms employ the K-means or kernel K-means in the final step, for each experiment we run the K-means or kernel K-means 20 times with random initializations, and report the averaged result.

5.1. Parameter Selection

The three algorithms are all graph-based and thus the inputs are assumed to be graphs. We use the weighted graphs for all the algorithms, where the similarity matrix $W = [w_{ij}]$ is given by

$$w_{ij} = \begin{cases} e^{-\|\mathbf{x}_i - \mathbf{x}_j\|^2/2\sigma^2} & i \neq j \\ 0 & i = j \end{cases}. \tag{24}$$

The most suitable scale factor σ is found over the set $S(0.1r, r, 5) \bigcup S(r, 10r, 5)$, where $S(r_1, r_2, m)$ denotes the set of m linearly equally spaced numbers between r_1 and r_1, and r denotes the averaged distance from each node to its 10-th nearest neighbor.

We use the SDP solver CSDP 6.0.1[1] (Borchers, 1999) to solve the SDP problem in the proposed PCP. For SSKK, we use its normalized cut version since it performs best in the experiments given in (Kulis et al., 2005). The constraint penalty in SSKK is set to $n/(kc)$, as suggested in (Kulis et al., 2005), where n is the number of objects, k is the number of classes, and c is the total number of pairwise constraints. All the algorithms are implemented in MATLAB 7.6, running on a 3.4 GHz, 2GB RAM Pentium IV PC.

5.2. A Toy Example

In this subsection, we illustrate the proposed PCP using a toy example. We mainly study its capability of propagating pairwise constraints to the whole data

[1] https://projects.coin-or.org/Csdp/.

Table 1. Description of the four sensory data sets from UCI.

Data	Iris	Wine	Ionosphere	Soybean
Number of objects	150	178	351	47
Dimension	4	13	34	35
Number of classes	3	3	2	4

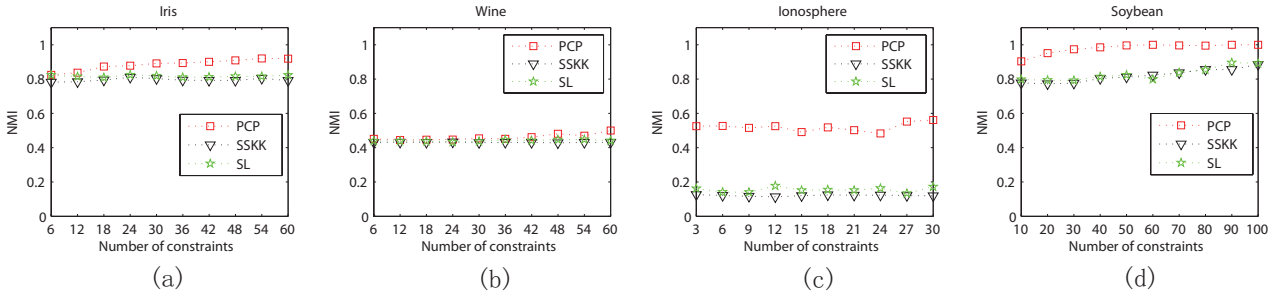


Figure 3. Classification results on the four sensory data sets: NMI vs. Number of constraints. (a) Results on Iris. (b) Results on Wine. (c) Results on Ionosphere. (d) Results on Soybean.

set. Specifically, we want to see how PCP reshapes the data in the feature space according to the original data structure and the given pairwise constraints. The classification task on the Three-Circle data is shown in Fig. 2(a), where the ground-truth classes are denoted by different colors and symbols, and one must-link (solid red line) and one cannot-link (dashed red line) constraints are also provided. At first glance, Three-Circle is composed of a mixture of curve-like and Gaussian-like groups. A more detailed observation is that there is one class composed of separate groups.

The distance matrices for Three-Circle in the input space and in the feature space are shown in Figs. 2(b) and (c), where the data are ordered such that all the objects in the outer circle appear first, all the objects in the inner circle appear second, and all the objects in the middle circle appear finally. Note that this arrangement does not affect the classification results but only for better illustration of the distance matrices. We can see that the distance matrix in the feature space, compared to the one in the input space, exhibits a clear block structure, meaning that each class becomes highly compact (although in the input space one of the two classes consists of two well-separated groups) and the two classes become far apart. Our computations show that the distance between any two points in the feature space in different classes falls in $[\sqrt{2} - 1.9262 \times 10^{-5}, \sqrt{2} + 1.3214 \times 10^{-6}]$, implying that the two classes are nearly $\sqrt{2}$ from each other, which comes from the requirement that two cannot-link objects are mapped to be orthogonal on the unit hypersphere.

5.3. On Sensory Data

Four sensory data sets from the UCI Machine Learning Repository[2] are used for testing in this experiment. The data sets are described in Table 1. These four data sets are widely used for evaluation of the classification and clustering methods in the machine learning community.

The results are shown in Fig. 3, from which two observations can be drawn. First, PCP performs better than SSKK and SL on all the four data sets under different settings of pairwise constraints, especially on the Ionosphere data. Second, as the number of constraints grows, the performances of all the algorithms increase accordingly on Soybean, but vary little on Wine and Ionosphere. On Iris, as the number of constraints grows the performance of PCP improves accordingly but those of SSKK and SL are almost unchanged.

5.4. On Imagery Data

In this subsection, we test the algorithms on three image databases USPS, MNIST, and CMU PIE (Pose, Illumination, and Expression). Both USPS and MNIST consist of images of handwritten digits with significantly different fashion and of sizes 16×16 and 28×28. The CMU PIE contains 41,368 images of 68 people, each person with 13 different poses, 43 different illumination conditions, and 4 different expressions. From these databases, we draw four data sets, which are described in Table 2. The USPS0123 and MNIST0123 are drawn respectively from USPS and MNIST, and PIE-10-20 and PIE-22-23 are drawn from CMU PIE.

[2] http://archive.ics.uci.edu/ml.

Table 2. Description of the four imagery data sets.

Data	USPS0123	MNIST0123	PIE-10-20	PIE-22-23
Number of objects	400	400	340	340
Dimension	256	784	1024	1024
Number of classes	4	4	2	2

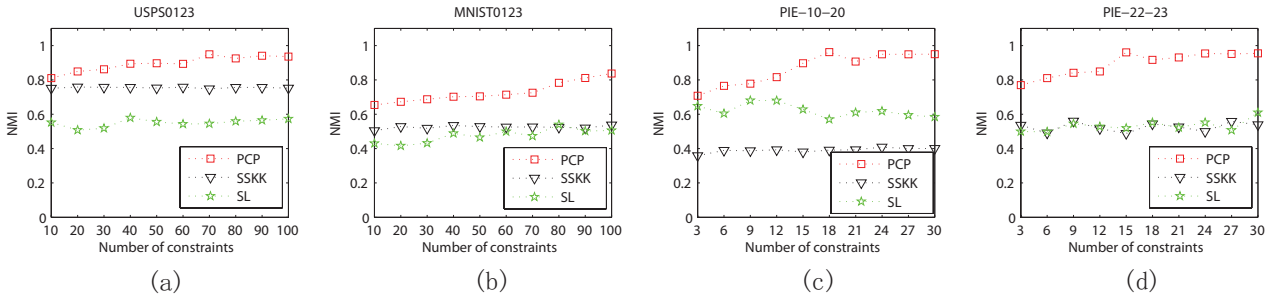

Figure 4. Classification results on the four imagery data sets: NMI vs. Number of constraints. (a) Results on USPS0123. (b) Results on MNIST0123. (c) Results on PIE-10-20. (d) Results on PIE-22-23.

USPS0123 (MNIST0123) consists of digits 0 to 3, with first 100 instances from each class. PIE-10-20 (PIE-22-23) contains five near frontal poses (C05, C07, C09, C27, C29) of two individuals indexed as 10 and 20 (22 and 23) under different illuminations and expressions. Original images in PIE-10-20 and PIE-22-23 are manually aligned (two eyes are aligned at the fixed positions), cropped, and then down-sampled to 32×32. Each image is represented by a vector of size equal to the product of its width and height.

The results are shown in Fig. 4, from which we can see that the proposed PCP consistently and significantly outperforms SSKK and SL on all the four data sets under different settings of pairwise constraints. As the number of constraints grows, the performance of PCP improves more significantly than those of SSKK and SL.

We also look at the computational costs of different algorithms. For example, for each run on USPS0123 (of size 400) with 100 pairwise constraints, PCP takes about 17 seconds while both SSKK and SL take less than 0.5 second. PCP does take more execution time than SSKK and SL since it involves solving for a kernel matrix with SDP, while either SSKK or SL uses predefined kernel matrix. The main computational cost in PCP is in solving the SDP problem.

6. Conclusions

A semi-supervised classification approach, *Pairwise Constraint Propagation* (PCP), for learning from pairwise constraints and unlabeled data is proposed. PCP seeks a smooth mapping to map the data onto a unit hypersphere, where any two must-link objects are mapped to the same point and any two cannot-link objects are mapped to be orthogonal. Consequently, PCP simultaneously implements the cluster assumption and the pairwise constraint assumption stated in Section 2. PCP implicitly derives such a mapping by explicitly finding a kernel matrix via semidefinite programming. In contrast to label propagation in traditional semi-supervised learning, PCP can effectively propagate pairwise constraints to the whole data set. Experimental results on a variety of synthetic and real data sets have demonstrated the superiority of PCP.

Note that PCP falls into semi-supervised learning since it performs learning from both constrained and unconstrained data. Most previous metric learning methods, however, belong to supervised learning. PCP always keeps every two must-link objects close and every two cannot-link objects far apart. Therefore it essentially addresses hard constrained classification.

Although extensive experiments have confirmed the effectiveness of the PCP algorithm, there are several issues worthy to be further investigated in future work. One issue is to accelerate PCP where solving the associated SDP problem is the bottleneck. Another issue is to handle noisy constraints effectively.

An Asymptotic Analysis of Generative, Discriminative, and Pseudolikelihood Estimators

Percy Liang PLIANG@CS.BERKELEY.EDU
Computer Science Division, University of California, Berkeley, CA, USA

Michael I. Jordan JORDAN@CS.BERKELEY.EDU
Computer Science Division and Department of Statistics, University of California, Berkeley, CA, USA

Abstract

Statistical and computational concerns have motivated parameter estimators based on various forms of likelihood, e.g., joint, conditional, and pseudolikelihood. In this paper, we present a unified framework for studying these estimators, which allows us to compare their relative (statistical) efficiencies. Our asymptotic analysis suggests that modeling more of the data tends to reduce variance, but at the cost of being more sensitive to model misspecification. We present experiments validating our analysis.

1. Introduction

Probabilistic models play a prominent role in domains such as natural language processing, bioinformatics, and computer vision, where they provide methods for jointly reasoning about many interdependent variables. For prediction tasks, one generally models a conditional distribution over outputs given an input. There can be reasons, however, for pursuing alternatives to conditional modeling. First, we might be able to leverage additional statistical strength present in the input by using generative methods rather than discriminative ones. Second, the exact inference required for a full conditional likelihood could be intractable; in this case, one might turn to computationally more efficient alternatives such as pseudolikelihood (Besag, 1975).

The generative-discriminative distinction has received much attention in machine learning. The standing intuition is that while discriminative methods achieve lower asymptotic error, generative methods might be better when training data are limited. This intuition is supported by the theoretical comparison of Naive Bayes and logistic regression (Ng & Jordan, 2002) and the recent empirical success of hybrid methods (McCallum et al., 2006; Lasserre et al., 2006).

Computational concerns have also spurred the development of alternatives to the full likelihood; these methods can be seen as optimizing an alternate objective or performing approximate inference during optimization. Examples include pseudolikelihood (Besag, 1975), composite likelihood (Lindsay, 1988), tree-reweighted belief propagation (Wainwright et al., 2003), piecewise training (Sutton & McCallum, 2005), agreement-based learning (Liang et al., 2008), and many others (Varin, 2008).

We can think of all these schemes as simply different estimators operating in a single model family. In this work, we analyze the statistical properties of a class of convex composite likelihood estimators for exponential families, which contains the generative, discriminative, and pseudolikelihood estimators as special cases.

The main focus of our analysis is on prediction error. Standard tools from learning theory based on uniform convergence typically only provide upper bounds on this quantity. Moreover, they generally express estimation error in terms of the overall complexity of the model family.[1] In our case, since all estimators operate in the same model family, these tools are inadequate for comparing different estimators.

Instead, we turn to asymptotic analysis, a mainstay of theoretical statistics. There is much relevant statistical work on the estimators that we treat; note in particular that Lindsay (1988) used asymptotic arguments to show that composite likelihoods are generally

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] There are more advanced techniques such as local Rademacher complexities, which focus on the relevant regions of the model family, but these typically only apply to empirical risk minimization.

less efficient than the joint likelihood. The majority of these results are, however, focused on parameter estimation. In the current paper, our focus is on prediction, and we also consider model misspecification.

We draw two main conclusions from our analysis: First, when the model is well-specified, conditioning on fewer variables increases statistical efficiency; this to some extent accounts for the better generalization enjoyed by generative estimators and the worse performance of pseudolikelihood estimators. Second, model misspecification can severely increase both the approximation and estimation errors of generative estimators. We confirm our theoretical results by comparing our three estimators on a toy example to verify the asymptotics and on a Markov model for part-of-speech tagging.

2. Exponential Family Estimators

In structured prediction tasks, we are interested in learning a mapping from an input space $\mathcal{X}$ to an output space $\mathcal{Y}$. Probabilistic modeling is a common platform for solving such tasks, allowing for the natural handling of missing data and the incorporation of latent variables.

In this paper, we focus on regular exponential families, which define distributions over an outcome space $\mathcal{Z}$ as follows:

$$p_\theta(z) \stackrel{\text{def}}{=} \exp\{\phi(z)^\top \theta - A(\theta)\} \text{ for } z \in \mathcal{Z}, \tag{1}$$

where $\phi(z) \in \mathbb{R}^d$ is a vector of sufficient statistics (features), $\theta \in \mathbb{R}^d$ is a vector of parameters, and $A(\theta) \stackrel{\text{def}}{=} \log \int e^{\phi(z)^\top \theta} \nu(dz)$ is the log-partition function. In our case, the outcomes are input-output pairs: $z = (x, y)$ and $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$.

Exponential families include a wide range of popular models used in machine learning. For example, for a conditional random field (CRF) (Lafferty et al., 2001) defined on a graph $G = (V, E)$, we have an output variable for each node ($y = \{y_i\}_{i \in V}$), and the features are $\phi(x, y) = \sum_{i \in V} \phi_{\text{node}}(y_i, \mathbf{x}, i) + \sum_{(i,j) \in E} \phi_{\text{edge}}(y_i, y_j)$.

From the density $p_\theta(z)$, we can compute event probabilities as follows:

$$p_\theta(z \in s) = \exp\{A(\theta; s) - A(\theta)\}, \tag{2}$$

where $A(\theta; s) = \log \int e^{\phi(z)^\top \theta} \mathbb{1}[z \in s] \nu(dz)$ is a conditional log-partition function.

2.1. Composite Likelihood Estimators

In this paper, we consider a class of *composite likelihood* estimators (Lindsay, 1988), which is incidentally equivalent to the multi-conditional learning framework of McCallum et al. (2006). A *composite likelihood* consists of a weighted sum of *component* likelihoods, each of which is the probability of one subset of variables conditioned on another. In this work, we only consider the case where the first set is all the variables.

We adopt the following more fundamental way of specifying the components: Each component r is defined by a *partitioning* of the outcome space $\mathcal{Z}$. We represent a partitioning by an associated *equivalence function* that maps each $z \in \mathcal{Z}$ to its partition:

Definition 1 (Equivalence function)**.** *An* equivalence function r *is a measurable map from* $\mathcal{Z}$ *to measurable subsets of* $\mathcal{Z}$ *such that for each* $z \in \mathcal{Z}$ *and* $z' \in r(z)$, $r(z) = r(z')$.

The component likelihood associated with r takes the following form:

$$p_\theta(z \mid z \in r(z)) = \exp\{\phi(z)^\top \theta - A(\theta; r(z))\}. \tag{3}$$

By maximizing this quantity, we are intuitively taking probability mass away from some neighborhood $r(z)$ of z and putting it on z.

Without loss of generality, assume the component weights sum to 1, so we can think of taking an expectation over a random component R drawn from some fixed distribution P_{r}. We then define the *criterion function*:

$$m_\theta(z) \stackrel{\text{def}}{=} \mathbb{E}_{R \sim P_{\text{r}}} \log p_\theta(z \mid z \in R(z)). \tag{4}$$

Given data points $Z^{(1)}, \ldots, Z^{(n)}$ drawn i.i.d. from some true distribution p^* (not necessarily in the exponential family), the maximum composite likelihood estimator is defined by averaging the criterion function over these data points:

$$\hat{\theta} = \operatorname*{argmax}_\theta \hat{\mathbb{E}} m_\theta(Z), \tag{5}$$

where $\hat{\mathbb{E}} m_\theta(Z) = \frac{1}{n} \sum_{i=1}^n m_\theta(Z^{(i)})$.

We can now place the three estimators of interest in our framework:

Generative: We have one component $r_{\text{g}}(x, y) = \mathcal{X} \times \mathcal{Y}$, which has one partition—the whole outcome space.

Fully discriminative: We have one component $r_{\text{d}}(x, y) = x \times \mathcal{Y}$. The outcomes in each partition have the same value of x, but different y.

Pseudolikelihood discriminative: Assume $y = \{y_i\}_{i \in V}$. For each $i \in V$, we have a component $r_i(x, y) = \{(x', y') : x' = x, y' \in \mathcal{Y}, y'_j = y_j \text{ for } j \neq i\}$. P_{r} is uniform over these components.

$v^{\otimes} = vv^{\top}$	
Parameter estimates	
p^*	true distribution of the data
m_θ	criterion function (defines the estimator)
$\mathcal{R}$	risk (expected log-loss)
$\hat{\theta}$	$= \operatorname{argmax}_\theta \hat{\mathbb{E}} m_\theta(Z)$ [empirical parameter estimate]
θ°	$= \operatorname{argmax}_\theta \mathbb{E} m_\theta(Z)$ [limiting parameter vector]
Random variables for asymptotic analysis	
R	$\sim P_{\mathrm{r}}$ [choose composite likelihood component]
$r_{\mathrm{d}}(x, y) = x \times \mathcal{Y}$	[fully discriminative component]
ϕ	$= \phi(Z)$, $Z \sim p^*$ [sample from true distribution]
ϕ^{t}	$= \phi(Z^{\mathrm{t}})$, $Z^{\mathrm{t}} \sim p^*(\cdot \mid \cdot \in R(Z))$ [from true distrib.]
ϕ^{m}	$= \phi(Z^{\mathrm{m}})$, $Z^{\mathrm{m}} \sim p_{\theta^\circ}(\cdot \mid \cdot \in R(Z))$ [for estimation]
ϕ^{e}	$= \phi(Z^{\mathrm{e}})$, $Z^{\mathrm{e}} \sim p_{\theta^\circ}(\cdot \mid \cdot \in r_{\mathrm{d}}(Z))$ [for prediction]

Table 1. Notation used in the paper.

2.2. Prediction and Evaluation

Given a parameter estimate $\hat{\theta}$, we make predictions based on $p_{\hat{\theta}}(y \mid x)$. In this paper, we evaluate our model according to log-loss; the risk is the expected log-loss:

$$\mathcal{R}(\theta) = \mathbb{E}_{(X,Y)\sim p^*}[-\log p_\theta(Y \mid X)]. \tag{6}$$

The quality of an estimator is determined by the gap between the risk of the estimate $\mathcal{R}(\hat{\theta})$ and the Bayes risk $\mathcal{R}^* = H(Y \mid X)$. It will be useful to relate these two via the risk of $\theta^\circ = \operatorname{argmax}_\theta \mathbb{E}_{Z\sim p^*} m_\theta(Z)$, which leads to the following standard decomposition:

$$\underbrace{\mathcal{R}(\hat{\theta}) - \mathcal{R}^*}_{\text{total error}} = \underbrace{(\mathcal{R}(\hat{\theta}) - \mathcal{R}(\theta^\circ))}_{\text{estimation error}} + \underbrace{(\mathcal{R}(\theta^\circ) - \mathcal{R}^*)}_{\text{approx. error}}. \tag{7}$$

The estimation error is due to having only finite data; the approximation error is due to the intrinsic suboptimality of the estimator.[2]

3. Asymptotic Analysis

We first compute the asymptotic estimation errors of composite likelihood estimators in general (Sections 3.1 and 3.2). Then we use these results to compare the estimators of interest (Sections 3.3 and 3.4).

In this paper, we assume that our exponential family is identifiable.[3] Also assume that our estimators converge ($\hat{\theta} \xrightarrow{P} \theta^\circ$) and are consistent when the model is well-specified (if $p^* = p_{\theta^*}$, then $\theta^\circ = \theta^*$). Note, however, that in general we do not assume that our model is well-specified.

Our asymptotic analysis is driven by Taylor expansions, so we need to compute a few derivatives. The derivatives of the log-partition function are moments of the sufficient statistics (a standard result, see Wainwright and Jordan (2003)):

$$\dot{A}(\theta; s) = \mathbb{E}_{Z\sim p_\theta(\cdot\mid\cdot\in s)}(\phi(Z)) \tag{8}$$

$$\ddot{A}(\theta; s) = \operatorname{var}_{Z\sim p_\theta(\cdot\mid\cdot\in s)}(\phi(Z)). \tag{9}$$

From these moments, we can obtain the derivatives of m_{θ° and $\mathcal{R}$ (to simplify notation, we express these in terms of random variables whose distributions are defined in Table 1):

$$\dot{m}_{\theta^\circ} = \phi - \mathbb{E}(\phi^{\mathrm{m}} \mid Z) \tag{10}$$

$$\ddot{m}_{\theta^\circ} = -\mathbb{E}[\operatorname{var}(\phi^{\mathrm{m}} \mid R(Z)) \mid Z] \tag{11}$$

$$\dot{\mathcal{R}}(\theta^\circ) = \mathbb{E}(\phi^{\mathrm{e}} - \phi) \tag{12}$$

$$\ddot{\mathcal{R}}(\theta^\circ) = \mathbb{E}\operatorname{var}(\phi^{\mathrm{e}} \mid Z). \tag{13}$$

3.1. Asymptotics of the Parameters

We first analyze how fast $\hat{\theta}$ converges to θ° by computing the asymptotic distribution of $\hat{\theta} - \theta^\circ$. In Section 3.2 we use this result to get the asymptotic distribution of the estimation error $\mathcal{R}(\hat{\theta}) - \mathcal{R}(\theta^\circ)$.

The following standard lemma will prove to be very useful in our analysis:

Lemma 1. *For random vectors X, Y, Z, we have* $\operatorname{var}(X \mid Z) = \mathbb{E}[\operatorname{var}(X \mid Y, Z) \mid Z] + \operatorname{var}[\mathbb{E}(X \mid Y, Z) \mid Z]$.

The important implication of this lemma is that conditioning on another variable Y reduces the variance of X. This lemma already hints at how conditioning on more variables can lead to poorer estimators: conditioning reduces the variance of the data, which can make it harder to learn about the parameters.

The following theorem gives us the asymptotic variance of a general composite likelihood estimator:

Theorem 1 (Asymptotic distribution of the parameters)**.** *Assume $\hat{\theta} \xrightarrow{P} \theta^\circ$. Then*

$$\sqrt{n}(\hat{\theta} - \theta^\circ) \to \mathcal{N}(0, \Sigma). \tag{14}$$

The asymptotic variance is

$$\Sigma = \Gamma^{-1} + \Gamma^{-1}(C_{\mathrm{c}} + C_{\mathrm{m}})\Gamma^{-1}, \tag{15}$$

where $\Gamma = \mathbb{E}\operatorname{var}(\phi^{\mathrm{m}} \mid R(Z))$ is the sensitivity, $C_{\mathrm{c}} = \mathbb{E}\operatorname{var}[\mathbb{E}(\phi^{\mathrm{m}} \mid R(Z)) \mid Z]$ is the component correction, and $C_{\mathrm{m}} = \mathbb{E}[\operatorname{var}(\phi^{\mathrm{t}} \mid Z) - \operatorname{var}(\phi^{\mathrm{m}} \mid Z)] + \mathbb{E}[\mathbb{E}(\phi^{\mathrm{t}} \mid Z) - \mathbb{E}(\phi^{\mathrm{m}} \mid Z)]^{\otimes}$ is the misspecification correction.

[2] Note that θ° is not necessarily the minimum risk parameter vector in the model family.

[3] In the non-identifiable case, the analysis becomes more cluttered, but the results are essentially the same, since predictions depend on only the distributions induced by the parameters. See the longer version of this paper for an in-depth discussion.

Proof. The standard asymptotic normality result for M-estimators (Theorem 5.21 of van der Vaart (1998)), which includes composite likelihood estimators, gives us the asymptotic variance:

$$\Sigma = (\mathbb{E}\ddot{m}_{\theta^\circ})^{-1}(\mathbb{E}\dot{m}_{\theta^\circ}^{\otimes})(\mathbb{E}\ddot{m}_{\theta^\circ})^{-1}. \tag{16}$$

The remainder of the proof simply re-expresses Σ in terms of more interpretable quantities. Algebraic manipulation of (10) yields:

$$\mathbb{E}\dot{m}_{\theta^\circ}^{\otimes} = \mathbb{E}[(\phi - \mathbb{E}(\phi^{\mathrm{t}} \mid Z)) + (\mathbb{E}(\phi^{\mathrm{t}} \mid Z) - \mathbb{E}(\phi^{\mathrm{m}} \mid Z))]^{\otimes}.$$

Note that cross terms cancel conditioned on Z and that $\mathbb{E}[\phi - \mathbb{E}(\phi^{\mathrm{t}} \mid Z)]^{\otimes} = \mathbb{E}[\phi^{\mathrm{t}} - \mathbb{E}(\phi^{\mathrm{t}} \mid Z)]^{\otimes}$, so

$$\mathbb{E}\dot{m}_{\theta^\circ}^{\otimes} = C_{\mathrm{m}} + \mathbb{E}\,\mathrm{var}(\phi^{\mathrm{m}} \mid Z). \tag{17}$$

We then apply Lemma 1 to decompose the second term of the right-hand side:

$$\mathbb{E}\,\mathrm{var}(\phi^{\mathrm{m}} \mid Z) = \mathbb{E}\,\mathrm{var}(\phi^{\mathrm{m}} \mid R(Z)) + \mathbb{E}\,\mathrm{var}[\mathbb{E}(\phi^{\mathrm{m}} \mid R(Z)) \mid Z]. \tag{18}$$

Substitute (18) into (17) to get an expression for $\mathbb{E}\dot{m}_{\theta^\circ}^{\otimes}$; (11) already provides one for $\mathbb{E}\ddot{m}_{\theta^\circ}$. Substitute these two expressions into (16) and simplify to get (15). □

The decomposition in (15) allows us to make several qualitative judgments. First, the *sensitivity* $\Gamma = \mathbb{E}\,\mathrm{var}(\phi^{\mathrm{m}} \mid R(Z))$ is the expected amount of variation in the features given Z and R (equivalently, given $R(Z)$). The larger the sensitivity, the more the data can tell us about the parameters, and thus the lower the asymptotic variance will be.

The *component correction* C_{c} intuitively measures how different the feature expectations $\mathbb{E}(\phi^{\mathrm{m}} \mid R(Z))$ under the various components are. C_{c} is zero for the generative and fully discriminative estimators, but the pseudolikelihood discriminative estimator pays a penalty for having more than one component.

The *misspecification correction* C_{m} is zero when the model is well-specified (in this case, $\phi^{\mathrm{m}} \mid Z \stackrel{d}{=} \phi^{\mathrm{t}} \mid Z$), but is in general nonzero under model misspecification. In this latter case, one incurs a nonzero approximation error (defined in (7)) as expected, but we see that there is also a nonzero effect on estimation error.

3.2. Asymptotics of the Risk

The following theorem turns Theorem 1 from a statement about the asymptotic distribution of the parameters into one about the risk:

Theorem 2 (Asymptotic distribution of the risk)**.** *Let Σ be the asymptotic variance as defined in (15). Denote $\dot{\mathcal{R}} \stackrel{\mathrm{def}}{=} \dot{\mathcal{R}}(\theta^\circ)$ and $\ddot{\mathcal{R}} \stackrel{\mathrm{def}}{=} \ddot{\mathcal{R}}(\theta^\circ)$. Then*

$$\sqrt{n}(\mathcal{R}(\hat{\theta}) - \mathcal{R}(\theta^\circ)) \xrightarrow{d} \mathcal{N}\left(0, \dot{\mathcal{R}}^\top \Sigma \dot{\mathcal{R}}\right). \tag{19}$$

Furthermore, if $\dot{\mathcal{R}} = 0$, then

$$n(\mathcal{R}(\hat{\theta}) - \mathcal{R}(\theta^\circ)) \xrightarrow{d} \frac{1}{2}\mathrm{tr}\,\mathcal{W}\left(\ddot{\mathcal{R}}^{\frac{1}{2}} \Sigma \ddot{\mathcal{R}}^{\frac{1}{2}}, 1\right), \tag{20}$$

where $\mathcal{W}(V, n)$ is the Wishart distribution with n degrees of freedom.

Proof. Perform a Taylor expansion of the risk function around θ°:

$$\mathcal{R}(\hat{\theta}) = \mathcal{R}(\theta^\circ) + \dot{\mathcal{R}}^\top(\hat{\theta} - \theta^\circ) + \frac{1}{2}(\hat{\theta} - \theta^\circ)^\top \ddot{\mathcal{R}}(\hat{\theta} - \theta^\circ) + o(||\hat{\theta} - \theta^\circ||^2). \tag{21}$$

We use a standard argument known as the delta method (van der Vaart, 1998). Multiplying (21) on both sides by $\sqrt{n}$, rearranging terms, and applying Slutsky's theorem, we get (19). However, when $\dot{\mathcal{R}} = 0$, the first-order term of the expansion (21) is zero, so we must consider the second-order term to get a non-degenerate distribution. Note that $\ddot{\mathcal{R}}$ is positive semidefinite. Multiplying (21) by n and rearranging yields the following:

$$n(\mathcal{R}(\hat{\theta}) - \mathcal{R}(\theta^\circ)) = \frac{1}{2}\mathrm{tr}\left([\ddot{\mathcal{R}}^{\frac{1}{2}}\sqrt{n}(\hat{\theta} - \theta^\circ)]^{\otimes}\right) + \cdots$$

Since $\ddot{\mathcal{R}}^{\frac{1}{2}}\sqrt{n}(\hat{\theta} - \theta^\circ) \xrightarrow{d} \mathcal{N}(0, \ddot{\mathcal{R}}^{\frac{1}{2}}\Sigma\ddot{\mathcal{R}}^{\frac{1}{2}})$, applying the continuous mapping theorem with the outer product function yields a Wishart as the limiting distribution. Thus, $n(\mathcal{R}(\hat{\theta}) - \mathcal{R}(\theta^\circ))$ is asymptotically equal in distribution to $\frac{1}{2}$ times the trace of a sample from that Wishart distribution. □

We can also understand (20) in the following way. Let $V = \ddot{\mathcal{R}}^{\frac{1}{2}}\Sigma\ddot{\mathcal{R}}^{\frac{1}{2}}$. Note that $\frac{1}{2}\mathrm{tr}\,\mathcal{W}(V, 1) \stackrel{d}{=} \frac{1}{2}\mathrm{tr}\,(V\mathcal{W}(I, 1))$, which is the distribution of a weighted sum of independent χ_1^2 variables, where the weights are determined by the diagonal elements of V. The mean of this distribution is $\frac{1}{2}\mathrm{tr}(V)$ and the variance is $\mathrm{tr}(V \bullet V)$, where $\bullet$ denotes elementwise product.

An important question is when we obtain the ordinary $O(n^{-\frac{1}{2}})$ convergence (19) versus the much better $O(n^{-1})$ convergence (20). A sufficient condition for $O(n^{-1})$ convergence is $\dot{\mathcal{R}}(\theta^\circ) = 0$. When the model is well-specified, this is true for any consistent estimator.

Even if the model is misspecified, the fully discriminative estimator still achieves the $O(n^{-1})$ rate. The

reason is that whenever a training criterion m_θ is the same (up to constants) as the test criterion $\mathcal{R}(\cdot)$, $\dot{\mathcal{R}}$ vanishes and we obtain the $O(n^{-1})$ rate. This is in concordance with a related observation made by Wainwright (2006) that it is better to use the same inference procedure at both training and test time.

When the model is well-specified, there is another appealing property that holds if the training and test criterion are the same up to constants: the asymptotic distribution of the risk depends on only the dimensionality of the exponential family, not the actual structure of the model. In particular, for composite likelihood estimators with one component, $\Sigma = \Gamma^{-1} = (-\mathbb{E}\ddot{m}_{\theta^\circ})^{-1} = \ddot{\mathcal{R}}^{-1}$. Therefore, $\ddot{\mathcal{R}}^{\frac{1}{2}}\Sigma\ddot{\mathcal{R}}^{\frac{1}{2}} = I_d$ and so $n(\mathcal{R}(\hat{\theta}) - \mathcal{R}(\theta^\circ)) \xrightarrow{d} \frac{1}{2}\mathrm{tr}\mathcal{W}(I_d, 1) \stackrel{d}{=} \frac{1}{2}\chi^2_d$, where d is the number of parameters. This result is essentially another way of looking at the fact that the likelihood ratio test statistic is asymptotically distributed as χ^2.

3.3. Comparing Estimation Errors

In the previous section, we analyzed the asymptotics of a single estimator. Now, given two estimators, we would like to be able to tell which one is better. In order to compare two estimators, it would be convenient if they converged to the same limit. In this section, we ensure this by assuming that the model is well-specified and that our estimators are consistent.

Since all parameter estimates are used in the same way for prediction, it suffices to analyze the relative efficiencies of the parameter estimates. The following theorem says that coarser partitionings of $\mathcal{Z}$ generally lead to more efficient estimators:

Theorem 3 (Asymptotic relative efficiency)**.** *Let $\hat{\theta}_1$ and $\hat{\theta}_2$ be two consistent estimators with asymptotic variances Σ_1 and Σ_2 as defined in (15). Assume that R_1 is constant ($\hat{\theta}_1$ has exactly one component) and $R_1(z) \supset R_2(z)$ for all $z \in \mathcal{Z}$. If the model is well-specified, then $\Sigma_1 \preceq \Sigma_2$ ($\hat{\theta}_1$ is no worse than $\hat{\theta}_2$).*

Proof. We first show that $\Gamma_1^{-1} \preceq \Gamma_2^{-1}$, where Γ_1 and Γ_2 are the sensitivities of the two estimators. Because the model is well-specified, $\Gamma_k = \mathbb{E}\,\mathrm{var}(\phi^{\mathrm{t}} \mid R_k(Z))$ for $k = 1, 2$. The assumption $R_1(Z) \supset R_2(Z)$ means that $R_2(Z)$ provides more information about Z than $R_1(Z)$; formally, the σ-fields satisfy $\sigma(R_1(Z)) \subset \sigma(R_2(Z))$. Thus, we can use Lemma 1 to decompose the variance: $\Gamma_1 = \mathbb{E}\,\mathrm{var}(\phi^{\mathrm{t}} \mid R_2(Z)) + \mathbb{E}\,\mathrm{var}[\mathbb{E}(\phi^{\mathrm{t}} \mid R_2(Z)) \mid R_1(Z)]$. The first term of the right-hand side is exactly Γ_2 and the second term is positive semidefinite, so $\Gamma_1 \succeq \Gamma_2$, which implies $\Gamma_1^{-1} \preceq \Gamma_2^{-1}$.

Let $C_{\mathrm{c}1}$ and $C_{\mathrm{c}2}$ be the component corrections of the two estimators. Note that $C_{\mathrm{c}1} = 0$ because the R_1 is constant, so $C_{\mathrm{c}1} \preceq C_{\mathrm{c}2}$. The misspecification corrections are both zero. Putting these results together yields the theorem. □

One might wonder if we really need R_1 to be constant. Is it not enough to just assume that $R_1(z) \supset R_2(z)$ (for some coupling of R_1 and R_2)? The answer is no, as the following counterexample shows:

Counterexample Let $\mathcal{Z} = \{1, 2, 3\}$. The general shape of the distribution is given by the single feature $\phi(1) = 1, \phi(2) = 3, \phi(3) = 2$ and a scalar parameter θ controls the peakiness of the distribution. Let the true parameter be $\theta^* = 1$. Consider two estimators: $\hat{\theta}_1$ has two components, $r_{1a} = \{\{1, 2\}, \{3\}\}$ and $r_{1b} = \{\{1\}, \{2, 3\}\}$; $\hat{\theta}_2$ also has two components, $r_{2a} = \{\{1, 2\}, \{3\}\}$ and $r_{2b} = \{\{1\}, \{2\}, \{3\}\}$.

Coupling r_{1a} with r_{2a} and r_{1b} with r_{2b}, we have $R_1(z) \supset R_2(z)$. However, we computed and found that $\Gamma_1 \approxeq 4.19$ and $\Gamma_2 \approxeq 3.15$, so $\hat{\theta}_2$ actually has lower asymptotic variance although it has finer partitionings.

To explain this, note that the contribution of r_{2b} to the criterion function is zero, so the second estimator is equivalent to just using the single component r_{2a} ($= r_{1a}$), so the first estimator actually suffers by using the additional component r_{1b}. In general, while we would still expect coarser partitionings to be better even for estimators with many components, this counterexample shows that we must exercise caution.

3.4. Comparing Estimators

Finally, we use Theorem 3 to compare the estimation and approximation errors of the generative ($\hat{\theta}_{\mathrm{g}}$), fully discriminative ($\hat{\theta}_{\mathrm{d}}$), and pseudolikelihood discriminative ($\hat{\theta}_{\mathrm{p}}$) estimators. The subscripts $\mathrm{g}, \mathrm{d}, \mathrm{p}$ will be attached to other variables to refer to the quantities associated with the corresponding estimators. In the following corollaries, we use the word "lower" loosely to mean "no more than," although in general we expect the inequality to be strict.

Corollary 1 (Generative versus fully discriminative)**.** *(1) If the model is well-specified, $\hat{\theta}_{\mathrm{g}}$ has lower asymptotic estimation error than $\hat{\theta}_{\mathrm{d}}$; both have zero approximation error. (2) If the model is misspecified, $\hat{\theta}_{\mathrm{d}}$ has lower approximation and asymptotic estimation errors than $\hat{\theta}_{\mathrm{g}}$.*

Proof. For (1), since $R_{\mathrm{d}}(z) \subset R_{\mathrm{g}}(z)$, we have $\Sigma_{\mathrm{g}} \preceq \Sigma_{\mathrm{d}}$ by Theorem 3. Zero approximation error follows from consistency. For (2), since the discriminative estimator

achieves the minimum risk in the model family, it has the lowest approximation error. Also, by Theorem 2 and the ensuing discussion, it always converges at a $O(n^{-1})$ rate, whereas the generative estimator will in general converge at a $O(n^{-\frac{1}{2}})$ rate. □

Note that there is a qualitative change of asymptotics in going from the well-specified to the misspecified scenario. This discontinuity demonstrates one weakness of asymptotic analyses: we would expect that for a very minor model misspecification, the generative estimator would still dominate the discriminative estimator for moderate sample sizes, but even a small misspecification is magnified in the asymptotic limit.

In the following toy example where the model is well-specified, we see concretely that the generative estimator has smaller asymptotic estimation error:

Example Consider a model where x and y are binary variables: $\phi(x,y)^\top\theta = \theta_0\mathbb{1}[x=0,y=1] + \theta_1\mathbb{1}[x=1,y=1]$, where the true parameters are $\theta^* = (0,0)$. We can compute $\Gamma_{\mathrm{g}} = \mathrm{var}(\phi) = \frac{1}{16}\begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix}$ and $\ddot{\mathcal{R}}(\theta^*) = \Gamma_{\mathrm{d}} = \mathbb{E}\,\mathrm{var}(\phi \mid X) = \frac{1}{16}\begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$. The mean asymptotic estimation error (scaled by n) of the generative estimator is $\frac{1}{2}\mathrm{tr}(\Gamma_{\mathrm{d}}\Gamma_{\mathrm{g}}^{-1}) = \frac{3}{4}$ while that of the discriminative estimator is $\frac{1}{2}\mathrm{tr}(\Gamma_{\mathrm{d}}\Gamma_{\mathrm{d}}^{-1}) = 1$.

We now show that fully discriminative estimators are statistically superior to pseudolikelihood discriminative estimators in all regimes, but of course pseudolikelihood is computationally more efficient.

Corollary 2 (Fully discriminative versus pseudolikelihood discriminative)**.** *(1) If the model is well-specified, $\hat{\theta}_{\mathrm{d}}$ has lower asymptotic estimation error than $\hat{\theta}_{\mathrm{p}}$; both have zero approximation error. (2) If the model is misspecified, $\hat{\theta}_{\mathrm{d}}$ has lower approximation and asymptotic estimation errors than $\hat{\theta}_{\mathrm{p}}$.*

Proof. For (1), since $R_{\mathrm{p}}(z) \subset R_{\mathrm{d}}(z)$, $\Sigma_{\mathrm{d}} \preceq \Sigma_{\mathrm{p}}$ by Theorem 3. Zero approximation error follows from consistency. For (2), the same arguments as the corresponding part of the proof of Corollary 1 apply. □

4. Experiments

In this section, we validate our theoretical analysis empirically. First, we evaluate the three estimators on a simple graphical model which allows us to plot the real asymptotics of the estimation error (Section 4.1). Then we show that in the non-asymptotic regime, the qualitative predictions of the asymptotic analyses are also valid (Section 4.2).

4.1. A Simple Graphical Model

Consider a four-node binary-valued graphical model where $z = (x_1, x_2, y_1, y_2)$. The true model family p^* is an Markov random field parametrized by $\theta^* = (\alpha^*, \beta^*, \gamma^*)$ as follows:

$$\phi(z)^\top\theta = \alpha\mathbb{1}[y_1 = y_2] + \beta(\mathbb{1}[x_1 = y_1] + \mathbb{1}[x_2 = y_2]) + \gamma(\mathbb{1}[x_1 = y_2] + \mathbb{1}[x_2 = y_1]).$$

To emulate misspecification, we set γ^* to be nonzero and force $\gamma = 0$ during parameter estimation.

In the first experiment, we estimated the variance (by running 10K trials) of the estimation error as we increased the number of data points. We set $\alpha^* = \beta^* = 1$ for the true model. When $\gamma^* = 0$ (the model is well-specified), Figures 1(a)–(c) show that scaling the variance by n yields a constant; this implies that all three estimators achieve $O(n^{-1})$ convergence.

When the model is misspecified with $\gamma^* = 0.5$ (Figures 1(d)–(f)), there is a sharp difference between the rates of the generative and discriminative estimators. The fully discriminative estimator still enjoys the $O(n^{-1})$ convergence; scaling by n reveals that the generative and pseudolikelihood discriminative estimators are only attaining a $O(n^{-\frac{1}{2}})$ rate as predicted by Theorem 2 (Figure 1(f)). Note that the generative estimator is affected most severely.

Figures 1(g)–(h) demonstrate the non-asymptotic impact of varying the parameters of the graphical model in terms of the total error. In (g), as we increase the amount of misspecification γ, the error increases for all estimators, but most sharply for the generative estimator. In (h), as we increase the strength of the edge potential α, the pseudolikelihood discriminative estimator suffers, the fully discriminative estimator is unaffected, and the generative estimator actually improves.

4.2. Part-of-speech Tagging

In this section, we present experiments on part-of-speech (POS) tagging. In POS tagging, the input is a sequence of words $x = (x_1, \ldots, x_\ell)$ and the output is a sequence of POS tags $y = (y_1, \ldots, y_\ell)$, e.g., noun, verb, etc. (There are 45 tags total.) We consider the following model, specified by the following features (roughly 2 million total):

$$\phi(x,y) = \sum_{i=1}^{\ell}\phi_{\mathrm{node}}(y_i, x_i) + \sum_{i=1}^{\ell-1}\phi_{\mathrm{edge}}(y_i, y_{i+1}), \quad (22)$$

where the node features $\phi_{\mathrm{node}}(y_i, x_i)$ are a vector of indicator functions of the form $\mathbb{1}[y_i = a, x_i = b]$, and

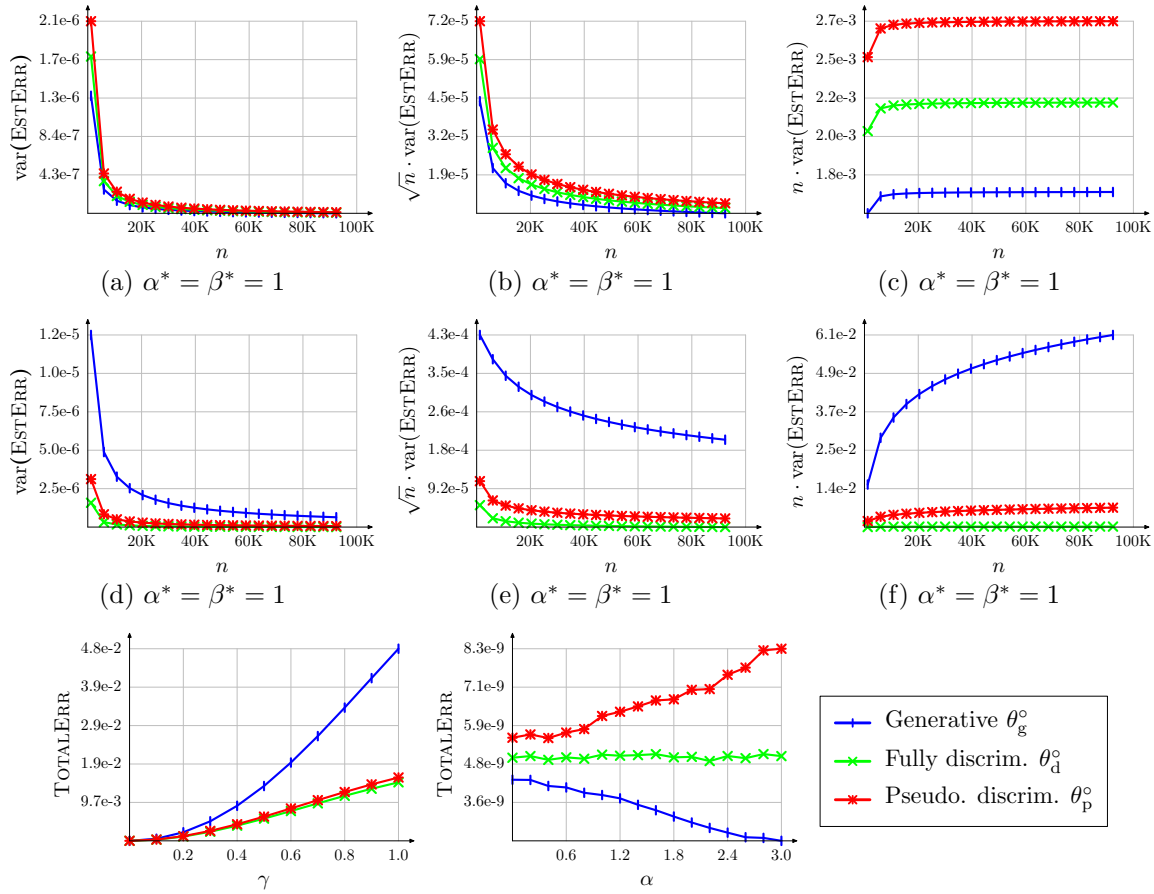

Figure 1. Asymptotics of the simple four-node graphical model. In (a)–(c), $\alpha^* = \beta^* = 1$ and $\gamma^* = 0$; we plot the asymptotic variance of the estimation error, scaled by 1, $\sqrt{n}$, and n. In (d)–(f), we repeat with $\gamma^* = 0.5$. In (g), we take $n = 20000$ examples, $\alpha^* = \beta^* = 1$ and vary γ. In (h), we take $n = 20000$, $\beta^* = 1, \gamma^* = 0$ and vary α.

the edge features $\phi_{\text{edge}}(y_i, y_{i+1})$ are a vector of indicator functions of the form $\mathbb{1}[y_i = a, y_{i+1} = b]$. Trained generatively, this model is essentially an HMM, but slightly more expressive. Trained (fully) discriminatively, this model is a CRF.

We used the Wall Street Journal (WSJ) portion of the Penn Treebank, with sections 0–21 for training (38K sentences) and 22–24 for testing (5.5K sentences). Table 2(a) shows that the discriminative estimators perform better than the generative one. This is not surprising given that the model is misspecified (language does not come from an HMM).

To verify that the generative estimator is superior when the model is well-specified, we used the learned generative model in the previous experiment to sample 1000 synthetic training and 1000 synthetic test examples. We then applied the estimators as before on this artificial data. Table 2(b) shows that the generative es-

Full dis.	**0.992**	0.879	**0.407**	12.431
Pseudo dis.	0.990	0.891	0.469	10.840

(b) Synthetic data (well-specified)

Table 2. Part-of-speech tagging results. Discriminative estimators outperform the generative estimator (on both test accuracy and log-loss) when the model is misspecified, but the reverse is true when the model is well-specified.

timator has an advantage over the fully discriminative estimator, and both are better than the pseudolikelihood estimator.

5. Discussion and Extensions

We believe our analysis captures the essence of the generative-discriminative distinction: by modeling the input, we reduce the variance of the parameter estimates. In related work, Ng and Jordan (2002) showed that Naive Bayes requires exponentially fewer examples than logistic regression to obtain the same estimation error. The key property needed in their proof was that the Naive Bayes estimator decouples into d independent closed form optimization problems, which does not seem to be the defining property of generative estimation. In particular, this property does not apply to general globally-normalized generative models, but one would still expect those models to have the advantages of being generative.

Given that the generative and discriminative estimators are complementary, one natural question is how to interpolate between the two to get the benefits of both. Our framework naturally suggests two ways to go about this. First, we could vary the coarseness of the partitioning. Generative and discriminative estimators differ only in this coarseness and there is a range of intermediate choices corresponding to conditioning on more or fewer of the input variables. Second, we could take a weighted combination of estimators (e.g., Bouchard and Triggs (2004); McCallum et al. (2006)). For one-parameter models, Lindsay (1988) derived the optimal weighting of the component likelihoods, but unfortunately these results cannot be applied directly in practice.

It would also be interesting to perform a similar asymptotic analysis on other estimators used in practice, for example marginal likelihoods with latent variables, tree-reweighted belief propagation (Wainwright et al., 2003; Wainwright, 2006), piecewise training (Sutton & McCallum, 2005), etc. Another important extension is to curved exponential families, which account for many of the popular generative models based on directed graphical models.

6. Conclusion

We have analyzed the asymptotic distributions of composite likelihood estimators in the exponential family. The idea of considering different partitionings of the outcome space allows a clean and intuitive characterization of the asymptotic variances, which enables us to compare the commonly used generative, discriminative, and pseudolikelihood estimators as special cases. Our work provides new theoretical support for existing intuitions and a basis for developing new estimators which balance the tradeoff between computational and statistical efficiency.

Abstract

Structured models often achieve excellent performance but can be slow at test time. We investigate *structure compilation*, where we replace structure with features, which are often computationally simpler but unfortunately statistically more complex. We analyze this tradeoff theoretically and empirically on three natural language processing tasks. We also introduce a simple method to transfer predictive power from structure to features via unlabeled data, while incurring a minimal statistical penalty.

1. Introduction

Structured models have proven to be quite effective for tasks which require the prediction of complex outputs with many interdependencies, e.g., sequences, segmentations, trees, etc. For example, conditional random fields (CRFs) can be used to predict tag sequences where there are strong dependencies between adjacent tags (Lafferty et al., 2001). In part-of-speech tagging, for instance, a CRF can easily model the fact that adjectives tend to precede nouns in English. However, the excellent performance of structured models comes at a computational cost: inference in loopy graphs requires approximate inference, and even for sequences, there is a quadratic dependence on the number of tags.

In this paper, we ask a bold question: do we really need structure? Consider replacing the edges in a CRF with additional contextual features, i.e., having an independent logistic regression (ILR) at each position. A fundamental question is whether there is a gap between the expressive power of the ILR and that of the CRF. Punyakanok et al. (2005) investigated this question for margin-based models[1] and concluded that structure was not needed when the independent problems were "easy." They characterized difficulty in terms of classifier separability, which is a very rigid notion. In Section 3.1, we provide an information-theoretic analysis, decomposing the gap between the ILR and CRF into three terms, each one representing a shortcoming of the ILR. The impact of each is investigated empirically.

Even if the ILR were made as expressive as the CRF by adding additional features, an important remaining question is whether the ILR could generalize as well as the CRF given limited labeled data. Indeed, the ILR overfits more easily, and we provide generalization bounds in Section 3.2 to quantify this effect.

At this point, it seems as though we are forced to make a tradeoff between the computational simplicity of the ILR and the statistical simplicity of the CRF. However, we propose *structure compilation* as a way to have the best of both worlds. Our strategy is to label a plethora of unlabeled examples using the CRF and then train the ILR on these automatically labeled examples. If we label enough examples, the ILR will be less likely to overfit. Although training now takes longer, it is only a one-time cost, whereas prediction at test time should be made as fast as possible.

Many authors have used unlabeled data to transfer the predictive power of one model to another, for example, from high accuracy neural networks to more interpretable decision trees (Craven, 1996), or from high accuracy ensembles to faster and more compact neural networks (Bucilă et al., 2006). Our fo-

[1] In their case, the independent models are not endowed with extra features, but coherence of the predictions is enforced at test time.

cus is on structured classification tasks, specifically on studying the tradeoff between structure and features. We ran experiments on three tasks: part-of-speech tagging (POS), named-entity recognition (NER), and constituency parsing (Figure 1).

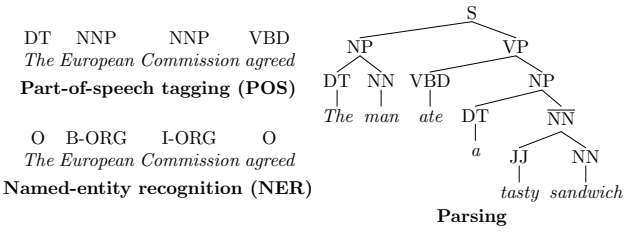

Figure 1. Examples of inputs and their outputs for the three tasks we experimented on. The input (what's seen at test time) is italicized.

2. From Structure to Features

In this section, we will walk through the process of replacing structure with features, using empirical results on POS[2] and NER[3] as running examples. Table 1 summarizes the notation we will use.

2.1. Conditional Random Fields (CRFs)

In structured classification, our goal is to learn to predict an output $\mathbf{y} \in \mathcal{Y}$ (e.g., a tag sequence, a segmentation, or a parse tree) given an input $\mathbf{x} \in \mathcal{X}$ (e.g., a sentence). In this paper, we consider *conditional exponential family* models, which have the following form:

$$p_\theta(\mathbf{y} \mid \mathbf{x}) = \exp\{\phi(\mathbf{x}, \mathbf{y})^\top \theta - A(\theta; \mathbf{x})\}, \quad (1)$$

where $\phi(\mathbf{x}, \mathbf{y})$ are the sufficient statistics (features), $\theta \in \mathbb{R}^d$ are the parameters, and $A(\theta; \mathbf{x}) = \log \sum_{\mathbf{y}} \exp\{\phi(\mathbf{x}, \mathbf{y})^\top \theta\}$ is the log-partition function.

One important type of conditional exponential family is a conditional random field (CRF) defined on a graph $G = (V, E)$. In this case, the output $\mathbf{y} = \{y_i\}_{i \in V}$ is a collection of labels, one for each node $i \in V$, with $y_i \in \{1, \ldots, K\}$. The features include functions over both nodes and edges:

$$\phi(\mathbf{x}, \mathbf{y}) = \sum_{i \in V} f(y_i, \mathbf{x}, i) + \sum_{(i,j) \in E} g(y_i, y_j).$$

[2]We used the Wall Street Journal (WSJ) portion of the Penn Treebank, with sections 0–21 as the training set (38K sentences) and sections 22–24 as the test set (5.5K sentences).

[3]We used the English data from the 2003 CoNLL Shared Task, consisting of 14.8K training sentences and 3.5K test sentences (set A).

In this work, we use a generic set of features for both POS and NER. The components of the node features $f(y_i, \mathbf{x}, i)$ are all indicator functions of the form $\mathbb{I}[y_i = a, s(x_{i+o}) = b]$, where a ranges over tags, $s(\cdot)$ ranges over functions on words,[4] b are values in the range of $s(\cdot)$, and $-L \le o \le L$ is an offset within a radius L window of the current position i (we used $L = 0$ for POS, $L = 1$ for NER). The components of the edge features $g(y_i, y_j)$ are of the form $\mathbb{I}[y_i = a, y_j = b]$. Let f_1 denote this *base feature set*.

Training Suppose we are given n labeled examples $(\mathbf{x}^{(1)}, \mathbf{y}^{(1)}), \ldots, (\mathbf{x}^{(n)}, \mathbf{y}^{(n)})$, which for the purposes of our theoretical analysis are assumed to be drawn i.i.d. from some unknown true distribution p^*. We train the CRF using standard maximum likelihood:[5] $\max_\theta \mathbb{E}_{p^{\text{L}}(\mathbf{x},\mathbf{y})} \log p(\mathbf{y} \mid \mathbf{x}; \theta)$, where $p^{\text{L}}(\mathbf{x}, \mathbf{y}) = \frac{1}{n} \sum_{i=1}^n \mathbb{I}[\mathbf{x} = \mathbf{x}^{(i)}, \mathbf{y} = \mathbf{y}^{(i)}]$ denotes the empirical distribution of the labeled data. Later, we will consider other training regimes, so we need to establish some new notation. Let $p_{\text{C}} = \text{TR}(\text{CRF}, f_1, p^{\text{L}})$ denote the CRF trained with the base feature set f_1 on the labeled data.

CRFs achieve state-of-the-art performance on POS and NER. Using just our generic feature set, we obtain 96.9% tagging accuracy on POS (training with 30K examples) and 85.3% F_1 on NER (training with 10K examples). However, the performance does come at a computational cost, since inference scales quadratically with the number of tags K. This cost only increases with more complex models.

2.2. Independent Logistic Regression (ILR)

Let us try something drastic: remove the edges from the CRF to get an independent logistic regression (ILR), where now $\phi(\mathbf{x}, \mathbf{y}) = \sum_{i \in V} f(y_i, \mathbf{x}, i)$. For an ILR trained on the labeled data with our base feature set (denoted formally as $\text{TR}(\text{ILR}, f_1, p^{\text{L}})$), inference can be done independently for each node. For POS, the ILR takes only 0.4ms to process one sentence whereas the CRF takes 2.7ms, which is a speedup of 5.8x, not including the time for precomputing features.[6] Unfortunately, the accuracy of POS drops from 96.9% to 93.7%. For NER, F_1 drops from 85.3% to 81.4%.

[4]We used 10 standard NLP functions which return the word, prefixes and suffixes (up to length 3) of the word, word signatures (e.g., *McPherson* maps to *AaAaaaaaa* and *AaAa*), and whether the word is capitalized.

[5]In our experiments, we ran stochastic gradient for 50 iterations with a $1/(\text{iteration} + 3)$ step-size.

[6]If we include the time for computing features, the speedup drops to 2.3x.

2.3. Adding New Features

Without edges, the ILR has less expressiveness compared to the CRF. We can compensate for this loss by expanding our base feature set. We will use f_2 to denote the *expanded feature set*.

We use a simple recipe to automatically construct f_2 from f_1, but in general, we could engineer the features more carefully for better performance (see the parsing experiments in Section 4, for example). Essentially, our recipe is to allow the ILR at node i to use the base features f_1 applied to the nodes in a local window around i. For the chain CRF, this amounts to simply increasing the window size from L to $L + r$ (Section 2.1), where we call r the *expansion radius*.

For POS, we used an expansion radius of $r = 1$; for NER, $r = 2$. By training with these new features ($\text{TR}(\text{ILR}, f_2, p^{\text{L}})$), we get 96.8% on POS (compared to the 96.9% of the CRF), taking 0.8ms per example (compared to 2.7ms for the CRF). In this case, we have successfully traded structure for features with a negligible loss in performance and a 3.4x speedup. For NER, the story is quite different: adding features actually makes F_1 drop from 81.1% to 78.8%.

We believe there are two reasons for the poor performance on NER. First, since NER is a segmentation problem, the structure plays a more integral role and thus cannot be easily replaced with features. In other words, the *approximation error* of the ILR with respect to the CRF is higher for NER than POS. Section 3.1 provides a more formal treatment of this matter. Second, adding more features increases the risk of overfitting. In other words, the *estimation error* is larger when there are more features. Section 3.2 analyzes this error theoretically.

2.4. Using Unlabeled Data

There seems to be a tradeoff between approximation error and estimation error: More features can provide a better substitute for structure (decreasing the approximation error), but at the risk of overfitting the data (increasing the estimation error).

The algorithmic contribution of this paper is using unlabeled data to reduce the estimation error of the ILR via structure compilation. Suppose we have m unlabeled examples $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(m)}$ (which we assume are also generated from p^*); let $p^{\text{U}}(\mathbf{x})$ denote the corresponding empirical distribution. We can use the CRF $p_{\text{C}}(\mathbf{y} \mid \mathbf{x})$ (which has been trained on p^{L}) to label this unlabeled data. Let $p^{\text{U}}_{\text{C}}(\mathbf{x}, \mathbf{y}) = p^{\text{U}}(\mathbf{x}) p_{\text{C}}(\mathbf{y} \mid \mathbf{x})$ denote this new plentiful source of labeled data. Instead of training the ILR on the limited amount of originally labeled data p^{L}, we instead train it on our automatically labeled data p^{U}_{C}.[7]

f_1	base feature set
f_2	expanded feature set
$p^*(\mathbf{x}, \mathbf{y})$	true data distribution
$p^{\text{L}}(\mathbf{x}, \mathbf{y})$	original labeled examples (few)
$p_{\text{C}}(\mathbf{y} \mid \mathbf{x})$	$= \text{TR}(\text{CRF}, f_1, p^{\text{L}})$ [trained CRF]
$p_{\text{C}^*}(\mathbf{y} \mid \mathbf{x})$	$= \text{TR}(\text{CRF}, f_1, p^*)$ [limiting CRF]
$p^{\text{U}}(\mathbf{x})$	unlabeled examples (many)
$p^{\text{U}}_{\text{C}}(\mathbf{x}, \mathbf{y})$	$= p^{\text{U}}(\mathbf{x}) p_{\text{C}}(\mathbf{y} \mid \mathbf{x})$ [labeled with CRF]
$p^*_{\text{C}}(\mathbf{x}, \mathbf{y})$	$= p^*(\mathbf{x}) p_{\text{C}}(\mathbf{y} \mid \mathbf{x})$ [labeled with CRF]
$p_{\text{I}}(\mathbf{y} \mid \mathbf{x})$	$= \text{TR}(\text{ILR}, f_2, p^{\text{U}}_{\text{C}})$ [trained ILR]
$p_{\text{I}^*}(\mathbf{y} \mid \mathbf{x})$	$= \text{TR}(\text{ILR}, f_2, p^*_{\text{C}})$ [limiting ILR]

Table 1. Notation used in this paper. In general, superscripts denote marginal distributions over $\mathbf{x}$ and subscripts denote conditional distributions over $\mathbf{y}$ given $\mathbf{x}$.

Structure compilation is most useful when there are few original labeled examples. Figure 2 shows the performance of a ILR obtained using structure compilation when the CRF is trained on only 2K labeled examples. We see that using more unlabeled data reduces the performance gap between the CRF and ILR as the estimation error is reduced. For POS, the gap is closed entirely, whereas for NER, there is a remaining approximation error.

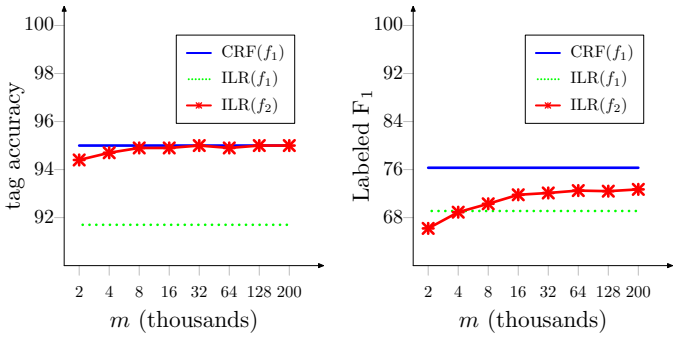

Figure 2. $\text{CRF}(f_1)$ is the CRF trained using the base feature set on 2K examples. $\text{ILR}(f_1)$ is the ILR trained the same way; performance suffers. However, by using the expanded feature set and training on m examples (New York Times articles from Gigawords) which are labeled with the CRF, $\text{ILR}(f_2)$ can recover all of the performance for POS and more than half of the performance for NER.

[7] Strictly speaking, training on p^{U}_{C} would involve creating many examples weighted by $p_{\text{C}}(y_i \mid \mathbf{x})$ for each original $\mathbf{x}$. But since the posteriors are sharply peaked, using $\text{argmax}_{\mathbf{y}} p_{\text{C}}(\mathbf{y} \mid \mathbf{x})$ was faster and an adequate approximation for our applications.

3. Analysis

In this section, we try to get a better understanding of when structure compilation would be effective. For the theoretical analysis, we will measure performance in terms of log-loss (negative cross-entropy):

$$\epsilon(p_1, p_2) \stackrel{\text{def}}{=} \mathbb{E}_{p_1(\mathbf{x},\mathbf{y})}[-\log p_2(\mathbf{y} \mid \mathbf{x})], \tag{2}$$

where $p_1(\mathbf{x}, \mathbf{y})$ is the data generating distribution and $p_2(\mathbf{y} \mid \mathbf{x})$ is the model under evaluation. We will also use conditional KL-divergence to quantify approximation error:

$$\kappa(p_1, p_2) \stackrel{\text{def}}{=} \epsilon(p_1, p_2) - \epsilon(p_1, p_1). \tag{3}$$

We are interested in $\epsilon(p^*, p_{\text{I}})$, the loss of the final compiled ILR. As we will later show in (7), this loss can be expressed in terms of two parts: (1) $\epsilon(p^*, p_{\text{C}})$, the loss of the CRF; and (2) $\kappa(p_{\text{C}}, p_{\text{I}})$, the penalty due to structure compilation.

The CRF loss can be decomposed into approximation and estimation errors as follows, using telescoping sums (refer to Table 1 for notation):

$$\begin{aligned}\epsilon(p^*, p_{\text{C}}) \;=\; & \underbrace{\epsilon(p^*, p_{\text{C}}) - \epsilon(p^{\text{L}}, p_{\text{C}})}_{\text{CRF-EST-ERR}} + \\ & \underbrace{\epsilon(p^{\text{L}}, p_{\text{C}}) - \epsilon(p^{\text{L}}, p_{\text{C}^*})}_{\leq 0} + \\ & \underbrace{\epsilon(p^{\text{L}}, p_{\text{C}^*}) - \epsilon(p^*, p_{\text{C}^*})}_{\text{CRF-EST-ERR}} + \underbrace{\epsilon(p^*, p_{\text{C}^*})}_{\text{CRF-APX-ERR}}.\end{aligned} \tag{4}$$

The second term on the RHS is non-positive because because p_{C} is chosen to minimize log-loss on p^{L}. The first and third terms are the estimation errors resulting from using p^{L} instead of p^*; these will be uniformly bounded in Section 3.2. Finally, the last term is an approximation error reflecting the modeling limitations of the CRF.

The structure compilation penalty can be decomposed analogously:

$$\begin{aligned}\kappa(p^*_{\text{C}}, p_{\text{I}}) \;=\; & \underbrace{\kappa(p^*_{\text{C}}, p_{\text{I}}) - \kappa(p^{\text{U}}_{\text{C}}, p_{\text{I}})}_{\text{ILR-EST-ERR}} + \\ & \underbrace{\kappa(p^{\text{U}}_{\text{C}}, p_{\text{I}}) - \kappa(p^{\text{U}}_{\text{C}}, p_{\text{I}^*})}_{\leq 0} + \\ & \underbrace{\kappa(p^{\text{U}}_{\text{C}}, p_{\text{I}^*}) - \kappa(p^*_{\text{C}}, p_{\text{I}^*})}_{\text{ILR-EST-ERR}} + \underbrace{\kappa(p^*_{\text{C}}, p_{\text{I}^*})}_{\text{ILR-APX-ERR}}.\end{aligned} \tag{5}$$

We would now like to combine $\epsilon(p^*, p_{\text{C}})$ and $\kappa(p_{\text{C}}, p_{\text{I}})$ to get a handle on $\epsilon(p^*, p_{\text{I}})$, but unfortunately, KL-divergence does not satisfy a triangle inequality. We can, however, derive the following approximate triangle inequality, where we pay an extra multiplicative factor (see Appendix A.1 for the proof):

Theorem 1. *Consider a conditional exponential family $\mathcal{P}$ with features ϕ. Let Θ be a compact subset of parameters, and define $\mathcal{P}_\Theta = \{p_\theta : \theta \in \Theta\}$. For any $p_1, p_2 \in \mathcal{P}_\Theta$ and any distribution p_0 such that $p'_0 = \operatorname{argmax}_{p \in \mathcal{P}} \mathbb{E}_{p^*(\mathbf{x})p_0(\mathbf{y}|\mathbf{x})} \log p(\mathbf{y} \mid \mathbf{x}) \in \mathcal{P}_\Theta$,*

$$\begin{aligned}\mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_0(\mathbf{y} \mid \mathbf{x}) \,||\, p_2(\mathbf{y} \mid \mathbf{x})\right) \leq \\ \alpha\left[\mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_0(\mathbf{y} \mid \mathbf{x}) \,||\, p_1(\mathbf{y} \mid \mathbf{x})\right) + \right. \\ \left. \mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_1(\mathbf{y} \mid \mathbf{x}) \,||\, p_2(\mathbf{y} \mid \mathbf{x})\right)\right],\end{aligned} \tag{6}$$

where $\alpha = 2\frac{\sup_{\theta\in\Theta} \lambda_{\max}(\mathbb{E}\,\mathrm{var}_\theta(\phi|\mathbf{x}))}{\inf_{\theta\in\Theta} \lambda^+_{\min}(\mathbb{E}\,\mathrm{var}_\theta(\phi|\mathbf{x}))}$. Here, $\lambda_{\max}(\Sigma)$ and $\lambda^+_{\min}(\Sigma)$ are the largest and smallest nonzero eigenvalues of Σ, respectively.

Theorem 1 generalizes Lemma 3 of Crammar et al. (2007) to conditional distributions and the case where p_0 is not necessarily in an exponential family.

Let us apply Theorem 1 with p^*, p_{C}, p_{I}. We then add the conditional entropy $\mathbb{E}\,H(p^*(\mathbf{y} \mid \mathbf{x}))$ to the LHS of the resulting inequality and $\alpha\mathbb{E}\,H(p^*(\mathbf{y} \mid \mathbf{x}))$ to the RHS (note that $\alpha \geq 1$), thus obtaining a bound for the total loss of the final compiled ILR:

$$\begin{aligned}\epsilon(p^*, p_{\text{I}}) \;&\leq\; \alpha(\epsilon(p^*, p_{\text{C}}) + \kappa(p^*_{\text{C}}, p_{\text{I}})) \\ &\leq\; \alpha(\textsc{crf-apx-err} + \textsc{ilr-apx-err}) + \\ &\quad\; 2\alpha(\textsc{crf-est-err} + \textsc{ilr-est-err}).\end{aligned} \tag{7}$$

In the remaining sections, we analyze the various pieces of this bound.

3.1. Approximation Error

We start by analyzing $\textsc{ilr-apx-err} = \kappa(p^*_{\text{C}}, p_{\text{I}^*})$, which measures how well the ILR can approximate the CRF. Specifically, we show that $\kappa(p^*_{\text{C}}, p_{\text{I}^*})$ decomposes into three terms, each reflecting a limitation of the ILR: (1) I_{C}, the inability to produce a coherent output; (2) I_{N}, the inability to express nonlinearities; and (3) I_{G}, the inability to use information about the input outside a local window. The following theorem formalizes these concepts (see Appendix A.2 for the proof):

Theorem 2 (Decomposition of approximation error)**.** $\kappa(p^*_{\text{C}}, p_{\text{I}^*}) = I_{\text{C}} + I_{\text{N}} + I_{\text{G}}$*, where*

$$\begin{aligned}I_{\text{C}} \;&=\; \mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_{\text{C}}(\mathbf{y} \mid \mathbf{x}) \,||\, \prod_{i\in V} p_{\text{C}}(y_i \mid \mathbf{x})\right), \\ I_{\text{N}} \;&=\; \mathbb{E}_{p^*(\mathbf{x})} \sum_{i\in V} \mathrm{KL}\left(p_{\text{C}}(y_i \mid \mathbf{x}) \,||\, p_{\text{A}^*}(y_i \mid \mathbf{x})\right), \\ I_{\text{G}} \;&=\; \mathbb{E}_{p^*(\mathbf{x})} \sum_{i\in V} \mathrm{KL}\left(p_{\text{A}^*}(y_i \mid \mathbf{x}) \,||\, p_{\text{I}^*}(y_i \mid \mathbf{x})\right),\end{aligned}$$

with $p_{\text{A}^*} = \text{TR}(\text{ILR}, f_\infty, p_{\text{C}}^*)$*, where the node features* f_∞ *are constructed from* f_1 *with an expansion radius of* ∞ *(so the entire input sequence* $\mathbf{x}$ *is used).*

Coherence One advantage of structured models is their ability to predict the output jointly. This could be especially important for NER, where the output tag sequence actually codes for a segmentation of the input. I_{C} measures the information lost by using the independent marginals of the CRF rather than the joint.[8]

For a chain CRF defined on $\mathbf{y} = (y_1, \ldots, y_\ell)$, one can check that I_{C} is the sum of mutual information terms along the edges: $I_{\text{C}} = \mathbb{E} \sum_{i=1}^{\ell-1} I(y_i, y_{i+1} \mid \mathbf{x})$. We computed I_{C} empirically: for POS, $I_{\text{C}} = 0.003$ and for NER, $I_{\text{C}} = 0.009$ (normalized by sequence length). Also, when we predict using the CRF marginals, the performance drops from 76.3% to 76.0% for NER but stays at 95.0% for POS. From these results, we conclude that coherence is not a big concern for our applications, although it is slightly more serious for NER, as we would expect.

Nonlinearities Although we think of CRFs as linear models, their marginal predictions actually behave nonlinearly. I_{N} captures the importance of this nonlinearity by comparing $p_{\text{C}}(y_i \mid \mathbf{x})$ and $p_{\text{A}^*}(y_i \mid \mathbf{x})$. Both depend on $\mathbf{x}$ through the same sufficient statistics $f_1(\cdot, \mathbf{x}, \cdot)$, but p_{A^*} acts on these sufficient statistics in a linear way whereas p_{C} allows the information about $\mathbf{x}$ to propagate in a nonlinear way through the other hidden labels $\mathbf{y}_{-i} = \{y_j : j \neq i\}$ in a manner roughly similar to that of a neural network. However, one difference is that the parameters of $p_{\text{C}}(y_i \mid \mathbf{x})$ are learned with $\mathbf{y}_{-i}$ fixed at training time; they are not arbitrary hidden units in service of y_i. A neural network therefore offers more expressive power but could be more difficult to learn.

We would like to measure the effect of nonlinearity empirically, but p_{A^*} has too many parameters to learn effectively. Thus, instead of comparing p_{A^*} and p_{C}, we compare p_{I^*} and a *truncated CRF* p_{TC}, which we train as follows:[9] For each labeled example $(\mathbf{x}, \mathbf{y})$ (which are sequences of length ℓ), we create ℓ new examples: $(\mathbf{x}_{i-L-r..i+L+r}, \mathbf{y}_{i-r..i+r})$ for $i = 1, \ldots, \ell$, where r is the expansion radius (Section 2.3). Then we train a CRF with features f_1 on these new examples to get p_{TC}. To label node i, we use $p_{\text{TC}}(y_i \mid \mathbf{x}_{i-L-r..i+L+r})$, marginalizing out $\mathbf{y}_{i-r..i-1,i+1..i+r}$. By this setup, both $p_{\text{TC}}(y_i \mid \mathbf{x})$ and $p_{\text{I}^*}(y_i \mid \mathbf{x})$ depend on $\mathbf{x}$ through the same features. Table 2 compares the NER performance of p_{TC} and p_{I}. As we can see, the truncated CRF significantly outperforms the ILR, demonstrating the power of nonlinearities.

Expansion radius r	1	2	3	∞
compiled ILR	0.725	0.727	0.721	—
truncated CRF	0.748	0.760	0.762	0.760

Table 2. NER F_1 (2K originally labeled examples, 200K automatically labeled examples for structure compilation) showing the importance of nonlinearity. Both the ILR and truncated CRF depend on the input $\mathbf{x}$ in the same way, but only the latter permits nonlinearities.

Global information I_{G} compares p_{A^*} and p_{I^*}, both of which are independent linear classifiers. The difference is that p_{A^*} uses all features of $\mathbf{x}$, while p_{I^*} uses only features of $\mathbf{x}$ in a local window.

Instead of comparing p_{A^*} and p_{I^*}, we compare their nonlinear counterparts p_{C} and p_{TC}. From Table 2, we can see that the truncated CRF with just an expansion radius of 2 has the same performance as the original CRF (expansion radius ∞). Therefore, we suspect that the features on $\mathbf{x}$ outside a local window have little impact on performance, and that most of the approximation error is due to lacking nonlinearities.

3.2. Estimation Error

In this section, we quantify the estimation errors for the CRF and ILR. First, we establish a general result about the estimation error of log-loss for exponential families. Our strategy is to uniformly bound the difference between empirical and expected log-losses across all parameter values of the exponential family. Our proof uses covering numbers and is based on Collins (2001), which derived an analogous result for a 0-1 margin loss.

Assume our parameters and features are bounded: $\Theta = \{\theta : ||\theta||_2 \leq B\}$ and $R = \sup_{\mathbf{x},\mathbf{y}} ||\phi(\mathbf{x}, \mathbf{y})||_2$. The following theorem relates the difference between empirical and expected log-loss to the number of examples n (see Appendix for proof):

Theorem 3. *For* $\delta > 0$*, with probability* $\geq 1 - \delta$*, for* $|\epsilon(p^*, p_\theta) - \epsilon(p^{\text{L}}, p_\theta)| \leq \eta$ *to hold for all* $\theta \in \Theta$*, it suffices to use* $n = \Omega(B^4 R^4 \log^2 |\mathcal{Y}| \eta^{-4} \log(1/\delta))$ *examples, where we have suppressed logarithmic factors.*

The above result gives uniform convergence of $\epsilon(\cdot, \cdot)$, which allows us to bound CRF-EST-ERR. In order to bound ILR-EST-ERR, we need uniform convergence of

[8] On the other hand, if we evaluate predictions using Hamming distance, it could actually be better to use the marginals. In that case, coherence is irrelevant.

[9] Truncated CRFs are closely related to piecewise-trained CRFs (Sutton & McCallum, 2005).

$\kappa(\cdot,\cdot)$ (5). This requires the convergence of one additional term: $|\epsilon(p_{\mathrm{C}}^{\mathrm{U}}, p_{\mathrm{C}}) - \epsilon(p_{\mathrm{C}}^{*}, p_{\mathrm{C}})| \xrightarrow{P} 0$ (p_{C} is non-random in this context). The asymptotics for n in Theorem 3 therefore remain unchanged.

We now apply Theorem 3 to the CRF and ILR with the features described in Section 2.1. For both models, $\log|\mathcal{Y}| = K|V|$. Where they differ is on the norms of the parameters and features (B and R). Let d_1 be the total number of features in the base feature set; d_2, the expanded feature set. Let c_k be the number of nonzero entries in $f_k(y_i, \mathbf{x}, i)$. Natural language processing is typified by sparse binary feature vectors, so $d_k \gg c_k$. For the CRF, $||\phi(\mathbf{x}, \mathbf{y})||_2$ is bounded by $R \leq \sqrt{c_1|V|^2 + |E|^2} \leq \sqrt{c_1}|V| + |E|$. The ILR has no edge potentials so $R \leq \sqrt{c_2}|V|$. In general, R is small for NLP applications.

On the other hand, $B \sim \sqrt{d_1}$ for the CRF and $B \sim \sqrt{d_2}$ for the ILR if the magnitude of the individual parameters are comparable. Since d_2 is significantly larger than d_1, the generalization bound for the ILR is much worse than for the CRF. While comparing upper bounds is inconclusive, showing that one upper bound is larger than another via the same methodology is weak evidence that the actual quantities obey a similar inequality.

4. Parsing Experiments

We now apply structure compilation to parsing. In this case, our structured model is a log-linear parser (Petrov & Klein, 2008), which we would like to replace with independent logistic regressions. For simplicity, we consider unlabeled binary trees. We could always use another independent classifier to predict node labels.

Standard parsing algorithms require $O(|G|\ell^3)$ time to parse a sentence with ℓ words, where $|G|$ is the size of the grammar. The ILR-based parser we will describe only requires $O(\ell^3)$ time. An extension to the labeled case would require $O(\ell^3 + K\ell)$ time, where K is the number of labels. This is a significant gain, since the grammars used in real-world parsers are quite large ($|G| \gg \ell, K$).

4.1. Independent Model

An example parse tree is shown in Figure 1 (recall that we do not predict the labels). For each span (i, j) ($1 \leq i < j \leq \ell$), the independent model predicts whether a node in the parse tree dominates the span. For example, of the 14 non-trivial spans in the sentence in Figure 1, the positively labeled spans are $(1, 2)$, $(5, 6)$, $(4, 6)$, and $(3, 6)$. To parse a sentence at test time, we first use the independent model to assign each span a probability and then use dynamic programming to find the most likely tree.

The independent model uses the following features evaluated (a) within the span, (b) at the boundary of the span, and (c) within a window of 3 words on either side of the span: identity, parts-of-speech, prefixes/suffixes (length 1-3), and case patterns. Additional features include 3- and 4-grams of the words and POS tags that occur within the span; the entire POS sequence; the entire word sequence; the 3-character suffix sequence; the case sequence within the span; the length of the span; the position of the span relative to the entire sentence; the number of verbs, conjunctions and punctuation marks within the span; and whether the span centers on a conjunction and has symmetric POS tags to the left and right.

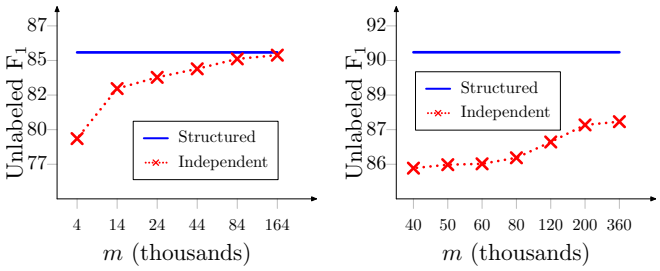
4.2. Results

In all of our experiments, we evaluate according to the F_1 score on unlabeled, binarized trees (using right-binarization). This scoring metric is slightly non-standard, but equally difficult: a parser that achieves a labeled F_1 (the usual metric) of 89.96% on the Treebank test data (section 23) achieves 90.29% under our metric; on 10% of the data, the two metrics are 82.84% and 85.16%, respectively.

To test our independent parser, we trained a structured parser on 10% of the WSJ portion of the Penn Treebank (4K sentences). We then used the structured parser to parse 160K unlabeled sentences,[10] which were then used, along with the original 4K sentences, to train the independent model. Figure 3(a) shows the F_1 scores of the various models. When only 4K is used, the independent parser achieves a score of 79.18%, whereas the structured parser gets 85.16%. With more automatically labeled examples, the performance of the independent parser approaches that of the structured parser (84.97% with 164K sentences).

On the other hand, if we trained the structured parser on 40K sentences, then the independent parser has a much harder time catching up, improving from 85.42% (40K sentences) to just 87.57% (360K sentences) compared to the structured parser's 90.78% (Figure 3(b)). Since parsing is a much more complex task compared to POS or NER, we believe that richer features would be needed to reduce this gap.

[10] These sentences are from the North American National Corpus, selected by test-set relativization.



(a) 4K sentences (b) 40K sentences

Figure 3. A comparison of the structured and independent parsers when the structured parser is trained on 4K (a) and 40K (b) sentences. m is the number of examples (original + automatically labeled) used to train the independent parser.

5. Conclusion

The importance of deploying fast classifiers at test time motivated our investigation into the feasibility of replacing structure with features. We presented a method to compile structure into features and conducted theoretical and empirical analyses of the estimation and approximation errors involved in structure compilation. We hope that a better understanding of the role structure plays will lead to more computationally efficient methods that can still reap the benefits of structure.

A. Proofs

Lemma 1 gives conditions under which a conditional KL-divergence can be decomposed exactly. Lemma 2 specializes to the exponential family. These lemmas are variants of standard results from information geometry (see Csiszár and Shields (2004)). We will use them in the proofs of Theorems 1 and 2.

Lemma 1 (Conditional Pythagorean identity)**.** *Let* $d(p, p') = \mathbb{E}_{p^*(\mathbf{x})p(\mathbf{y}|\mathbf{x})} \log p'(\mathbf{y} \mid \mathbf{x})$ *be the negative conditional cross-entropy. For any three conditional distributions* p_0, p_1, p_2*, if* $d(p_0, p_1) = d(p_1, p_1)$ *and* $d(p_0, p_2) = d(p_1, p_2)$*, then*

$$\begin{aligned}\mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_0(\mathbf{y} \mid \mathbf{x}) \,||\, p_2(\mathbf{y} \mid \mathbf{x})\right) = \\ \mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_0(\mathbf{y} \mid \mathbf{x}) \,||\, p_1(\mathbf{y} \mid \mathbf{x})\right) + \\ \mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_1(\mathbf{y} \mid \mathbf{x}) \,||\, p_2(\mathbf{y} \mid \mathbf{x})\right).\end{aligned} \tag{8}$$

Proof. Use the fact that $\mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p \,||\, p'\right) = d(p, p) - d(p, p')$ and perform algebra. □

Lemma 2 (Conditional Pythagorean identity for exponential families)**.** *Let* $\mathcal{P}$ *be a conditional exponential family. If* $p_1 = \operatorname{argmax}_{p \in \mathcal{P}} \mathbb{E}_{p^*(\mathbf{x})p_0(\mathbf{y}|\mathbf{x})} \log p(\mathbf{y} \mid \mathbf{x})$ *and* $p_2 \in \mathcal{P}$*, (8) holds for* p_0, p_1, p_2*.*

Proof. Since p_1 is the maximum likelihood solution, $\mu \stackrel{\text{def}}{=} \mathbb{E}_{p^*(\mathbf{x})p_0(\mathbf{y}|\mathbf{x})}\phi(\mathbf{x}, \mathbf{y}) = \mathbb{E}_{p^*(\mathbf{x})p_1(\mathbf{y}|\mathbf{x})}\phi(\mathbf{x}, \mathbf{y})$, where ϕ are the features of $\mathcal{P}$. Then for $p \in \mathcal{P}$ with parameters θ, $d(p_0, p) = \mu^\top \theta - \mathbb{E}\, A(\theta; \mathbf{x}) = d(p_1, p)$ (follows from (1)). Plug in $p = p_1, p_2$ and apply Lemma 1. □

A.1. Proof of Theorem 1

Proof. The first part of the proof is similar to that of Lemma 3 in Crammar et al. (2007). Denote $k(p, p') = \mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p(\mathbf{y} \mid \mathbf{x}) \,||\, p'(\mathbf{y} \mid \mathbf{x})\right)$ and $B(\theta) = \mathbb{E}_{p^*(\mathbf{x})} A(\theta; \mathbf{x})$.

The key is to note that for $p, p' \in \mathcal{P}$, the conditional KL-divergence is the residual term in the first-order approximation of B: $k(p, p') = \nabla B(\theta)^\top (\theta - \theta') - (B(\theta) - B(\theta'))$, where θ, θ' are the parameters of p, p'. Thus, we can use Taylor's theorem to get that

$k(p,p') = \frac{1}{2}||\theta - \theta'||^2_{V_{p,p'}}$, where $V_{p,p'} = \nabla^2 B(\tilde{\theta}) = \mathbb{E}\,\mathrm{var}_{\tilde{\theta}}(\phi \mid \mathbf{x})$ for some $\tilde{\theta} \in \Theta$.

One can check that $||\theta'_0 - \theta_2||^2_{V_{0,2}} \le 2[||\theta'_0 - \theta_1||^2_{V_{0,2}} + ||\theta_1 - \theta_2||^2_{V_{0,2}}]$, where $V_{0,2} = V_{p'_0,p_2}$. By definition of α, $V_{0,2} \preceq \frac{\alpha}{2} V_{0,1}$ and $V_{0,2} \preceq \frac{\alpha}{2} V_{1,2}$,[11] so $||\theta'_0 - \theta_2||^2_{V_{0,2}} \le \alpha[||\theta'_0 - \theta_1||^2_{V_{0,1}} + ||\theta_1 - \theta_2||^2_{V_{1,2}}]$. Rewritten another way: $k(p'_0, p_2) \le \alpha[k(p'_0, p_1) + k(p_1, p_2)]$.

Applying Lemma 2 twice to p_0, p'_0, p_1 and p_0, p'_0, p_2 yields $k(p_0,p_2) - k(p_0,p'_0) \le \alpha[k(p_0,p_1) - k(p_0,p'_0) + k(p_1,p_2)]$. Subtracting $k(p_0,p'_0)$ from both sides and noting $\alpha \ge 1$ yields the theorem. □

A.2. Proof of Theorem 2

Proof. Define $p_{\text{MC}}(\mathbf{y} \mid \mathbf{x}) = \prod_{i \in V} p_{\text{C}}(y_i \mid \mathbf{x})$. Check that $d(p_{\text{C}}(\mathbf{y} \mid \mathbf{x}), \prod_{i \in V} p(y_i \mid \mathbf{x})) = d(\prod_{i \in V} p_{\text{C}}(y_i \mid \mathbf{x}), \prod_{i \in V} p(y_i \mid \mathbf{x}))$ for any p, in particular, p_{MC} and p_{I^*}. Thus we can apply Lemma 1 with $p_{\text{C}}, p_{\text{MC}}, p_{\text{I}^*}$ to get $\kappa(p^*_{\text{C}}, p_{\text{I}^*}) = I_{\text{C}} + \mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_{\text{MC}}(\mathbf{y} \mid \mathbf{x}) \,||\, p_{\text{I}^*}(\mathbf{y} \mid \mathbf{x})\right)$.

Since f_∞ is a superset of f_2, both p_{I^*} and p_{A^*} are members of the f_∞-exponential family, with p_{A^*} being the maximum likelihood solution. Apply Lemma 2 with $p_{\text{MC}}, p_{\text{A}^*}, p_{\text{I}^*}$ to get $\mathbb{E}_{p^*(\mathbf{x})}\mathrm{KL}\left(p_{\text{MC}}(\mathbf{y} \mid \mathbf{x}) \,||\, p_{\text{I}^*}(\mathbf{y} \mid \mathbf{x})\right) = I_{\text{N}} + I_{\text{G}}$. □

A.3. Proof of Theorem 3

We use covering numbers to bound the complexity of the class of log-losses. Our proof is inspired by Collins (2001), who works with a 0-1 margin-based loss. Define the loss class:

$$\mathcal{M} \stackrel{\text{def}}{=} \{(\mathbf{x},\mathbf{y}) \mapsto -\log p_\theta(\mathbf{y} \mid \mathbf{x}) : \theta \in \Theta\}. \tag{9}$$

We first show that the elements of $\mathcal{M}$ are bounded:

Lemma 3. *For each $f \in \mathcal{M}$ and $(\mathbf{x},\mathbf{y})$, $0 \le f(\mathbf{x},\mathbf{y}) \le L$, where $L \stackrel{\text{def}}{=} BR(1 + \log|\mathcal{Y}|)$.*

Proof. The lower bound holds since probabilities are bounded above by 1. For the upper bound, consider the absolute value of the two terms in (1) separately. For the linear term, $|\phi(\mathbf{x},\mathbf{y})^\top \theta| \le BR$ by the Cauchy-Schwartz inequality. The log-partition function can be bounded by $BR\log|\mathcal{Y}|$ by applying the linear term result to the exponent. Add the two bounds. □

Theorem 1 of Zhang (2002) (originally due to Pollard (1984)) applied to $\mathcal{M}$: With probability $\ge 1 - \delta$,

$$P\left(\sup_{\theta \in \Theta} |\epsilon(p^*, p_\theta) - \epsilon(p^{\text{L}}, p_\theta)| > \eta\right) \le 8\mathcal{N}_1(\mathcal{M}, \eta/8, n) \exp\left\{\frac{-n\eta^2}{128L^2}\right\}, \tag{10}$$

where $\mathcal{N}_p(\mathcal{F}, \epsilon, n)$, the covering number of function class $\mathcal{F}$, is the supremum over all points $\mathbf{z}_1, \ldots, \mathbf{z}_n$, of the size of the smallest cover $\{g_1, \ldots, g_k\}$ such that for all $f \in \mathcal{F}$, there exists a g_j in the cover with $(\frac{1}{n}\sum_{i=1}^n |f(\mathbf{z}_i) - g_j(\mathbf{z}_i)|^p)^{1/p} \le \epsilon$.

We now upper bound $\mathcal{N}_\infty(\mathcal{M}, \epsilon/8, n)$, adapting the method used in Collins (2001). First define the set of linear functions:

$$\mathcal{L} \stackrel{\text{def}}{=} \left\{\mathbf{v} \mapsto \theta^\top \mathbf{v} : \theta \in \Theta\right\}. \tag{11}$$

Theorem 4 of Zhang (2002) (with $p = q = 2$) allows us to bound the complexity of this class:

$$\log_2 \mathcal{N}_\infty(\mathcal{L}, \epsilon, n) \le 36(BR/\epsilon)^2 \log_2(2\lceil 4BR/\epsilon + 2\rceil n + 1). \tag{12}$$

We now relate the covering numbers of $\mathcal{L}$ and $\mathcal{M}$:

Lemma 4. $\mathcal{N}_\infty(\mathcal{M}, \epsilon, n) \le \mathcal{N}_\infty(\mathcal{L}, \epsilon/2, n|\mathcal{Y}|)$.

Proof. Let $S = \{(\mathbf{x}^{(1)}, \mathbf{y}^{(1)}), \ldots, (\mathbf{x}^{(n)}, \mathbf{y}^{(n)})\}$. We will construct a covering of $\mathcal{M}$ (with respect to S) by reducing to the problem of finding a covering of $\mathcal{L}$. Let $\mathbf{v}_{i\mathbf{y}} = \phi(\mathbf{x}^{(i)}, \mathbf{y})$ and $V = \{\mathbf{v}_{i\mathbf{y}} : i = 1, \ldots, n, \mathbf{y} \in \mathcal{Y}\}$. By (12), we can cover $\mathcal{L}$ with respect to V with a set $C_{\mathcal{L}}$. Consider the corresponding set $C_{\mathcal{M}} \subset \mathcal{M}$ (note the natural 3-way bijections between Θ, $\mathcal{L}$, and $\mathcal{M}$).

To prove the lemma, it suffices to show that $C_{\mathcal{M}}$ is a covering of $\mathcal{M}$. Fix some $g \in \mathcal{M}$, which is associated with some $f \in \mathcal{L}$ and $\theta \in \Theta$. There exists a $\tilde{f} \in C_{\mathcal{L}}$ (corresponding to a $\tilde{\theta} \in \Theta$ and a $\tilde{g} \in C_{\mathcal{M}}$) such that $|f(\mathbf{x},\mathbf{y}) - \tilde{f}(\mathbf{x},\mathbf{y})| = |\theta^\top \phi(\mathbf{x},\mathbf{y}) - \tilde{\theta}^\top \phi(\mathbf{x},\mathbf{y})| \le \epsilon/2$ for all $(\mathbf{x},\mathbf{y}) \in S$ and $\mathbf{y} \in \mathcal{Y}$. We now argue that $\tilde{g}$ is close to g. For each $(\mathbf{x},\mathbf{y}) \in S$,

$$\begin{aligned} g(\mathbf{x},\mathbf{y}) &= -\log p_\theta(\mathbf{y} \mid \mathbf{x}) \\ &= -\theta^\top \phi(\mathbf{x},\mathbf{y}) + \log \sum_{\mathbf{y}' \in \mathcal{Y}} e^{\theta^\top \phi(\mathbf{x},\mathbf{y}')} \\ &\le -(\tilde{\theta}^\top \phi(\mathbf{x},\mathbf{y}) - \epsilon/2) + \log \sum_{\mathbf{y}' \in \mathcal{Y}} e^{\tilde{\theta}^\top \phi(\mathbf{x},\mathbf{y}') + \epsilon/2} \\ &= \tilde{g}(\mathbf{x},\mathbf{y}) + \epsilon. \end{aligned}$$

Similarly, $g(\mathbf{x},\mathbf{y}) \ge \tilde{g}(\mathbf{x},\mathbf{y}) - \epsilon$. Therefore, $C_{\mathcal{M}}$ is a cover of $\mathcal{M}$. □

Substitute (12) into Lemma 4 to get an expression for $\mathcal{N}_\infty(\mathcal{M}, \epsilon, n)$; substitute that into (10), using the fact that $\mathcal{N}_1 \le \mathcal{N}_\infty$. Solving for n yields the theorem.

[11] It suffices to consider nonzero eigenvalues because zero eigenvalues correspond to non-identifiable directions, which are the same for all parameters θ.

ManifoldBoost: Stagewise Function Approximation for Fully-, Semi- and Un-supervised Learning

Abstract

We describe a manifold learning framework that naturally accommodates supervised learning, partially supervised learning and unsupervised clustering as particular cases. Our method chooses a function by minimizing loss subject to a manifold regularization penalty. This augmented cost is minimized using a greedy, stagewise, functional minimization procedure, as in Gradientboost. Each stage of boosting is fast and efficient. We demonstrate our approach using both radial basis function approximations and trees. The performance of our method is at the state of the art on many standard semi-supervised learning benchmarks, and we produce results for large scale datasets.

1. Introduction

Manifold Learning algorithms exploit geometric (or correlation) properties of datasets in high-dimensional spaces. The literature is too large to review in detail here (163 references in a recent review (Zhu, 2006)). Many different approaches have been pursued that utilize manifold structure such as constructing an explicit parametrization (e.g. (Tenenbaum et al., 2000; Roweis & Saul, 2000; Donoho & Grimes, 2003)), introducing a penalty term that imposes smoothness conditions on functions restricted to the manifold (e.g. (Sindhwani et al., 2006)), adjusting kernel smoothing bandwidths to account for manifold properties (e.g. (Bickel & Li, 2007)), and infering labels for unlabeled data using a harmonic smoother (e.g. (Zhu et al., 2003)).

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

There is a rough distinction in semi-supervised learning between manifold based algorithms that expect data to lie embedded in a space of lower intrisic dimensionality, and cluster-based algorithms that expect data to lie in clumps (the distinction seems to explain some differences in performance on different datasets (Chapelle et al., 2006)). There is some disagreement about the benefits of using unlabeled data, which may not always improve the asymptotic error rate of a regression estimator (Lafferty & Wasserman, 2007). On the other hand, (Niyogi, 2008) argues that manifold learning is useful insofar as the marginal of the data P_x can be linked with the conditional $P_{y|x}$ via the manifold.

Computational Complexity is a common problem for most semi-supervised approaches. Write l for the number of labeled data items and u for the number of unlabeled data items. Many algorithms scale as badly as $O((l+u)^3)$ (Zhu, 2006). Transductive support vector machines must solve a quadratic programming problem in $(l+u)$ variables (Joachims, 1999). Manifold smoothing of an SVM solves a quadratic programming problem in l variables, followed by a linear problem in $l+u$ variables; the situation is better for a linear SVM if feature vectors are sufficiently sparse (Sindhwani et al., 2006). Harmonic smoothing solves a relatively sparse linear system in l variables. This problem is relatively tractable, because the linear system involves the Laplacian of the smoothing kernel and so should be diagonally dominant (see (Dyn et al., 1986) for relevant observations in the context of radial basis functions). Each method must pay the cost of forming the Laplacian. For functional approximation schemes other than kernel smoothing, the complexity of current manifold learning methods in the number of training examples appears to be high. This is a problem – it is natural to want to use a manifold regularization term

with such methods as tree-structured classifiers, and with very large datasets.

Gradient Boosting poses function approximation as a variational problem, then uses a form of coordinate ascent on that problem ((Friedman, 1999); section 2). In this paper, we describe a variation on gradient boosting that can exploit a manifold regularization term, is fast and efficient for many forms of functional approximation (section 2.1), provides out of sample extensions (section 4), offers performance at the state of the art on standard datasets, and is capable of handling very large datasets (section 6). In the extreme case, when there is no supervision, the generalized method gracefully degrades into a clustering method (section 4). Finally, we show that our framework also easily extends to multi-class problems by choosing suitable loss functions (section 5).

2. Semi-Supervised Boosting

We follow convention by minimizing the sum of an expected loss and a regularization term. We must predict labels $y \in \mathcal{Y}$ for patterns $x \in \mathcal{X}$. We assume a probability distribution $P_{x,y}$ over $\mathcal{X} \times \mathcal{Y}$.

We will further assume the support of the marginal P_x lies on a domain $\mathcal{M} \subset \mathcal{X}$. Typically, this domain is of lower intrinsic dimension than $\mathcal{X}$; the term manifold is widely used to refer to such domains, though we require no manifold properties.

Write the predictor as $F(x)$, and the cost function as $\psi(y, F(x))$. We would like to find the function minimizer $F^* = \arg\min_{F \in \mathcal{H}} V[F]$, of the cost functional

$$\begin{aligned} V[F] &= \underbrace{\int \psi(y, F(x)) dP_{x,y}}_{\text{Expected Loss}} \\ &+ \underbrace{\gamma_{\mathcal{M}} \int_{\mathcal{M}} ||\nabla_{\mathcal{M}} F(x)||^2 dP_x}_{\text{Manifold Regularization}} \end{aligned} \quad (1)$$

restricted to some function family $\mathcal{H}$. Our regularization term is of the same form as that of (Sindhwani et al., 2006), and encourages smoothness of the solution in regions of high probability density. We control the complexity of the solution by choosing $\mathcal{H}$ and using the *shrinkage* approach of (Friedman, 1999).

This expression is very general. There are many possible choices for $\psi[y, F]$. Expressions such as $|y - F|$ and $(y - F)^2$ are typically used for regression. Expressions such as $\exp(-yF)$ and the binomial log likelihood $\log(1 + \exp(-2yF))$ penalize the *margin* yF, and are typically used for classification.

2.1. ManifoldBoost Framework

2.1.1. Stagewise Functional Minimization (P_x Known)

Following the work of Friedman (Friedman, 1999), we will find a *additive* solution of the form

$$F_M(x) = \sum_{m'=0}^{M} f_{m'}(x) \quad (2)$$

We will proceed in a greedy fashion. Assume we have a solution for $M = m$; we will then minimize $V[F_m + f_{m+1}]$ with respect to f_{m+1}. After (Friedman, 1999), we obtain a descent direction from the first variation of V

$$V[F_m + \epsilon f] = V[F_m] + \epsilon \delta V[F_m, f] + O(\epsilon^2) \quad (3)$$

where

$$\delta V[F_m, f] = \frac{d}{d\epsilon} V[F_m + \epsilon f]|_{\epsilon=0}$$

Write $\langle u, v \rangle$ for the usual inner product in L^2. Now $\delta V[F_m, f]$ is a linear functional of f, so there is some $G_V(F_m)$ — which we regard as the "gradient" of the cost — such that $\delta V[F_m, f] = \langle G_V(F_m), f \rangle$. Now we have that $\langle G_V(F_m), f \rangle$ is equal to

$$\int \left\{ \begin{array}{c} f(x) \left[\int_y \frac{\partial}{\partial u} \psi(y, u)\big|_{u=F_m(x)} dP_{y|x} \right] \\ +2\gamma_{\mathcal{M}} \nabla f(x)^t \nabla F_m(x) \end{array} \right\} dP_x \quad (4)$$

Assuming sufficient regularity, recalling that $P_x = 0$ on the boundary of the support of P_x, and using the first Green identity, we have that $\langle G_V(F_m), f \rangle$ is equal to

$$\int \left\{ \begin{array}{c} f(x) \left[\int_y \frac{\partial}{\partial u} \psi(y, u)\big|_{u=F_m(x)} dP_{y|x} \right] \\ +2\gamma_{\mathcal{M}} f(x) \nabla^2_{\mathcal{M}} F_m(x) \end{array} \right\} dP_x \quad (5)$$

where $\nabla^2_{\mathcal{M}} = -\nabla \cdot \nabla_{\mathcal{M}}$ is the *Laplace-Beltrami* operator. The optimal descent direction is a function f that maximizes $-\langle G_V(F_m), f \rangle$ (subject, if necessary to a norm constraint on f). The term $f_{m+1} = \alpha f$ is obtained using line search, minimizing the true cost $V[F_m + \alpha f]$ with respect to α.

2.1.2. Finite Data

Generally, neither P_x nor $P_{x,y}$ are known. Instead, we have sample of labelled data $\{x_i, y_i\}_{i=1}^{l}$, and of unlabelled data $\{x_i\}_{i=l+1}^{u}$. Now integrals become sums over data points. Generally, $\{f_m(x)\}$ will belong to a parametric family of functions (e. g. Radial Basis functions, decision trees, etc).

The Laplacian operator in equation 5 must be discretized. In high dimensions, we cannot triangulate

the data set. A smoothed Laplacian is equivalent to the difference between a short-scale average of the data and a long-scale average (e.g. the use of unsharp masking in photography, or the difference of Gaussians in computer vision). The graph Laplacian is a linear operator that takes a function on the graph to the weighted difference between the function value and the average of the K nearest neighbours. This means it is usual to approximate the Laplacian operator with the graph Laplacian $\mathcal{L}$ (e.g. see (Sindhwani et al., 2006)).

Write the graph Laplacian as $\mathcal{L}^{\mathcal{M}}$. The cost function becomes

$$\begin{aligned} V[F] &= \frac{1}{l}\sum_{i=1}^{l}\psi(y_i, F(x_i)) \\ &+ \frac{\gamma_{\mathcal{M}}}{(l+u)K}\sum_{i,j}F(x_i)\mathcal{L}^{\mathcal{M}}_{i,j}F(x_j) \end{aligned} \quad (6)$$

Again, assume we know F_m, and seek f_{m+1}. We will find a function f that maximizes $-\langle G_V(F_m), f\rangle$ then we will weight this function using line search. The inner product is $\langle a, b\rangle = \frac{1}{N}\sum_{i=1}^{N} a(x_i)\cdot b(x_j)$ and we have that

$$\begin{aligned} \langle G_V(F_m), f\rangle &= \frac{1}{l}\sum_i \frac{\partial}{\partial u}\psi(y,u)\Big|_{u=F_m(x_i)} f(x_i) \\ &+ \frac{2\gamma_{\mathcal{M}}}{(l+u)^2}\sum_{i,j} f(x_i)\mathcal{L}^{\mathcal{M}}_{i,j}F_{m-1}(x_j) \end{aligned} \quad (7)$$

Now $-\langle G_V, f\rangle$ is linear in f, and so we should maximize subject to a norm constraint on f. If the norm is fixed, then maximizing this expression is equivalent to minimizing $||G_V - f||^2 = ||G_V||^2 - 2\langle G_V, f\rangle + ||f||^2$. This means any squared loss regression algorithm can be used to find the optimal parameters. Our variational formulation explains why Friedman's *choosing* to make f parallel to the gradient G_V and posing the problem as squared error minimization is natural. Once the descent direction f is found, the final $f_{m+1} = \alpha f$ is obtained using line search, minimizing the true cost $V[F_m + \alpha f]$.

3. Two Examples: Tree and RBF ManifoldBoost Algorithms

We offer two example algorithms with calculations to illustrate our extremely general formalism. For each example, we consider the binary case ($y \in \{-1, 1\}$, $y = 0$ for unlabeled data), and use the negative binomial log likelihood as the loss function (Friedman, 1999): $\psi(y, F) = \log(1 + \exp(-2yF))$ For this case, whatever classifier we use represents $F(x) = \frac{1}{2}[\log(p(y=1|x)) - \log(p(y=-1|x))]$ and so at round m, the inner product with the "gradient" becomes,

$$\begin{aligned} \langle G_V(F_m), f\rangle &= \frac{1}{l}\sum_i \frac{2y_i}{1+\exp(2y_iF_m(x_i))} f(x_i) \\ &+ \frac{2\gamma_{\mathcal{M}}}{(l+u)K}\sum_{i,j} f(x_i)\mathcal{L}^{\mathcal{M}}_{i,j}F_m(x_j) \end{aligned} \quad (8)$$

The cases now differ by the procedures used to choose the optimal f

Tree-ManifoldBoost: As in L_2 TreeBoost (Friedman, 1999), we use regression trees as base learners. A tree has the form $f_{m+1}(x) = \sum_{s=1}^{S}\eta_{m+1,s}I[x \in R_s]$, where $I[\cdot] = 1$ if the expression inside is true, and $I[\cdot] = 0$ otherwise.

To minimize $||G_V - f||^2$, we must search for the parameters R_s (which determine the geometry of the tree) and η_s (which determine weights within region). Once a tree has been found, we fix R_s and minimize $V(F_m(x) + \sum_{s=1}^{S}\eta_{m,s}[x \in R_s])$ with respect to $\{\eta_s\}$, using a standard continuous optimization method (BFGS; see (Bertsekas, 1996)). In each round, we use a small number of descent steps to prevent overfitting.

Algorithm 1 Tree ManifoldBoost Algorithm

1: $F_0(x) = 1/2[\log(1+\overline{y}) - \log(1-\overline{y})]$
2: **for** $m = 1$ to M **do**
3: Compute G_V as in (8)
4: Obtain regression tree $\{R_{s,m}\}$ by minimizing $\sum_i (G_V(x_i) - \sum_s \eta_{m,s}I[x_i \in R_{m,s}])^2$
5: Find $\{\eta_{m,s}\}$ using BFGS and $\frac{\partial V}{\partial \eta_s}$, and fixing $\{R_{m,s}\}$
6: $F_m(x) = F_{m-1}(x) + \sum_s \eta_{m,s}[x \in R_{m,s}]$
7: **end for**

The algorithm converges when M rounds have been run, or the relative change in the cost function in a round is below a threshold. Probability estimates for each x can then be estimated by inverting the loss function: $p(y=1|x) = 1/(1+\exp(-2F_M(x)))$. This in turn can be used for classification:

$$\tilde{y_i} = \begin{cases} 1 & p(y=1|x)k_{-1,1} > p(y=-1|x)k_{1,-1} \\ -1 & \text{otherwise} \end{cases} \quad (9)$$

where cost $k_{a,b}$ is the penalty for choosing label a when b is the correct label.

Figure 1 shows a toy example for semisupervised classification taken from (Sindhwani et al., 2006) (two moons dataset). The unlabeled datapoints are depicted in green and the diamonds represent the labeled examples (one for each class). The algorithm also can

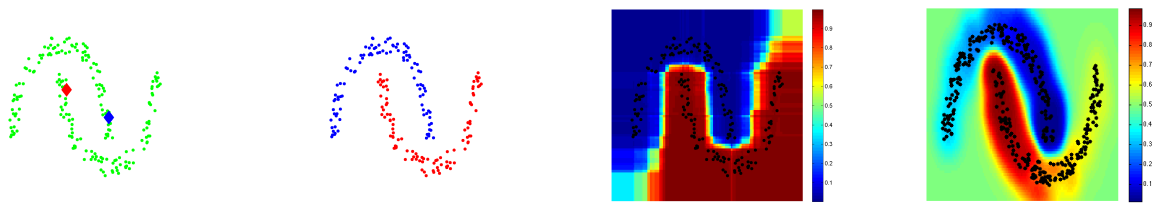

Figure 1. **Semi-supervised learning** using Tree- and RBF-ManifoldBoost. **first** figure from left to right shows a toy example introduced in (Sindhwani et al., 2006) (two moons dataset): the unlabeled datapoints are depicted in green, the diamonds represent the labeled examples (one for each class). The output classification of both algorithm is the same and is depicted on the **second** image (for datapoints). The **third** and **fourth** figures depict the likelihood predicted by the classifiers for the whole space for the tree- and rbf-based classifier respectively.

provide likelihood estimates, as seen in the right figures.

RBF-ManifoldBoost: Tree functions are not the only possible approximation to the "gradient". Step 4 in algorithm 1 can be modified so that R radial basis function of width σ, each with a weight w_r and centered in a datapoint are chosen as approximation. Again, a BFGS step can be performed to improve the loss by fitting the weights w_r. Algorithm 2 describes this.

Algorithm 2 RBF ManifoldBoost Algorithm

1: $F_0(x) = 1/2[\log(1+\overline{y}) - \log(1-\overline{y})]$
2: **for** $m = 1$ to M **do**
3: Compute G_V as in (8)
4: Choose R RBFs greedily to minimize $\sum_i (G_V(x_i) - \sum_r w_r RBF_{r,\sigma}(x_i)])^2$
5: Find $\{w_r\}$ using BFGS and $\frac{\partial V}{\partial w_r}$
6: $F_m(x) = F_{m-1}(x) + \nu \sum_r w_r RBF_{r,\sigma}(x)$
7: **end for**

Complexity: The procedure itself is linear in $n = l+u$, in the Laplacian neighborhood K, the dimensionality of x and the number of rounds. The complexity of the algorithm depends then on the base regressor, and the computation of the Laplacian matrix. Influence trimming can also be used to get tenfold speedups (Friedman, 1999), although the algorithm is still linear in the number of datapoints.

4. Unsupervised Boosting

The essential step in semi-supervised learning is the observation that similar data items should tend to have similar labels, which means that semi-supervised learning method should be capable of clustering. Our framework can naturally be extended to unsupervised learning, where one wishes to cluster data and the choice of label for a cluster is arbitrary. As there are no labeled data, the first term in equation 6 becomes zero and the problem is,

$$F^* = \arg\min_{F\in\mathcal{H}} \sum_{i,j} F(x_i)\mathcal{L}^{\mathcal{M}}_{i,j}F(x_j) \qquad (10)$$

under the constraints $\sum_i F(x_i) = 0$, $\sum_i F(x_i)^2 = N$ (this is a form of spectral clustering problem, see (Sindhwani et al., 2006); without the constraints, the problem is ill-posed). Our formalism yields a greedy method for this problem, rather than the usual generalized eigenvalue problem. To manage constraints, we use the Augmented Lagrangian method (Bertsekas, 1996), which adds a penalty in each round for constraint violations in the unconstrained problem. We choose F^* to be

$$\arg\min_{F\in\mathcal{H}} \sum_{i,j} F(x_i)\mathcal{L}_{i,j}F(x_j) + \lambda_1^m \sum_i F(x_i) + \dots$$
$$\lambda_2^m \left(\sum_i F(x_i)^2 - N\right) + \frac{c_1^m}{2}\left(\sum_i F(x_i)\right)^2 + \dots$$
$$\frac{c_2^m}{2}\left(\sum_i F(x_i)^2 - N\right)^2 \qquad (11)$$

for non-decreasing sequences $\{c_1^m, c_2^m\}_{m=1}^M$. After each round, the values of the Lagrange multipliers are increased by the constraint violation (Bertsekas, 1996) $\lambda_1^{m+1} \leftarrow \lambda_1^m + c_1^m(\sum_i F(x_i))$ and $\lambda^{m+1} \leftarrow \lambda_1^m + c_1^m(\sum_i F(x_i)^2 - N)$. As before, BFGS is applied in each round. Algorithm 3 describes the tree-based version.

The algorithm converges to a local minimum of the constrained problem. This formulation, unlike ISOMAP, naturally takes care of out-of-sample evaluation. Compared to (Sindhwani et al., 2006), the computational complexity is greatly reduced. On the other hand the solution is greedy, and there is no straightforward term for controlling the complexity of the function in the ambient space; this is achieved through the depth of the trees used in the algorithm.

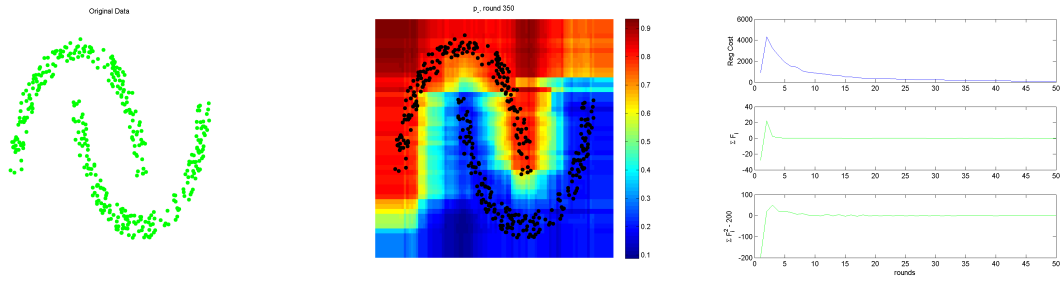

Figure 2. **Unsupervised learning**. The framework can be extended to unsupervised learning. The same problem as in figure 1 is presented without labels (**left** image). The result of the Tree-based algorithm is shown in the **center** image. The plots on the **right** show the constraint violations go to zero as learning progresses. This figure is best viewed in color.

Algorithm 3 Unsupervised Tree ManifoldBoost Algorithm

1: Initialize $F_0(x)$ randomly, with zero mean and low variance.
2: **for** $m = 1$ to M **do**
3: Compute G_V of the penalized, uncontrained problem.
4: Obtain regression tree $\{R_{m,s}\}$ by minimizing $\sum_i (G_V(x_i) - \sum_s \eta_{m,s}[x_i \in R_{m,s}])^2$
5: Find $\{\eta_{m,s}\}$ using BFGS and fixing $\{R_{m,s}\}$
6: $F_m(x) = F_{m-1}(x) + \sum_s \eta_{m,s}[x \in R_{m,s}]$
7: Update Lagrange multipliers using the constrain violations.
8: **end for**

5. Multiclass Case

Algorithm 1 can be extended to K-class problems by introducing a multinomial cost in equation 1,

$$\psi(\{y^{(c)}, F^{(c)}(x)\}_{c=1}^{C}) = -\sum_{c'=1}^{C} y^{(c')} \log p^{(c')}(x) \quad (12)$$

where $p^{(c)}(x)$ represents the belief example x belongs to class c, and $y^{(c)}$ is a binary variable which is one if example x belongs to class c. As in (Friedman, 1999) we use the symmetric multiple logistic transform

$$p^{(c)}(x) = \exp F^{(c)}(x) \cdot \left(\sum_{c'=1}^{C} \exp F^{(c')}(x) \right)^{-1} \quad (13)$$

Smoothness of $F^{(c)}$ is enforced by defining the cost $V(\{F^{(c)}\})$ to be

$$\frac{1}{l} \sum_i \psi(\{y_i^{(c)}, F^{(c)}(x_i)\}_{c=1}^{C}) + \dots$$
$$\frac{1}{C \cdot (l+u) \cdot K} \sum_{c'} \sum_{i,j} \gamma_{\mathcal{M}}^{(c')} F^{(c')}(x_i) \mathcal{L}_{i,j}^{\mathcal{M}} F^{(c')}(x_j)$$

The inner product of $f^{(c)}$ with gradient of V becomes, for class c,

$$\begin{aligned} \langle G_V^{(c)}(F_m^{(c)}), f \rangle &= \frac{1}{l} \sum_i (-y_i^{(c)} + p_m^{(c)}(x_i)) f(x_i) \quad (14) \\ &+ \frac{2\gamma_c^{\mathcal{M}}}{C \cdot (l+u)^2} \sum_{i,j} f(x_i) \mathcal{L}_{i,j}^{\mathcal{M}} F_m^{(c)}(x_j) \end{aligned}$$

Now one regression tree is fitted per class at each round to approximate each descent direction. As in the two class problem, the S regions $\{R_{m,s}^{(c)}\}_{s=1}^{S}$ defined by the terminal nodes are fixed, and the parameters $\eta_{m,s}^{(c)}$ for regions in each tree are learned in order to minimize the total cost V. We use a couple of BFGS iterations per round to find these parameters. In order to do this, the derivatives of the cost with respect to $\eta_{m,s}^{(c)}$ have to be computed.

Once the final $\{F_M^{(c)}(x)\}$ are computed, the probability for a given example of each label can be estimated and thus the label can be classified as $\hat{c}(x_i) = \arg\min_c \sum_{c'=1}^{C} k_{c,c'} p_M^{(c')}(x)$ for costs $k_{c,c'}$ when label c is assigned when label c' is correct. The complexity of this algorithm is also linear in the number of classes, but it scales highly sub-linearly with the number of rounds M when inluence trimming is used (Friedman, 1999).

6. Experiments and Discussion

6.1. Comparison to Other Regularized Boosting Algorithms

Kegl et. al. (Kégl & Wang, 2005) introduce RegBoost, an extension to AdaBoost which incorporates a weight decay that depends on a Laplacian regularizer. Our approach is different several senses: first, ours is based on the GradientBoost framework while theirs is based on AdaBoost, second, in the sense that ManifoldBoost does not require manifold-regularized base learners. This makes their approach limited in

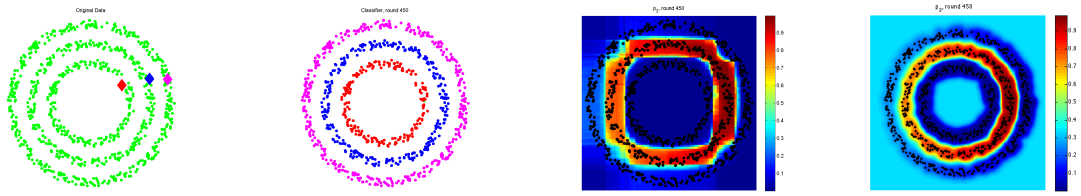

Figure 3. The framework also handles **multiclass learning**. **Left** figure shows another toy example (three rings): the unlabeled datapoints are depicted in green, the diamonds represent the labeled examples (one for each class). The output of the algorithm is depicted on the **center** figure. The blue classification function $F^2(x)$ is shown on the **right**. This figure is best viewed in color.

Algorithm 4 K-Tree ManifoldBoost Algorithm

Let $p_0^{(c)}$ be the frequencies of each class c.
$F_0^{(c)}(x) = \log p_0^{(c)} - \frac{1}{C}\sum_{c'=1}^{C} \log p_0^{(c)}$
for $m = 1$ to C **do**
  Compute $p_m^{(c)}(x)$ as in eq. 13 for all c.
  for $c = 1$ to C **do**
    Compute $G_V^{(c)}$ as in (14)
    Obtain regression tree $\{R_{m,s}^{(c)}\}$ by minimizing $\sum_i (G_V^{(c)}(x_i) - \sum_s \eta_{m,s}^{(c)} I[x_i \in R_{m,s}^{(c)}])^2$
  end for
  Find $\{\eta_{m,s}^{(c)}\}$ using BFGS and $\frac{\partial V}{\partial \eta_{m,s}}$, and fixing $\{R_{m,s}^{(c)}\}$ for all c.
  $F_m^{(c)}(x) = F_{m-1}^{(c)}(x) + \sum_s \eta^{(}(c))_{m,s} I[x \in R_{m,s}^{(c)}]$ for all c.
end for

the types of learners to be used (they use stumps only). Also, the ensemble classifier should be smooth on the manifold, but regularizing each of the base learners may result in over-smoothing of the overall solution.

We compare our results with (Kégl & Wang, 2005) on standard UCI benchmark datasets. Whenever possible we tried to use the same configuration as (Kégl & Wang, 2005)[1]. We set number of nearest neighbors $K = 8$ and used binary weights to compute the graph Laplacian. We used regression trees of fixed depth 3 as learners. The datasets were normalized to zero mean and unit variance. The learning rate was set to $\nu = 0.1$ after (Friedman, 1999). Only γ was explored for different values. We used 5-fold cross validation for determining parameters and 10-fold cross validation for error estimation. Table 1 compares our performance with that of AdaBoost, RegBoost, and (M. Belkin & Niyogi, 2004) as reported in (Kégl & Wang, 2005).

In the fully supervised problems, there is a difference in performance for the Sonar dataset, an impovement in the Ionosphere dataset, and a very slight decrease in performance in the Pima Indians dataset with respect to RegBoost, well within a standard deviation. It should be noted that the variance in the performance of the algorithm is consistently smaller for our algorithm. (Kégl & Wang, 2005) also tests the algorithm under semi-supervision, using 100 labeled and 251 unlabeled examples. We ran our algorithm under the same conditions, using the stumps to prevent overfitting. In this case our algorithm outperforms (Kégl & Wang, 2005) and (M. Belkin & Niyogi, 2004), as our mean performance over 10 runs is more than a standard deviation above theirs. No variance of results is reported in (Kégl & Wang, 2005).

(Chen & Wang, 2008) proposes an interesting alternative approach to regularized boosting based on the more traditional framework of boosting "weak" learners outlined in (Mason et al., 2000). As a consequence, they need to assign pseudo-class labels to unlabeled data (labels assigned with the current $F_t(x)$) while learning the ensemble. In contrast, ManifoldBoost uses base regressors to measure the confidence of the prediction and does not commit to $\{-1, +1\}$ classification at each step. Smoothing this seems more natural in a formulation that penalizes second derivatives (Laplacian cost).

6.2. Comparison to Other Semi-Supervised Learning Algorithms

We measured the performance of our two-class RBF-ManifoldBoost algorithm on the SSL data sets, a standard benchmark for semi-supervised learning problems introduced in (Chapelle et al., 2006), and compared with the 14 other state-of-the-art semi-supervised learning algorithms discussed there. In table 2 we present results for five data sets, 2 of which are cluster-like and 3 manifold-like. On the manifold-like data sets, we are at the state of the art and no single algorithm does uniformly better than us. On the cluster-

[1]The breast cancer dataset was not used because (Kégl & Wang, 2005) does not explain what metric they use for categorical data in the Lalacian, making any comparison meaningless.

Table 1. Performance results of TREE-MANIFOLDBOOST and different boosting approaches on standard UCI datasets, as reported in (Kégl & Wang, 2005) (variance in parenthesis)

Algorithm	Ionosphere Train / Test	Pima Indians Train / Test	Sonar Train / Test	Ionosphere (semisup.)
AdaBoost	0% / 9.2% (7.1)	10.9% / 25.3% (5.3)	0% / 32.5% (19.8)	-
RegBoost	0% / 7.7% (6.0)	16.0% / 23.3% (6.8)	0% / 29.8% (18.8)	12%
Tree-ManifoldBoost	0% (0) / 6.5% (4.8)	6.5% (0.5) / 24.0% (5.2)	0% (0) / 18.7% (6.1)	10.4% (0.8)
Belkin et al., 04 [2]	- / -	- / -	- / -	18%

like data sets, our performance is good compared to most other regularization-based and manifold learners but is not as good as the specialized clustering algorithms Cluster-Kernel and SGT (Spectral Graph Transducer).

Parameter search was performed following section 21.2.5 of (Chapelle et al., 2006) when possible, using the same ranges for γ, the RBF width σ, distance metric, K, etc. For the base regressors, we used $R \in \{15, 30\}$ as the numbers of RBFs, and $M = 500$ rounds. The learning rate was again chosen as $\nu = 0.1$. These parameters were obtained in small-scale experiments and then fixed. Results reported are the means over the different splits.

The running times for a MATLAB implementation on a 2 GHz machine was in the order of minutes. Unfortunately, running times for the other algorithms were not reported in (Chapelle et al., 2006).

6.3. `SecStr` Data Set

We also ran experiments on the `SecStr` data set (Chapelle et al., 2006), which is a problem of predicting the secondary structure of protein sequences from their amino acid chains. This is a large-scale and challenging data set with 83,000 labeled and 1.2 million unlabeled examples. Semi-supervised algorithms have made little improvement to this benchmark so far (Table 3), and the best result is the manifold-regularized learning algorithm (Sindhwani et al., 2006), which yields a 29% error rate on a subset of the data with 10,000 labeled and 73,000 unlabeled examples.

Tree-ManifoldBoost with $\gamma \in \{0, 10^{-5}, 10^{-3}, 0.1, 1\}$ achieved similar performance on the same subset in approximately 45 minutes of training time (after computing the Laplacian matrix). We used stumps, $K = 6$ and $\nu = 0.05$. No model selection was performed. We used as similarity measure the Hamming distance between the best alignment of sequences. The results reported are the mean over the 10 splits.

When we used the whole dataset (1.3 million sequences) with $\gamma \in \{0, 10^{-3}, 1\}$, there is virtually no performance improvement. This may be due to the smaller parameter search space, or to peculiarities of the dataset. When we analysed the structure of the manifold on the labeled subset, we observed that almost 20% of sequences at distance 1 (that is, shifted by one position to the left or right) had a different label. Therefore the manifold assumption is not strong on this set.

As far as we know, this is the first time results are reported on the complete `SecStr` dataset. Our algorithm is efficient and therefore can handle datasets of this size. Learning time is in the order of three hours for 1.3 million samples (leaving aside the computation of the graph Laplacian, which took significantly longer)

Table 3. Error rates on `SecStr` dataset. l is the number of labeled examples.

7. Conclusion

We have presented a new boosting framework for regularized learning in a greedy, stage-wise procedure. It is flexible enough to handle the whole range of supervision, from fully supervised classification to unsupervised clustering. The framework is general, accepts many different function approximation techniques, is

Random Classification Noise Defeats All Convex Potential Boosters

Abstract

A broad class of boosting algorithms can be interpreted as performing coordinate-wise gradient descent to minimize some potential function of the margins of a data set. This class includes AdaBoost, LogitBoost, and other widely used and well-studied boosters. In this paper we show that for a broad class of convex potential functions, any such boosting algorithm is highly susceptible to random classification noise. We do this by showing that for any such booster and any nonzero random classification noise rate η, there is a simple data set of examples which is efficiently learnable by such a booster if there is no noise, but which cannot be learned to accuracy better than 1/2 if there is random classification noise at rate η. This negative result is in contrast with known branching program based boosters which do not fall into the convex potential function framework and which can provably learn to high accuracy in the presence of random classification noise.

1. Introduction

1.1. Background

Much work has been done on viewing boosting algorithms as greedy iterative algorithms that perform a coordinate-wise gradient descent to minimize a potential function of the margin of the examples, see e.g. [3, 12, 19, 7, 18, 2]. In this framework every potential function ϕ defines an algorithm that may possibly be a boosting algorithm; we denote the algorithm corresponding to ϕ by $\mathcal{B}_\phi$. For example, AdaBoost [11] and its confidence-rated generalization [20] may be viewed as the algorithm $\mathcal{B}_\phi$ corresponding to the potential function $\phi(z) = e^{-z}$. The MadaBoost algorithm of Domingo and Watanabe [5] may be viewed as the algorithm $\mathcal{B}_\phi$ corresponding to

$$\phi(z) = \begin{cases} 1 - z & \text{if } z \leq 0 \\ e^{-z} & \text{if } z > 0. \end{cases} \quad (1)$$

(We give a more detailed description of exactly what the algorithm $\mathcal{B}_\phi$ is for a given potential function ϕ in Section 2.2.)

1.2. Motivation: noise-tolerant boosters?

It has been widely observed that AdaBoost can suffer poor performance when run on noisy data, see e.g. [10, 17, 4]. The most commonly given explanation for this is that the exponential reweighting of examples which it performs (a consequence of the exponential potential function) can cause the algorithm to invest too much "effort" on correctly classifying noisy examples. Boosting algorithms such as MadaBoost [5] and LogitBoost [12] based on a range of other potential functions have subsequently been provided, sometimes with an explicitly stated motivation of rectifying AdaBoost's poor noise tolerance. However, we are not aware of rigorous results establishing provable noise tolerance for any boosting algorithms that fit into the potential functions framework, even for mild forms of noise such as random classification noise (henceforth abbreviated RCN) at low noise rates. This motivates the following question: are Adaboost's difficulties in dealing with noise due solely to its exponential weighting scheme, or are these difficulties inherent in the potential function approach to boosting?

1.3. Our results: convex potential boosters cannot withstand random classification noise

This paper shows that the potential function boosting approach provably cannot yield learning algorithms that tolerate even low levels of random classification noise when convex potential functions are used. More

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

precisely, we exhibit a fixed natural set of base classifiers $h_1, \ldots, h_n$ and show that for every convex function ϕ satisfying some very mild conditions and every noise rate $\eta > 0$, there is a multiset S of labeled examples such that the following holds:

- There is a linear separator $\mathrm{sgn}(\alpha_1 h_1 + \cdots + \alpha_n h_n)$ over the base classifiers $h_1, \ldots, h_n$ that correctly labels every example in S with margin $\gamma > 0$ (and hence it is easy for a boosting algorithm trained on S to efficiently construct a final hypothesis that correctly classifies all examples in S). However,
- When the algorithm $\mathcal{B}_\phi$ is run on the distribution $\mathcal{D}_{\eta,S}$, it constructs a classifier that has error rate 1/2 on the examples in S. Here $\mathcal{D}_{\eta,S}$ is the uniform distribution over S but where examples are corrupted with random classification noise at rate η, i.e. labels are independently flipped with probability η.

This result shows that random classification noise can cause convex potential function boosters to fail in a rather strong sense. We note that as discussed in Section 7, there do exist known boosting algorithms [13, 16] that can tolerate random classification noise, and in particular can efficiently achieve perfect accuracy on S, after at most $\mathrm{poly}(1/\gamma)$ stages of boosting, when run on $\mathcal{D}_{\eta,S}$ in the scenario described above.

Recently Bartlett and Traskin proved that the AdaBoost algorithm is consistent if it is stopped after a suitable number of iterations, given certain conditions on a random source generating the data [1]. Our analysis does not contradict theirs because the source in our construction does not satisfy Condition 1 of their paper. To see why this is the case it is useful, as has become customary, to think of the contribution that a given example makes to the potential as a "loss" paid by the learning algorithm. Informally, Condition 1 from [1] requires linear combinations of base classifier predictions to have total loss arbitrarily close to the best possible loss for any measurable function. Our analysis takes advantage of the fact that, for linear combinations of base classifiers with a convex loss function, large-margin errors are especially egregious: we present the learner with a choice between a lot of cheap errors and relatively few expensive errors. If optimization were to be performed over all measurable functions, roughly speaking, it would be possible to make all errors cheap.

Though the analysis required to establish our main result is somewhat delicate, the actual construction is quite simple and admits an intuitive explanation (see Section 4.2). For every convex potential function ϕ we use the same set of only $n = 2$ base classifiers (these are confidence-rated base classifiers which output real values in the range $[-1, 1]$), and the multiset S contains only three distinct labeled examples; one of these occurs twice in S, for a total multiset size of four. We expect that many other constructions which similarly show the brittleness of convex potential boosters to random classification noise can be given. We describe experiments with one such construction that uses Boolean-valued weak classifiers rather than confidence-rated ones in Section 6.

2. Background and Notation

Throughout the paper X will denote the instance space. $\mathcal{H} = \{h_1, \ldots, h_n\}$ will denote a fixed finite collection of *base classifiers* over X, where each base classifier is a function $h_i : X \to [-1, 1]$; i.e. we shall work with confidence-rated base classifiers. $S = (x^1, y^1), \ldots, (x^m, y^m) \in (X \times \{-1, 1\})^m$ will denote a multiset of m examples with binary labels.

2.1. Convex potential functions

We adopt the following natural definition which, as we discuss in Section 5, captures a broad range of different potential functions that have been studied.

Definition 1 *We say that $\phi : \mathbf{R} \to \mathbf{R}$ is a* convex potential function *if ϕ satisfies the following properties:*

1. *ϕ is convex and nonincreasing and $\phi \in C^1$ (i.e. ϕ is differentiable and ϕ' is continuous);*
2. *$\phi'(0) < 0$ and $\lim_{x \to +\infty} \phi(x) = 0$.*

2.2. Convex potential boosters

Let ϕ be a convex potential function, $\mathcal{H} = \{h_1, \ldots, h_n\}$ a fixed set of base classifiers, and $S = (x^1, y^1), \ldots, (x^m, y^m)$ a multiset of labeled examples.

Similarly to Duffy and Helmbold [6, 7], we consider an iterative algorithm which we denote $\mathcal{B}_\phi$. The algorithm performs a coordinatewise gradient descent through the space of all possible coefficient vectors for the weak hypotheses, in an attempt to minimize the convex potential function of the margins of the examples. We now give a more precise description of how $\mathcal{B}_\phi$ works when run with $\mathcal{H}$ on S.

Algorithm $\mathcal{B}_\phi$ maintains a vector $(\alpha_1, ..., \alpha_n)$ of voting weights for the base classifiers $h_1, ..., h_n$. The weights are initialized to 0. In a given round T, the algorithm chooses an index i_T of a base classifier, and modifies

the value of α_{i_T}. If α_{i_T} had previously been zero, this can be thought of as adding base classifier number i_T to a pool of voters, and choosing a voting weight.

Let $F(x;\alpha_1,...,\alpha_n) = \sum_{i=1}^n \alpha_i h_i(x)$ be the master hypothesis that the algorithm has constructed prior to stage T (so at stage $T = 1$ the hypothesis F is identically zero.) We write $P_{\phi,S}$ to denote the "global" potential function over S

$$P_{\phi,S}(\alpha_1,...,\alpha_n) = \sum_{i=1}^m \phi(y^i F(x^i;\alpha_1,...,\alpha_n)) \qquad (2)$$

which represents the overall potential of a hypothesis vector $(\alpha_1,\ldots,\alpha_n)$ on the sample S. It is easy to check that this is a convex function from $\mathbf{R}^n$ (the space of all possible $(\alpha_1,\ldots,\alpha_n)$ coefficient vectors for F) to $\mathbf{R}$.

In stage T the algorithm $\mathcal{B}_\phi$ first chooses a base classifier by choosing i_T to be the index $i \in [n]$ which maximizes

$$-\frac{\partial}{\partial \alpha_i} P_{\phi,S}(\alpha_1,...,\alpha_n),$$

and then choosing a new value of α_{i_T} in order to minimize $P_{\phi,S}(\alpha_1,...,\alpha_n)$ for the resulting $\alpha_1,...,\alpha_n$. Thus, in the terminology of [6] we consider "un-normalized" algorithms which preserve the original weighting factors α_1, α_2, etc. The AdaBoost algorithm is an example of an algorithm that falls into this framework, as are the other algorithms we discuss in Section 5. Note that the fact that $\mathcal{B}_\phi$ can determine the exactly optimal weak classifier to add in each round errs on the side of pessimism in our analysis.

In our analysis, we will consider the case in which $\mathcal{B}_\phi$ as being run on a distribution $\mathcal{D}_{\eta,S}$ obtained by starting with a finite multiset of examples, and adding independent misclassification noise. One can naturally extend the definition of $\mathcal{B}_\phi$ to apply to probability distributions over $X \times \{-1,1\}$ by extending the definition of potential in (2) as follows

$$P_{\phi,\mathcal{D}}(\alpha_1,...,\alpha_n) = \mathbf{E}_{(x,y)\sim\mathcal{D}}(\phi(yF(x;\alpha_1,...,\alpha_n))). \qquad (3)$$

For rational values of η, running $\mathcal{B}_\phi$ on (3) for $\mathcal{D} = \mathcal{D}_{\eta,S}$ is equivalent to running $\mathcal{B}_\phi$ over a finite multiset in which each element of S occurs a number of times proportional to its weight under $\mathcal{D}$.

2.3. Boosting

Fix a classifier $c : X \to \{-1,1\}$ and a multiset $S = (x^1,y^1),\ldots,(x^m,y^m)$ of labeled examples. We say that a set of base classifiers $\mathcal{H} = \{h_1,\ldots,h_n\}$ is *boostable with respect to c and S* if there is a vector $\alpha \in \mathbf{R}^n$ such that for all $i = 1,\ldots,m$, we have

$$\mathrm{sgn}[\alpha_1 h_1(x^i) + \cdots + \alpha_n h_n(x^i)] = y^i.$$

If $\gamma > 0$ is such that

$$\frac{y^i \cdot \big(\alpha_1 h_1(x^i) + \cdots + \alpha_n h_n(x^i)\big)}{\sqrt{\alpha_1^2 + \cdots + \alpha_n^2}} \geq \gamma$$

for all i, we say that $\mathcal{H}$ is *boostable w.r.t. c and S with margin γ*.

It is well known that if $\mathcal{H}$ is boostable w.r.t. c and S with margin γ, then a range of different boosting algorithms (such as AdaBoost) can be run on the noise-free data set S to efficiently construct a final classifier that correctly labels every example in S. As one concrete example, after $O(\frac{\log m}{\gamma^2})$ stages of boosting AdaBoost will construct a linear combination $F(x) = \sum_{i=1}^n \gamma_i h_i(x)$ of the base classifiers such that $\mathrm{sgn}(F(x^i)) = y^i$ for all $i = 1,\ldots,m$; see [11, 20] for details.

2.4. Random classification noise and noise-tolerant boosting

Random classification noise is a simple, natural, and well-studied model of how benign (nonadversarial) noise can affect data. Given a multiset S of labeled examples and a value $0 < \eta < \frac{1}{2}$, we write $\mathcal{D}_{\eta,S}$ to denote the distribution corresponding to S corrupted with random classification noise at rate η. A draw from $\mathcal{D}_{\eta,S}$ is obtained by drawing (x,y) uniformly at random from S and independently flipping the binary label y with probability η.

We say that an algorithm $\mathcal{B}$ is a *boosting algorithm which tolerates RCN at rate η* if $\mathcal{B}$ has the following property. Let c be a target classifier, S be a multiset of m examples, and $\mathcal{H}$ be a set of base classifiers such that $\mathcal{H}$ is boostable w.r.t. c and S. Then for any $\epsilon > 0$, if $\mathcal{B}$ is run with $\mathcal{H}$ as the set of base classifiers on $\mathcal{D}_{\eta,S}$, at some stage of boosting $\mathcal{B}$ constructs a classifier g which has accuracy

$$\frac{|\{(x^i,y^i) \in S : g(x^i) = y^i\}|}{m} \geq 1 - \eta - \epsilon.$$

The accuracy rate above is in some sense optimal, since known results [13] show that no "black-box" boosting algorithm can be guaranteed to construct a classifier g whose accuracy exceeds $1-\eta$ in the presence of RCN at rate η. As we discuss in Section 7, there are known boosting algorithms [13, 16] which can tolerate RCN at rate η for any $0 < \eta < 1/2$. These algorithms, which do not follow the convex potential function approach but instead build a branching program over the base classifiers, use $\mathrm{poly}(1/\gamma, \log(1/\epsilon))$ stages to achieve accuracy $1-\eta-\epsilon$ in the presence of RCN at rate η if $\mathcal{H}$ is boostable w.r.t. c and S with margin γ.

3. Main Result

As was just noted, there do exist boosting algorithms (based on branching programs) that can tolerate RCN. Our main result is that no convex potential function booster can have this property:

Theorem 2 *Fix any convex potential function ϕ. For any noise rate $0 < \eta < 1/2$, the algorithm $\mathcal{B}_\phi$ does not tolerate RCN at rate η.*

We obtain Theorem 2 as a direct consequence of the following stronger result, which shows that there is a simple RCN learning problem for which $\mathcal{B}_\phi$ will in fact misclassify half the examples in S.

Theorem 3 *Fix the instance space $X = [-1,1]^2 \subset \mathbf{R}^2$ and the set $\mathcal{H} = \{h_1(x) = x_1, h_2(x) = x_2\}$ of confidence-rated base classifiers over X.*

For any noise rate $0 < \eta < 1/2$ and any convex potential function ϕ, there is a target classifier c, a value $\gamma > 0$, and a multiset S of four labeled examples (three of which are distinct) such that (a) $\mathcal{H}$ is boostable w.r.t. c and S with margin γ, but (b) when $\mathcal{B}_\phi$ is run on the distribution $\mathcal{D}_{\eta,S}$, it constructs a classifier which misclassifies two of the four examples in S.

4. Proof of Theorem 3

We are given an RCN noise rate $0 < \eta < 1/2$ and a convex potential function ϕ.

4.1. The basic idea

Before specifying the sample S we explain the high-level structure of our argument. Recall from (3) that $P_{\phi,\mathcal{D}}$ is defined as

$$P_{\phi,\mathcal{D}}(\alpha_1,\alpha_2) = \sum_{(x,y)} \mathcal{D}_{\eta,S}(x,y)\phi(y(\alpha_1 x_1 + \alpha_2 x_2)). \quad (4)$$

As noted in Section 2.2 the function $P_{\phi,\mathcal{D}}(\alpha_1,\alpha_2)$ is convex. It follows immediately from the definition of a convex potential function that $P_{\phi,\mathcal{D}}(\alpha_1,\alpha_2) \geq 0$ for all $(\alpha_1,\alpha_2) \in \mathbf{R}^2$.

The high-level idea of our proof is as follows. We shall construct a multiset S of four labeled examples in $[-1,1]^2$ (actually in the unit disc $\{x : \|x\| \leq 1\} \subset \mathbf{R}^2$) such that there is a global minimum (α_1^*,α_2^*) of the corresponding $P_{\phi,\mathcal{D}}(\alpha_1,\alpha_2)$ which has the following two properties:

1. **("high error")** The corresponding classifier $g(x) = \mathrm{sgn}(\alpha_1^* x_1 + \alpha_2^* x_2)$ misclassifies two of the points in S (and thus has error rate 1/2); and
2. **("steep slope")** At the point $(0,0)$, the directional derivative of $P_{\phi,\mathcal{D}}(\alpha_1,\alpha_2)$ in any direction orthogonal to (α_1^*,α_2^*) is not as steep as the directional derivative toward (α_1^*,α_2^*).

We now show that it suffices to establish these two properties to prove part (b) of Theorem 3.[1] Suppose we have such an S. Since $P_{\phi,\mathcal{D}}(\alpha_1,\alpha_2)$ depends only on the inner product between (α_1,α_2) and the (normalized) example vectors (yx_1, yx_2), it follows that rotating the set S around the origin by any fixed angle induces a corresponding rotation of the function $P_{\phi,\mathcal{D}}$, and in particular of its minima. (Note that we have used here the fact that every example point in S lies within the unit disc; this ensures that for any rotation of S each weak hypothesis x_i will always give outputs in $[-1,1]$ as required.) Consequently a suitable rotation of S to S' will result in the corresponding rotated function $P_{\phi,\mathcal{D}}$ having a global minimum at a vector which lies on one of the two coordinate axes (say a vector of the form $(0,\tau)$). If this is the case, then the "steep slope" property (2) ensures that the directional derivative at $(0,0)$ in this direction will be steepest, so the convex potential booster $\mathcal{B}_\phi$ will pick a base classifier corresponding to this direction (in this case h_2). Since a globally optimal weight vector is available in this direction (the vector of length $\sqrt{(\alpha_1^*)^2 + (\alpha_2^*)^2}$ is such a vector), $\mathcal{B}_\phi$ will select such a vector. Once it has achieved such a global optimum it will not change its hypothesis in any subsequent stage, and thus $\mathcal{B}_\phi$'s hypothesis will have error rate 1/2 on the points in the rotated set S' by the "high error" property (1).

4.2. The sample S

Now let us define the multiset S of examples. S consists of three distinct examples, one of which is repeated twice. (We shall specify the value of γ later and show that $0 < \gamma < \frac{1}{6}$.)

- S contains one copy of the example $x = (1,0)$ with label $y = +1$. (We call this the "large margin" example.)
- S contains two copies of the example $x = (\gamma, -\gamma)$ with label $y = +1$. (We call these examples the "penalizers" since they are the points that $\mathcal{B}_\phi$ will misclassify.)
- S contains one copy of the example $x = (\gamma, 5\gamma)$ with label $y = +1$. (We call this example the "puller" for reasons described below.)

[1] To prove part (a) we need to show that $\mathcal{H}$ is boostable w.r.t. some classifier c and S with margin γ, but as we shall see this is easy to achieve.

Thus all examples in S are positive. It is immediately clear that the classifier $c(x) = \mathrm{sgn}(x_1)$ correctly classifies all examples in S with margin $\gamma > 0$, so the set $\mathcal{H} = \{h_1(x) = x_1, h_2(x) = x_2\}$ of base classifiers is boostable w.r.t. c and S with margin γ. We further note that since $\gamma < \frac{1}{6}$, each example in S does indeed lie in the unit disc $\{x : \|x\| \leq 1\}$.

Let us give some intuition for why this set S has the "high error" property. The halfspace whose normal vector is $(1, 0)$ classifies all examples correctly, but the noisy (negative labeled) version of the "large margin" example causes a convex potential function to incur a very large cost for this hypothesis vector. Consequently a lower cost hypothesis can be obtained with a vector that points rather far away from $(1, 0)$. The "puller" example (whose y-coordinate is 5γ) outweights the two "penalizer" examples (whose y-coordinates are $-\gamma$), so it "pulls" the minimum cost hypothesis vector to point up into the first quadrant – in fact, so far up that the two "penalizer" examples are misclassified by the optimal hypothesis vector for the potential function ϕ.

In Section 4.3 below we make this intuition precise and show that there is a global minimum (α_1^*, α_2^*) of $P_{\phi,\mathcal{D}}$ for which $\alpha_1^* < \alpha_2^*$. This immediately implies that the corresponding classifier $g(x) = \mathrm{sgn}(\alpha_1^* x_1 + \alpha_2^* x_2)$ misclassifies the two copies of $(\gamma, -\gamma)$ in S and gives us the "high error" property (1). In Section 4.4 we show that this (α_1^*, α_2^*) moreover has the "steep slope" property (2).

4.3. The "high error" property: analyzing a global minimum of $P_{\phi,\mathcal{D}}$

Let $1 < N < \infty$ be such that $\eta = \frac{1}{N+1}$, so $1-\eta = \frac{N}{N+1}$.

We have that

$$\begin{aligned} P_{\phi,\mathcal{D}}(\alpha_1, \alpha_2) &= \sum_{(x,y)} \mathcal{D}_{\eta,S}(x, y)\phi(y(\alpha_1 x_1 + \alpha_2 x_2)) \\ &= \frac{1}{4} \sum_{(x,y)\in S} [(1-\eta)\phi(\alpha_1 x_1 + \alpha_2 x_2) \\ &\qquad + \eta\phi(-\alpha_1 x_1 - \alpha_2 x_2)]\,. \end{aligned}$$

It is clear that minimizing $4(N+1)P_{\phi,\mathcal{D}}$ is the same as minimizing $P_{\phi,\mathcal{D}}$ so we shall henceforth work with $4(N+1)P_{\phi,\mathcal{D}}$ since it gives rise to cleaner expressions. We have that $4(N+1)P_{\phi,\mathcal{D}}(\alpha_1, \alpha_2)$ equals

$$\begin{aligned} &\sum_{(x,y)\in S} [N\phi(\alpha_1 x_1 + \alpha_2 x_2) + \phi(-\alpha_1 x_1 - \alpha_2 x_2)] \\ &= N\phi(\alpha_1) + \phi(-\alpha_1) \\ &\quad +2N\phi(\alpha_1\gamma - \alpha_2\gamma) + 2\phi(-\alpha_1\gamma + \alpha_2\gamma) \\ &\quad +N\phi(\alpha_1\gamma + 5\alpha_2\gamma) + \phi(-\alpha_1\gamma - 5\alpha_2\gamma). \quad (5) \end{aligned}$$

Let $L_1(\alpha_1, \alpha_2)$ and $L_2(\alpha_1, \alpha_2)$ be defined as follows:

$$\begin{aligned} L_1(\alpha_1, \alpha_2) &\stackrel{\text{def}}{=} \frac{\partial}{\partial\alpha_1} 4(N+1)P_{\phi,\mathcal{D}}(\alpha_1, \alpha_2) \text{ and} \\ L_2(\alpha_1, \alpha_2) &\stackrel{\text{def}}{=} \frac{\partial}{\partial\alpha_2} 4(N+1)P_{\phi,\mathcal{D}}(\alpha_1, \alpha_2). \end{aligned}$$

For $B > 1$ to be fixed later, let us write $L_1(\alpha)$ to denote $L_1(\alpha, B\alpha)$ and similarly write $L_2(\alpha)$ to denote $L_2(\alpha, B\alpha)$. It is easy to verify that we have

$$\begin{aligned} L_1(\alpha) \;=\; & N\phi'(\alpha) - \phi'(-\alpha) + 2\gamma N\phi'(-(B-1)\alpha\gamma) \\ & -2\gamma\phi'((B-1)\alpha\gamma) + N\gamma\phi'((5B+1)\alpha\gamma) \\ & -\gamma\phi'(-(5B+1)\alpha\gamma) \end{aligned}$$

and

$$\begin{aligned} L_2(\alpha) \;=\; & -2\gamma N\phi'(-(B-1)\alpha\gamma) + 2\gamma\phi'((B-1)\alpha\gamma) \\ & +5\gamma N\phi'((5B+1)\alpha\gamma) - 5\gamma\phi'(-(5B+1)\alpha\gamma). \end{aligned}$$

We introduce the following function to help in the analysis of $L_1(\alpha)$ and $L_2(\alpha)$:

$$\text{for } \alpha \in \mathbf{R}, \qquad Z(\alpha) \stackrel{\text{def}}{=} N\phi'(\alpha) - \phi'(-\alpha).$$

Let us establish some basic properties of this function. Since ϕ is differentiable and convex, we have that ϕ' is a non-decreasing function. This is easily seen to imply that $Z(\cdot)$ is a non-decreasing function. We moreover have $Z(0) = \phi'(0)(N-1) < 0$. The definition of a convex potential function implies that as $\alpha \to +\infty$ we have $\phi'(\alpha) \to 0^-$, and consequently we have

$$\lim_{\alpha\to+\infty} Z(\alpha) = 0 + \lim_{\alpha\to+\infty} -\phi'(-\alpha) > 0,$$

where the inequality holds since $\phi'(\alpha)$ is a nonincreasing function and $\phi'(0) < 0$. Since ϕ' and hence Z is continuous, we have that over the interval $[0, +\infty)$ the function $Z(\alpha)$ assumes every value in the range $[\phi'(0)(N-1), -\phi'(0))$.

Next observe that we may rewrite $L_1(\alpha)$ and $L_2(\alpha)$ as

$$L_1(\alpha) = Z(\alpha) + 2\gamma Z(-(B-1)\alpha\gamma) + \gamma Z((5B+1)\gamma\alpha) \quad (6)$$

and

$$L_2(\alpha) = -2\gamma Z(-(B-1)\alpha\gamma) + 5\gamma Z((5B+1)\gamma\alpha). \quad (7)$$

In the rest of this section we shall show that there are values $\alpha > 0$, $0 < \gamma < 1/6$, $B > 1$ such that $L_1(\alpha) = L_2(\alpha) = 0$. Since $P_{\phi,\mathcal{D}}$ is convex, this will imply that $(\alpha_1^*, \alpha_2^*) \stackrel{\text{def}}{=} (\alpha, B\alpha)$ is a global minimum for the dataset constructed using this γ, as required.

Let us begin with the following claim which will be useful in establishing $L_2(\alpha) = 0$.

Claim 4 *For any $B \geq 1$ there is a finite value $\epsilon(B) > 0$ such that*

$$2Z(-(B-1)\epsilon(B)) = 5Z((5B+1)\epsilon(B)) < 0 \quad (8)$$

Proof: Fix any value $B \geq 1$. Recalling that $Z(0) = \phi'(0)(N-1) < 0$, at $\epsilon = 0$ the quantity $2Z(-(B-1)\epsilon)$ equals $2\phi'(0)(N-1) < 0$, and as ϵ increases this quantity does not increase. On the other hand, at $\epsilon = 0$ the quantity $5Z((5B+1)\epsilon)$ equals $5\phi'(0)(N-1) < 2\phi'(0)(N-1)$, and as ϵ increases this quantity increases to a limit, as $\epsilon \to +\infty$, which is at least $5(-\phi'(0))$. Since Z is continuous, there must be some $\epsilon > 0$ at which the two quantities are equal and are each at most $2\phi'(0)(N-1) < 0$. □

Observation 5 *The function $\epsilon(B)$ is a continuous and nonincreasing function of B for $B \in [0, \infty)$.*

Proof: The larger $B \geq 1$ is, the faster $-(B-1)\epsilon)$ decreases as a function of ϵ and the faster $(5B+1)\epsilon$ increases as a function of ϵ. Continuity of $\epsilon(\cdot)$ follows from continuity of $Z(\cdot)$. □

We now fix the value of B to be $B \stackrel{\text{def}}{=} 1+\gamma$, where the parameter γ will be fixed later. We shall only consider settings of $\alpha, \gamma > 0$ such that $\alpha\gamma = \epsilon(B) = \epsilon(1+\gamma)$; i.e. given a setting of γ, we shall take $\alpha = \frac{\epsilon(1+\gamma)}{\gamma}$. For any such α, γ we have

$$\begin{aligned} L_2(\alpha) &= (7) = \gamma[-2Z(-(B-1)\epsilon(1+\gamma)) \\ &\qquad +5Z((5B+1)\epsilon(1+\gamma))] = 0 \end{aligned}$$

where the last equality is by Claim 4. Now let us consider (6); our goal is to show that for some $\gamma > 0$ it is also 0. For any (α, γ) pair with $\alpha\gamma = \epsilon(1+\gamma)$, we have by Claim 4 that

$$\begin{aligned} &2\gamma Z(-(B-1)\gamma\alpha) + \gamma Z((5B+1)\gamma\alpha) \\ &= 2\gamma Z(-(B-1)\epsilon(1+\gamma)) + \gamma Z((5B+1)\epsilon(1+\gamma)) \\ &= 6\gamma Z((5B+1)\epsilon(1+\gamma)) \end{aligned}$$

where the second equality is by Claim 4. Plugging this into (6), we have that for $\alpha = \frac{\epsilon(1+\gamma)}{\gamma}$, the quantity $L_1(\alpha)$ equals 0 if and only if

$$\begin{aligned} Z\left(\frac{\epsilon(1+\gamma)}{\gamma}\right) &= -6\gamma Z((5B+1)\epsilon(1+\gamma)) \\ &= 6\gamma \cdot (-Z((6+5\gamma)\cdot\epsilon(1+\gamma))). \quad (9) \end{aligned}$$

Let us analyze (9). We first note that Observation 5 implies that $\epsilon(1+\gamma)$ is a nonincreasing function of γ for $\gamma \in [0, \infty)$. Consequently $\frac{\epsilon(1+\gamma)}{\gamma}$ is a decreasing function of γ, and since Z is a nonincreasing function, the LHS is a nonincreasing function of γ. Recall that at $\gamma = 0$ we have $\epsilon(1+\gamma) = \epsilon(1)$ which is some fixed finite positive value by Claim 4. So we have $\lim_{\gamma\to 0^+}$ LHS $= \lim_{x\to+\infty} Z(x) \geq -\phi'(0)$. On the other extreme, since $\epsilon(\cdot)$ is nonincreasing, we have

$$\lim_{\gamma\to+\infty} \text{LHS} \leq \lim_{\gamma\to+\infty} Z\left(\frac{\epsilon(1)}{\gamma}\right) = Z(0) = \phi'(0)(N-1) < 0.$$

So as γ varies through $(0, \infty)$, the LHS decreases through all values between $-\phi'(0)$ and 0.

On the other hand, at $\gamma = 0$ the RHS of (9) is clearly 0. Moreover the RHS is always positive for $\gamma > 0$ by Claim 4. Since the RHS is continuous (by continuity of $Z(\cdot)$ and $\epsilon(\cdot)$), this together with the previous paragraph implies that there must be some $\gamma > 0$ for which the LHS and RHS of (9) are the same positive value. So we have shown that there are values $\alpha > 0$, $\gamma > 0$, $B = 1+\gamma$ such that $L_1(\alpha) = L_2(\alpha) = 0$. This concludes the proof of the "high error" property (1).

We close this section by showing that the value of $\gamma > 0$ obtained above is indeed at most $1/6$ (and hence every example in S lies in the unit disc as required). To see this, note that we have shown that for this γ, we have $Z((6+5\gamma)\epsilon(1+\gamma)) < 0$ and $Z\left(\frac{\epsilon(1+\gamma)}{\gamma}\right) > 0$. Since Z is a nondecreasing function this implies $6+5\gamma < \frac{1}{\gamma}$ which clearly implies $\gamma < 1/6$ as desired.

4.4. The "steep slope" property: analyzing directional derivatives

Now we turn to proving that the directional derivative in the orthogonal direction is less steep than in the direction of the global minimum (α_1^*, α_2^*). We have just established that $(\alpha, B\alpha) = (\alpha, (1+\gamma)\alpha)$ is a global minimum for the data set as constructed above. The directional derivative at $(0,0)$ in the direction of this optimum is $\frac{L_1(0)+BL_2(0)}{\sqrt{1+B^2}}$.

Since $\phi'(0) < 0$, by (6) and (7) we have

$$\begin{aligned} L_1(0) &= (1+3\gamma)\phi'(0)(N-1) < 0 \\ L_2(0) &= 3\gamma\phi'(0)(N-1) < 0. \end{aligned}$$

This implies that $L_1(0) < L_2(0) < 0$, which, since $B > 1$, implies $BL_1(0) - L_2(0) < 0$. This means that $(B, -1)$ rather than $(-B, 1)$ is the direction orthogonal to the optimal $(1, B)$ which has negative slope.

Recalling that $B = 1+\gamma$, we have the following in-

equalities:

$$\begin{aligned} B &< 1 + 6\gamma = \frac{(1+3\gamma)+3\gamma}{(1+3\gamma)-3\gamma} \\ B &< \frac{-L_1(0) - L_2(0)}{-L_1(0) + L_2(0)} \quad (10) \\ B(-L_1(0) + L_2(0)) &< -L_1(0) - L_2(0) \quad (11) \\ L_1(0) + BL_2(0) &< BL_1(0) - L_2(0) < 0, \quad (12) \end{aligned}$$

where (11) follows from (10) using $L_1(0) < L_2(0) < 0$. So the directional derivative in the optimal direction $(1, B)$ is steeper than in $(B, -1)$, and the proof of the "steep slope" property, and with it Theorem 3, is complete. □

5. Consequences for Known Boosting Algorithms

A wide range of well-studied boosting algorithms are based on potential functions ϕ that satisfy our Definition 1. Theorem 2 thus implies that each of the corresponding convex potential function boosters as defined in Section 2.2 cannot tolerate random classification noise at any noise rate $0 < \eta < \frac{1}{2}$. (In some cases the original versions of the algorithms discussed below are not exactly the same as the $\mathcal{B}_\phi$ algorithm as described in Section 2.2 because of small differences such as the way the step size is chosen at each update. Thus we do not claim that Theorem 2 applies directly to each of the original boosting algorithms; however we feel that our analysis strongly suggests that the original boosters may, like the corresponding $\mathcal{B}_\phi$ algorithms, be highly susceptible to random classification noise.)

AdaBoost and MadaBoost. As discussed in the Introduction and in [6, 18] the Adaboost algorithm [11] is the algorithm $\mathcal{B}_\phi$ obtained by taking the convex potential function to be $\phi(x) = \exp(-x)$. Similarly the MadaBoost algorithm [5] is based on the potential function $\phi(x)$ defined in Equation (1). Each of these functions clearly satisfies Definition 1.

LogitBoost and FilterBoost. As described in [6, 18, 2], the LogitBoost algorithm of [12] is based on the logistic potential function $\ln(1 + \exp(-x))$, which is easily seen to fit our Definition 1. Roughly, FilterBoost [2] combines a variation on the rejection sampling of MadaBoost with the reweighting scheme, and therefore the potential function, of LogitBoost.

6. Experiments with Binary-valued Weak Learners

The analysis of this paper leaves open the possibility that a convex potential booster could still tolerate noise if the base classifiers were restricted to be binary-valued. In this section we describe empirical evidence that this is not the case. We generated 100 datasets, applied three convex potential boosters to each, and calculated the training error.

Data. Each dataset consisted of 4000 examples, divided into three groups, 1000 large margin examples, 1000 pullers, and 2000 penalizers. The large margin examples corresponded to the example $(1, 0)$ in Section 4.2, the pullers play the role of $(\gamma, 5\gamma)$, and the penalizers collectively play the role of $(\gamma, -\gamma)$.

Each labeled example (x, y) in our dataset is generated as follows. First the label y is chosen randomly from $\{-1, 1\}$. There are 21 features $x_1, \ldots, x_{21}$ that take values in $\{-1, 1\}$. Each large margin example sets $x_1 = \cdots = x_{21} = y$. Each puller assigns $x_1 = \cdots = x_{11} = y$ and $x_{12} = \cdots = x_{21} = -y$. Each penalizer is chosen at random in three stages: (1) the values of a random subset of five of the first eleven features $x_1, \ldots, x_{11}$ are set equal to y, (2) the values of a random subset of six of the last ten features $x_{12}, \ldots, x_{21}$ are set equal to y, and (3) the remaining ten features are set to $-y$.

At this stage, if we associate a base classifier with each feature x_i, then each of the 4000 examples is classified correctly by a majority vote over these 21 base classifiers. Intuitively, when an algorithm responds to the pressure exerted by the noisy large margin examples and the pullers to move toward a hypothesis that is a majority vote over the first 11 features only, then it tends to incorrectly classify the penalizers, because in the penalizers only 5 of those first 11 features agree with the class.

Finally, each class designation y is corrupted with classification noise with probability 0.1.

Boosters. We experimented with three boosters: AdaBoost, MadaBoost (which is arguably, loosely speaking, the least convex of the convex potential boosters), and LogitBoost. Each booster was run for 100 rounds.

Results. The average training error of AdaBoost over the 100 datasets was 33%. The average for LogitBoost was 30%, and for MadaBoost, 27%.

7. Discussion

We have shown that any boosting algorithm based on coordinate-wise gradient descent to optimize a convex potential function satisfying mild conditions cannot tolerate random classification noise. While our results imply strong limits on the noise-tolerance of algorithms that fit this framework, they do not apply to other boosting algorithms such as Freund's Boost-By-Majority algorithm [8] and BrownBoost [9] for which the corresponding potential function is non-convex. An interesting direction for future work is to extend our negative results to a broader class of potential functions, or to other types of boosters such as "regularized" boosters [19, 14].

We close by observing that there do exist efficient boosting algorithms (which do not follow the potential function approach) that can provably tolerate random classification noise [13, 16]. These noise-tolerant boosters work by constructing a branching program over the weak classifiers; the original algorithms of [13, 16] were presented only for binary-valued weak classifiers, but recent work [15] extends the algorithm from [16] to work with confidence-rated base classifiers. A standard analysis (omitted because of space constraints) shows that this boosting algorithm for confidence-rated base classifiers can tolerate random classification noise at any rate $0 < \eta < 1/2$ according to our definition from Section 2.4. In particular, for any noise rate η bounded below $1/4$, if this booster is run on the data sets considered in this paper, it can construct a final classifier with accuracy $1-\eta-\epsilon > 3/4$ after $O(\frac{\log 1/\epsilon}{\gamma^2})$ stages of boosting. Since our set of examples S is of size four, though, this means that the booster's final hypothesis will in fact have *perfect* accuracy on these data sets which thwart convex potential boosters.

Abstract

Tensorial data are frequently encountered in various machine learning tasks today and dimensionality reduction is one of their most important applications. This paper extends the classical principal component analysis (PCA) to its multilinear version by proposing a novel unsupervised dimensionality reduction algorithm for tensorial data, named as uncorrelated multilinear PCA (UMPCA). UMPCA seeks a tensor-to-vector projection that captures most of the variation in the original tensorial input while producing uncorrelated features through successive variance maximization. We evaluate the UMPCA on a second-order tensorial problem, face recognition, and the experimental results show its superiority, especially in low-dimensional spaces, through the comparison with three other PCA-based algorithms.

1. Introduction

Various machine learning problems take multi-dimensional data as input, which are formally called tensors. The elements of a tensor are to be addressed by several indices and the number of indices used in the description defines the order of the tensor object, with each index defining one "mode" (Lathauwer et al., 2000). Many real-world data are naturally tensor objects. For example, matrix data such as gray-level images are second-order tensors, gray-scale video sequences and 3-D objects are third-order tensors. In addition, streaming data and mining data are frequently organized as third-order tensors. For instance, data in environmental sensor monitoring are often organized in three modes of time, location and type, and data in web graph mining are commonly organized in three modes of source, destination and text. Other applications involving tensorial data include data center monitoring, social network analysis, network forensics and face recognition (Faloutsos et al., 2007). In these practical applications, tensor objects are often specified in a high-dimensional tensor space, leading to the so-called curse of dimensionality. Nonetheless, the class of tensor objects in most applications are highly constrained to a subspace, a manifold of intrinsically low dimension (Shakhnarovich & Moghaddam, 2004), and feature extraction or dimensionality reduction is frequently employed to transform a high-dimensional data set into a low-dimensional space of equivalent representation while retaining most of the underlying structure (Law & Jain, 2006).

The PCA is a classical linear method for unsupervised dimensionality reduction that transforms a data set consisting of a large number of interrelated variables to a new set of uncorrelated variables, while retaining as much as possible the variations present in the original data set (Jolliffe, 2002). PCA on tensor objects requires their reshaping (vectorization) into vectors in a very high-dimensional space, which not only results in high computational and memory demands but also breaks the natural structure and correlation in the original data (Ye, 2005; Ye et al., 2004; Lu et al., 2008a). It is believed by many researchers that potentially more compact or useful representations can be obtained from the original form and PCA extensions operating directly on the tensor objects rather than their vectorized versions are emerging recently (Ye et al., 2004; Lu et al., 2008a; Xu et al., 2005).

In (Shashua & Levin, 2001), the tensor rank-one de-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

composition (TROD) is used to represent a class of images based on variance maximization and (greedy) successive residue calculation. A two-dimensional PCA (2DPCA) is proposed in (Yang et al., 2004) that constructs an image covariance matrix using image matrices as inputs. However, linear transformation is applied only to the right side of image matrices so the image data is projected in one mode only, resulting in poor dimensionality reduction. A more general algorithm named generalized low rank approximation of matrices (GLRAM) was introduced in (Ye, 2005), which applies two linear transforms to both the left and right sides of input image matrices and results in a better dimensionality reduction than 2DPCA. GLRAM is developed from the perspective of approximation while the generalized PCA (GPCA) is proposed in (Ye et al., 2004) from the view of variation maximization, as an extension of PCA. Later, the concurrent subspaces analysis (CSA) is formulated in (Xu et al., 2005) for optimal reconstruction of general tensor objects, which can be considered as a generalization of GLRAM, and the multilinear PCA (MPCA) introduced in (Lu et al., 2008a) targets at variation maximization for general tensor objects in the extension of PCA to the multilinear case, which can be considered as a further generalization of GPCA.

However, none of the existing multilinear extensions of PCA mentioned above takes an important property of PCA into account, i.e., PCA derives uncorrelated features, which contain minimum redundancy and ensure independence among features. Instead, most of them produce orthogonal bases in each mode. Although uncorrelated features imply orthogonal projection bases in PCA, this is not necessarily the case for its multilinear extension. With this motivation, this paper investigates multilinear extension of PCA that can produce uncorrelated features. We propose a novel uncorrelated multilinear PCA (UMPCA) for unsupervised tensor object dimensionality reduction (feature extraction). UMPCA is based on the tensor-to-vector projection (TVP) (Lu et al., 2008b) and it follows the classical PCA derivation of successive variance maximization (Jolliffe, 2002). Thus, a number of elementary multilinear projections (EMPs) are solved to maximize the captured variance with the zero-correlation constraint. The solution is iterative in nature, as many other multilinear algorithms (Xu et al., 2005; Ye et al., 2004; Shashua & Levin, 2001).

The rest of this paper is organized as follows. Section 2 reviews basic multilinear notations and operations, as well as the concept of tensor-to-vector projection. In Sec. 3, the problem of UMPCA is formulated and the solution is derived as a sequential iterative process.

Table 1. Notations

Notations	Descriptions
$\mathcal{X}_m$, $m = 1, ..., M$	the m^{th} input tensor sample
$\mathbf{u}^{(n)}$, $n = 1, ..., N$	the n-mode projection vector
$\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}$	the p^{th} EMP, where p is the index of the EMP
$\mathbf{y}_m$	the projection of $\mathcal{X}_m$ on the TVP $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}_{p=1}^{P}$
$\mathbf{y}_m(p) = y_{m_p} = \mathbf{g}_p(m)$	the projection of $\mathcal{X}_m$ on the p^{th} EMP $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}$
$\mathbf{g}_p$	the p^{th} coordinate vector

Next, Sec. 4 evaluates the effectiveness of UMPCA in the popular face recognition task through comparison with PCA, MPCA and TROD. Finally, the conclusions are drawn in Sec. 5.

2. Multilinear Fundamentals

This section introduces the multilinear notations, operations and projections needed in the presentation of UMPCA, and for further pursuing of multilinear algebra, (Lathauwer et al., 2000) is a good reference. The important notations used in this paper are listed in Table 1 for handy reference.

2.1. Notations and basic multilinear operations

Due to the multilinear nature of tensor objects, new notations have been introduced in the literature for mathematical analysis. Following the notations in (Lathauwer et al., 2000), we denote vectors by lowercase boldface letters, e.g., $\mathbf{x}$; matrices by uppercase boldface letters, e.g., $\mathbf{U}$; and tensors by calligraphic letters, e.g., $\mathcal{A}$. Their elements are denoted with indices in parentheses. Indices are denoted by lowercase letters and span the range from 1 to the uppercase letter of the index, e.g., $n = 1, 2, ..., N$.

An N^{th}-order tensor $\mathcal{A} \in \mathbb{R}^{I_1 \times I_2 \times ... \times I_N}$ is addressed by N indices i_n, $n = 1, ..., N$, and each i_n addresses the n-mode of $\mathcal{A}$. The n-mode product of a tensor $\mathcal{A}$ by a matrix $\mathbf{U} \in \mathbb{R}^{J_n \times I_n}$, denoted by $\mathcal{A} \times_n \mathbf{U}$, is a tensor with entries:

$$(\mathcal{A} \times_n \mathbf{U})(i_1, ..., i_{n-1}, j_n, i_{n+1}, ..., i_N) = \sum_{i_n} \mathcal{A}(i_1, i_2, ..., i_N) \cdot \mathbf{U}(j_n, i_n). \quad (1)$$

The scalar product of two tensors $\mathcal{A}, \mathcal{B} \in \mathbb{R}^{I_1 \times I_2 \times ... \times I_N}$ is defined as:

$$< \mathcal{A}, \mathcal{B} >= \sum_{i_1} ... \sum_{i_N} \mathcal{A}(i_1, ..., i_N) \cdot \mathcal{B}(i_1, ..., i_N). \quad (2)$$

A rank-one tensor $\mathcal{A}$ equals to the outer product of N

vectors: $\mathcal{A} = \mathbf{u}^{(1)} \circ \mathbf{u}^{(2)} \circ ... \circ \mathbf{u}^{(N)}$, which means that $\mathcal{A}(i_1, i_2, ..., i_N) = \mathbf{u}^{(1)}(i_1) \cdot \mathbf{u}^{(2)}(i_2) \cdot ... \cdot \mathbf{u}^{(N)}(i_N)$ for all values of indices.

2.2. Tensor-to-vector projection

In order to extract uncorrelated features from tensorial data directly, we employ the TVP introduced in (Lu et al., 2008b), which is a more general form of the projection in (Shashua & Levin, 2001) and consists of multiple EMPs. An EMP is a multilinear projection $\{\mathbf{u}^{(1)^T}, \mathbf{u}^{(2)^T}, ..., \mathbf{u}^{(N)^T}\}$ consisting of one unit projection vector in each mode, i.e., $\| \mathbf{u}^{(n)} \| = 1$ for $n = 1, ..., N$, where $\| \cdot \|$ is the Euclidean norm for vectors. It projects a tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times ... \times I_N}$ to a scalar y through the N unit projection vectors as

$$y = \mathcal{X} \times_1 \mathbf{u}^{(1)^T} \times_2 \mathbf{u}^{(2)^T} ... \times_N \mathbf{u}^{(N)^T} = < \mathcal{X}, \mathcal{U} >,$$

where $\mathcal{U} = \mathbf{u}^{(1)} \circ \mathbf{u}^{(2)} \circ ... \circ \mathbf{u}^{(N)}$. An EMP can be viewed as a constrained linear projection since $< \mathcal{X}, \mathcal{U} > = < vec(\mathcal{X}), vec(\mathcal{U}) > = [vec(\mathcal{U})]^T vec(\mathcal{X})$, where $vec(\cdot)$ denotes the vectorized representation.

The TVP of a tensor object $\mathcal{X}$ to a vector $\mathbf{y} \in \mathbb{R}^P$ consists of P EMPs $\{\mathbf{u}_p^{(1)^T}, \mathbf{u}_p^{(2)^T}, ..., \mathbf{u}_p^{(N)^T}\}, p = 1, ..., P$, which can be written concisely as $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}_{p=1}^P$:

$$\mathbf{y} = \mathcal{X} \times_{n=1}^N \{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}_{p=1}^P, \qquad (3)$$

where the p^{th} component of $\mathbf{y}$ is obtained from the p^{th} EMP as: $\mathbf{y}(p) = \mathcal{X} \times_1 \mathbf{u}_p^{(1)^T} \times_2 \mathbf{u}_p^{(2)^T} ... \times_N \mathbf{u}_p^{(N)^T}$. The TROD (Shashua & Levin, 2001) in fact seeks a TVP to maximize the captured variance, however, it takes a heuristic greedy approach. In the next section, we propose a systematic, more principled formulation by taking consideration of the correlation among features.

In addition, the TVP for dimensionality reduction here is related mathematically to the parallel factor analysis (PARAFAC) originated from psychometrics (Harshman, 1970), also known as the canonical decomposition (CANDECOMP) (Carroll & Chang, 1970), which is popular in factor analysis of multi-way data, i.e., tensors. However, they are developed from different perspectives. The PARAFAC in the factorization literature aims to decompose a higher-order tensor, often formed by arranging lower-order tensors, into a number of rank-one tensorial factors explaining the formation of the data. In contrast, the objective of the TVP for dimensionality reduction here is to learn a low-dimensional (subspace) representation of a class of tensor objects from a number of samples so that the underlying (class) structure is well captured.

3. Uncorrelated Multilinear PCA

This section proposes the UMPCA for unsupervised dimensionality reduction of tensor objects by first formulating the UMPCA objective function and then adopting the successive variance maximization approach and alternating projection method to solve the problem. In the presentation, for the convenience of discussion, the training samples are assumed to be zero-mean [1] so that the constraint of uncorrelated features is the same as orthogonal features (Koren & Carmel, 2004).

3.1. Problem formulation

Following the standard derivation of PCA given in (Jolliffe, 2002), we consider the variance of the principal components (PCs) one by one. In the TVP setting, the p^{th} PCs are $\{y_{m_p}, m = 1, ..., M\}$, where M is the number of training samples and y_{m_p} is the projection of the m^{th} sample $\mathcal{X}_m$ by the p^{th} EMP $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}$: $y_{m_p} = \mathcal{X}_m \times_{n=1}^N \{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}$. Accordingly, the variance is measure by their total scatter $S_{T_p}^{\mathbf{y}}$, which is defined as

$$S_{T_p}^{\mathbf{y}} = \sum_{m=1}^{M} (y_{m_p} - \bar{y}_p)^2, \qquad (4)$$

where $\bar{y}_p = \frac{1}{M} \sum_m y_{m_p}$. In addition, let $\mathbf{g}_p$ denote the p^{th} coordinate vector, with its m^{th} component $\mathbf{g}_p(m) = y_{m_p}$. A formal definition of the unsupervised multilinear feature extraction problem to be solved in UMPCA is then given in the following:

A set of M tensor object samples $\{\mathcal{X}_1, \mathcal{X}_2, ..., \mathcal{X}_M\}$ are available for training. Each tensor object $\mathcal{X}_m \in \mathbb{R}^{I_1 \times I_2 \times ... \times I_N}$ assumes values in the tensor space $\mathbb{R}^{I_1} \bigotimes \mathbb{R}^{I_2} ... \bigotimes \mathbb{R}^{I_N}$, where I_n is the n-mode dimension of the tensor and $\bigotimes$ denotes the Kronecker product. The objective of the UMPCA is to find a TVP, which consists of P EMPs $\{\mathbf{u}_p^{(n)} \in \mathbb{R}^{I_n \times 1}, n = 1, ..., N\}_{p=1}^P$, mapping from the original tensor space $\mathbb{R}^{I_1} \bigotimes \mathbb{R}^{I_2} ... \bigotimes \mathbb{R}^{I_N}$ into a vector subspace $\mathbb{R}^P$ (with $P < \prod_{n=1}^N I_n$):

$$\mathbf{y}_m = \mathcal{X}_m \times_{n=1}^N \{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}_{p=1}^P, m = 1, ..., M, \qquad (5)$$

such that the variance of the projected samples, measured by $S_{T_p}^{\mathbf{y}}$, is maximized in each EMP direction, subject to the constraint that the P coordinate vectors $\{\mathbf{g}_p \in \mathbb{R}^M, p = 1, ..., P\}$ are uncorrelated.

[1] When the training sample mean is not zero, it can be subtracted to make the training samples to be zero-mean.

In other words, the UMPCA objective is to determine a set of P EMPs $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}_{p=1}^{P}$ that maximize the variance while producing features with zero-correlation. Thus, the objective function for the p^{th} EMP is

$$\begin{aligned} \{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\} &= \arg\max \sum_{m=1}^{M} (y_{m_p} - \overline{y}_p)^2, \\ \texttt{subject to} \quad & \mathbf{u}_p^{(n)^T} \mathbf{u}_p^{(n)} = 1 \text{ and} \\ \frac{\mathbf{g}_p^T \mathbf{g}_q}{\| \mathbf{g}_p \| \| \mathbf{g}_q \|} &= \delta_{pq},\ p, q = 1, ..., P, \end{aligned} \tag{6}$$

where δ_{pq} is the Kronecker delta (defined as 1 for $p = q$ and as 0 otherwise).

3.2. The UMPCA algorithm

To solve the UMPCA problem (6), we follow the successive variance maximization approach in the derivation of PCA in (Jolliffe, 2002). The P EMPs $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}_{p=1}^{P}$ are determined one by one in P steps, with the p^{th} step obtaining the p^{th} EMP:

Step 1: Determine the first EMP $\{\mathbf{u}_1^{(n)^T}, n = 1, ..., N\}$ by maximizing $S_{T_1}^{\mathbf{y}}$ without any constraint.

Step 2: Determine the second EMP $\{\mathbf{u}_2^{(n)^T}, n = 1, ..., N\}$ by maximizing $S_{T_2}^{\mathbf{y}}$ subject to the constraint that $\mathbf{g}_2^T \mathbf{g}_1 = 0$.

Step $p (p = 3, ..., P)$**:** Determine the p^{th} EMP $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}$ by maximizing $S_{T_p}^{\mathbf{y}}$ subject to the constraint that $\mathbf{g}_p^T \mathbf{g}_q = 0$ for $q = 1, ..., p-1$.

In order to solve for the p^{th} EMP $\{\mathbf{u}_p^{(n)^T}, n = 1, ..., N\}$, we need to determine N sets of parameters corresponding to N projection vectors, $\mathbf{u}_p^{(1)}, \mathbf{u}_p^{(2)}, ...\mathbf{u}_p^{(N)}$, one in each mode. Unfortunately, simultaneous determination of these N sets of parameters in all modes is a complicated non-linear problem without an existing optimal solution, except when $N = 1$, which is the classical PCA where only one projection vector is to be solved. Therefore, we follow the approach in the alternating least square (ALS) algorithm (Harshman, 1970) to solve this multilinear problem. For each EMP to be determined, the parameters of the projection vector $\mathbf{u}_p^{(n^*)}$ for each mode n^* are estimated one mode by one mode separately, conditioned on $\{\mathbf{u}_p^{(n)}, n \neq n^*\}$, the parameter values of the projection vectors in the other modes.

To solve for $\mathbf{u}_p^{(n^*)}$ in the n^*-mode, assuming that $\{\mathbf{u}_p^{(n)}, n \neq n^*\}$ is given, the tensor samples are projected in these $(N-1)$ modes $\{n \neq n^*\}$ first to obtain the vectors

$$\begin{aligned} \tilde{\mathbf{y}}_{m_p}^{(n^*)} = \quad & \mathcal{X}_m \times_1 \mathbf{u}_p^{(1)^T} ... \times_{n^*-1} \mathbf{u}_p^{(n^*-1)^T} \\ & \times_{n^*+1} \mathbf{u}_p^{(n^*+1)^T} ... \times_N \mathbf{u}_p^{(N)^T}, \end{aligned} \tag{7}$$

where $\tilde{\mathbf{y}}_{m_p}^{(n^*)} \in \mathbb{R}^{I_{n^*}}$. This conditional subproblem then becomes to determine $\mathbf{u}_p^{(n^*)}$ that projects the vector samples $\{\tilde{\mathbf{y}}_{m_p}^{(n^*)}, m = 1, ..., M\}$ onto a line so that the variance is maximized, subject to the zero-correlation constraint, which is a PCA problem with the input samples $\{\tilde{\mathbf{y}}_{m_p}^{(n^*)}, m = 1, ..., M\}$. The corresponding total scatter matrix $\tilde{\mathbf{S}}_{T_p}^{(n^*)}$ is then defined as

$$\tilde{\mathbf{S}}_{T_p}^{(n^*)} = \sum_{m=1}^{M} (\tilde{\mathbf{y}}_{m_p}^{(n^*)} - \bar{\tilde{\mathbf{y}}}_p^{(n^*)})(\tilde{\mathbf{y}}_{m_p}^{(n^*)} - \bar{\tilde{\mathbf{y}}}_p^{(n^*)})^T, \tag{8}$$

where $\bar{\tilde{\mathbf{y}}}_p^{(n^*)} = \frac{1}{M} \sum_m \tilde{\mathbf{y}}_{m_p}^{(n^*)}$. With (8), we are ready to solve for the P EMPs. For $p = 1$, the $\mathbf{u}_1^{(n^*)}$ that maximizes the total scatter $\mathbf{u}_1^{(n^*)^T} \tilde{\mathbf{S}}_{T_1}^{(n^*)} \mathbf{u}_1^{(n^*)}$ in the projected space is obtained as the unit eigenvector of $\tilde{\mathbf{S}}_{T_1}^{(n^*)}$ associated with the largest eigenvalue. Next, we show how to determine the p^{th} $(p > 1)$ EMP given the first $(p-1)$ EMPs. Given the first $(p-1)$ EMPs, the p^{th} EMP aims to maximize the total scatter $S_{T_p}^{\mathbf{y}}$, subject to the constraint that features projected by the p^{th} EMP are uncorrelated with those projected by the first $(p-1)$ EMPs. Let $\tilde{\mathbf{Y}}_p^{(n^*)} \in \mathbb{R}^{I_{n^*} \times M}$ be a matrix with $\tilde{\mathbf{y}}_{m_p}^{(n^*)}$ as its m^{th} column, i.e., $\tilde{\mathbf{Y}}_p^{(n^*)} = \left[\tilde{\mathbf{y}}_{1_p}^{(n^*)}, \tilde{\mathbf{y}}_{2_p}^{(n^*)}, ..., \tilde{\mathbf{y}}_{M_p}^{(n^*)}\right]$, then the p^{th} coordinate vector is $\mathbf{g}_p = \tilde{\mathbf{Y}}_p^{(n^*)^T} \mathbf{u}_p^{(n^*)}$. The constraint that $\mathbf{g}_p$ is uncorrelated with $\{\mathbf{g}_q, q = 1, ..., p-1\}$ can be written as

$$\mathbf{g}_p^T \mathbf{g}_q = \mathbf{u}_p^{(n^*)^T} \tilde{\mathbf{Y}}_p^{(n^*)} \mathbf{g}_q = 0, q = 1, ..., p-1. \tag{9}$$

Thus, $\mathbf{u}_p^{(n^*)}$ $(p > 1)$ can be determined by solving the following constrained optimization problem:

$$\begin{aligned} & \mathbf{u}_p^{(n^*)} = \arg\max \mathbf{u}_p^{(n^*)^T} \tilde{\mathbf{S}}_{T_p}^{(n^*)} \mathbf{u}_p^{(n^*)}, \\ & \texttt{subject to } \mathbf{u}_p^{(n^*)^T} \mathbf{u}_p^{(n^*)} = 1 \text{ and} \\ & \mathbf{u}_p^{(n^*)^T} \tilde{\mathbf{Y}}_p^{(n^*)} \mathbf{g}_q = 0, q = 1, ..., p-1, \end{aligned} \tag{10}$$

The solution is given by the following theorem:

Theorem 1. *The solution to the problem (10) is the (unit-length) eigenvector corresponding to the largest eigenvalue of the following eigenvalue problem:*

$$\mathbf{\Psi}_p^{(n^*)} \tilde{\mathbf{S}}_{T_p}^{(n^*)} \mathbf{u} = \lambda \mathbf{u}, \tag{11}$$

where

$$\mathbf{\Psi}_p^{(n^*)} = \mathbf{I}_{I_{n^*}} - \tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{G}_{p-1}\mathbf{\Phi}_p^{-1}\mathbf{G}_{p-1}^T\tilde{\mathbf{Y}}_p^{(n^*)^T}, \quad (12)$$

$$\mathbf{\Phi}_p = \mathbf{G}_{p-1}^T\tilde{\mathbf{Y}}_p^{(n^*)^T}\tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{G}_{p-1}, \quad (13)$$

$$\mathbf{G}_{p-1} = [\mathbf{g}_1 \quad \mathbf{g}_2 \quad ...\mathbf{g}_{p-1}] \in \mathbb{R}^{M\times(p-1)}, \quad (14)$$

and $\mathbf{I}_{I_{n^*}}$ *is an identity matrix of size* $I_{n^*} \times I_{n^*}$.

Proof. First, Lagrange multipliers can be used to transform the problem (10) to the following to include all the constraints:

$$\begin{aligned} F(\mathbf{u}_p^{(n^*)}) &= \mathbf{u}_p^{(n^*)^T}\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)} - \nu\left(\mathbf{u}_p^{(n^*)^T}\mathbf{u}_p^{(n^*)} - 1\right) \\ &- \sum_{q=1}^{p-1}\mu_q\mathbf{u}_p^{(n^*)^T}\tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{g}_q, \end{aligned} \quad (15)$$

where ν and $\{\mu_q, q = 1, ..., p-1\}$ are Lagrange multipliers.

The optimization is performed by setting the partial derivative of $F(\mathbf{u}_p^{(n^*)})$ with respect to $\mathbf{u}_p^{(n^*)}$ to zero:

$$\begin{aligned} \frac{\partial F(\mathbf{u}_p^{(n^*)})}{\partial \mathbf{u}_p^{(n^*)}} &= 2\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)} - 2\nu\mathbf{u}_p^{(n^*)} \\ &- \sum_{q=1}^{p-1}\mu_q\tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{g}_q = 0. \end{aligned} \quad (16)$$

Multiplying (16) by $\mathbf{u}_p^{(n^*)^T}$ results in

$$\begin{aligned} &2\mathbf{u}_p^{(n^*)^T}\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)} - 2\nu\mathbf{u}_p^{(n^*)^T}\mathbf{u}_p^{(n^*)} = 0 \\ &\Rightarrow \nu = \frac{\mathbf{u}_p^{(n^*)^T}\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)}}{\mathbf{u}_p^{(n^*)^T}\mathbf{u}_p^{(n^*)}}, \end{aligned} \quad (17)$$

which indicates that ν is exactly the criterion to be maximized, with the constraint on the norm of the projection vector incorporated.

Next, a set of $(p-1)$ equations are obtained by multiplying (16) by $\mathbf{g}_q^T\tilde{\mathbf{Y}}_p^{(n^*)^T}$, $q = 1, ..., p-1$, respectively:

$$\begin{aligned} &2\mathbf{g}_q^T\tilde{\mathbf{Y}}_p^{(n^*)^T}\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)} - \sum_{q=1}^{p-1}\mu_q\mathbf{g}_q^T\tilde{\mathbf{Y}}_p^{(n^*)^T}\cdot\tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{g}_q \\ &= 0. \end{aligned} \quad (18)$$

Let

$$\boldsymbol{\mu}_{p-1} = [\mu_1 \ \mu_2 \ ... \ \mu_{p-1}]^T \quad (19)$$

and use (13) and (14), then the $(p-1)$ equations of (18) can be represented in a single matrix equation as following:

$$2\mathbf{G}_{p-1}^T\tilde{\mathbf{Y}}_p^{(n^*)^T}\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)} - \mathbf{\Phi}_p\boldsymbol{\mu}_{p-1} = 0. \quad (20)$$

Thus,

$$\boldsymbol{\mu}_{p-1} = 2\mathbf{\Phi}_p^{-1}\cdot\mathbf{G}_{p-1}^T\tilde{\mathbf{Y}}_p^{(n^*)^T}\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)}. \quad (21)$$

Since from (14) and (19),

$$\sum_{q=1}^{p-1}\mu_q\tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{g}_q = \tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{G}_{p-1}\boldsymbol{\mu}_{p-1}, \quad (22)$$

the equation (16) can be written as

$$\begin{aligned} &2\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)} - 2\nu\mathbf{u}_p^{(n^*)} - \tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{G}_{p-1}\boldsymbol{\mu}_{p-1} = 0 \\ &\Rightarrow\nu\mathbf{u}_p^{(n^*)} = \tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)} - \tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{G}_{p-1}\frac{\boldsymbol{\mu}_{p-1}}{2} \\ &= \left[\mathbf{I}_{I_{n^*}} - \tilde{\mathbf{Y}}_p^{(n^*)}\mathbf{G}_{p-1}\mathbf{\Phi}_p^{-1}\mathbf{G}_{p-1}^T\tilde{\mathbf{Y}}_p^{(n^*)^T}\right]\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u}_p^{(n^*)}. \end{aligned}$$

Using the definition in (12), an eigenvalue problem is obtained as $\mathbf{\Psi}_p^{(n^*)}\tilde{\mathbf{S}}_{T_p}^{(n^*)}\mathbf{u} = \nu\mathbf{u}$. Since ν is the criterion to be maximized, the maximization is achieved by setting $\mathbf{u}_p^{(n)^*}$ to be the (unit) eigenvector corresponding to the largest eigenvalue of (11). □

By setting $\mathbf{\Psi}_1^{(n^*)} = \mathbf{I}_{I_{n^*}}$ and from Theorem 1, we have a unified solution for UMPCA: for $p = 1, ..., P$, $\mathbf{u}_p^{(n^*)}$ is obtained as the unit eigenvector of $\mathbf{\Psi}_p^{(n^*)}\tilde{\mathbf{S}}_{T_p}^{(n^*)}$ associated with the largest eigenvalue. Algorithm 1 summarizes the UMPCA developed here.

Algorithm 1 Uncorrelated Multilinear Principal Component Analysis (UMPCA)

Input: A set of tensor samples $\{\mathcal{X}_m \in \mathbb{R}^{I_1\times...\times I_N}, m = 1, ..., M\}$, the subspace dimensionality P, and the maximum number of iterations K.
for $p = 1$ **to** P **do**
  for $n = 1$ **to** N **do**
    Initialize $\mathbf{u}_{p_{(0)}}^{(n)} = \mathbf{1}/\parallel\mathbf{1}\parallel$.
  end for
  for $k = 1$ **to** K **do**
    for $n = 1$ **to** N **do**
      Calculate $\tilde{\mathbf{y}}_{m_p}^{(n)} = \mathcal{X}_m \times_1 \mathbf{u}_{p_{(k)}}^{(1)^T} ... \times_{n-1} \mathbf{u}_{p_{(k)}}^{(n-1)^T} \times_{n+1} \mathbf{u}_{p_{(k-1)}}^{(n+1)^T} ... \times_N \mathbf{u}_{p_{(k-1)}}^{(N)^T}$, for $m = 1, ..., M$.
      Calculate $\mathbf{\Psi}_p^{(n)}$ and $\tilde{\mathbf{S}}_{T_p}^{(n)}$. Set $\mathbf{u}_{p_{(k)}}^{(n)}$ to be the (unit) eigenvector of $\mathbf{\Psi}_p^{(n)}\tilde{\mathbf{S}}_{T_p}^{(n)}$ associated with the largest eigenvalue.
    end for
  end for
  Set $\mathbf{u}_p^{(n)} = \mathbf{u}_{p_k}^{(n)}$ for all n.
  Calculate the coordinate vector $\mathbf{g}_p$.
end for

3.3. Initialization, projection order and termination

As an iterative algorithm, the UMPCA may be affected by the initialization method, the projection order and the termination conditions. Due to the space constraint, these issues, as well as the convergence and computational issues, are not studied here. Instead, we adopt simple implementation strategies for them. First, we use the uniform initialization for UMPCA, where all n-mode projection vectors are initialized to have unit length and the same value along the I_n dimensions in n-mode, which is equivalent to the all ones vector $\mathbf{1}$ with proper normalization. Second, as shown in Algorithm 1, the projection order, which is the mode ordering in computing the projection vectors, is from 1-mode to N-mode, as in other multilinear algorithms (Ye, 2005; Xu et al., 2005; Lu et al., 2008a). Third, the iteration is terminated by setting K, the maximum number of iterations.

4. Experimental Evaluation

The proposed UMPCA can potentially benefit various applications involving tensorial data, as mentioned in Sec. 1. Since face recognition has practical importance in security-related applications such as biometric authentication and surveillance, it has been used widely for evaluation of unsupervised learning algorithms (Shashua & Levin, 2001; Yang et al., 2004; Xu et al., 2005; Ye, 2005). Therefore, in this section, we focus on evaluating the effectiveness of UMPCA on this popular classification task through performance comparison with existing unsupervised dimensionality reduction algorithms.

4.1. The FERET database

The Facial Recognition Technology (FERET) database (Phillips et al., 2000) is widely used for testing face recognition performance, with 14,126 images from 1,199 subjects covering a wide range of variations in viewpoint, illumination, facial expression, races and ages. A subset of this database is selected in our experimental evaluation and it consists of those subjects with each subject having at least eight images with at most 15 degrees of pose variation, resulting in 721 face images from 70 subjects. Since our focus here is on the recognition of faces rather than their detection, all face images are manually cropped, aligned (with manually annotated coordinate information of eyes) and normalized to 80×80 pixels, with 256 gray levels per pixel. Figure 1 shows some sample face images from two subjects in this FERET subset.

Figure 1. Examples of face images from two subjects in the FERET subset used in our experimental evaluation.

4.2. Face recognition performance comparison

In the evaluation, we compare the performance of the UMPCA against three PCA-based unsupervised learning algorithms: the PCA (eigenface) algorithm (Turk & Pentland, 1991), the MPCA algorithm (Lu et al., 2008a)[2] and the TROD algorithm (Shashua & Levin, 2001). The number of iterations in TROD and UMPCA is set to ten, with the same (uniform) initialization used. For MPCA, we obtain the full projection and select the most descriptive P features for recognition. The features obtained by these four algorithms are arranged in descending variation captured (measured by respective total scatter). For classification of extracted features, we use the nearest neighbor classifier (NNC) with Euclidean distance measure.

Gray-level face images are naturally second-order tensors (matrices), i.e., $N = 2$. Therefore, they are input directly as 80×80 tensors to the multilinear algorithms (MPCA, TROD, UMPCA), while for PCA, they are vectorized to 6400×1 vectors as input. For each subject in a face recognition experiment, $L(= 1, 2, 3, 4, 5, 6, 7)$ samples are randomly selected for unsupervised training and the rest are used for testing. We report the results averaged over ten such random splits (repetitions).

Figures 2 and 3 show the detailed results[3] for $L = 1$ and $L = 7$, respectively. $L = 1$ is an extreme small sample size scenario where only one sample per class is available for training, the so-called one training sample (OTS) case important in practice (Wang et al., 2006), and $L = 7$ is the maximum number of training samples we can use in our experiments. Figures 2(a) and 3(a) plot the correct recognition rates against P, the dimensionality of the subspace for $P = 1, ..., 10$, and Figs 2(b) and 3(b) plot those for $P = 15, ..., 80$. From the figures, UMPCA outperforms the other three methods in both cases and across all dimensionality, indicating that the uncorrelated features extracted directly from the tensorial face data are more effective in classifi-

[2]Note that MPCA with $N = 2$ is equivalent to GPCA.

[3]Note that for PCA and UMPCA, there are at most 69 features when $L = 1$ (only 70 faces for training).

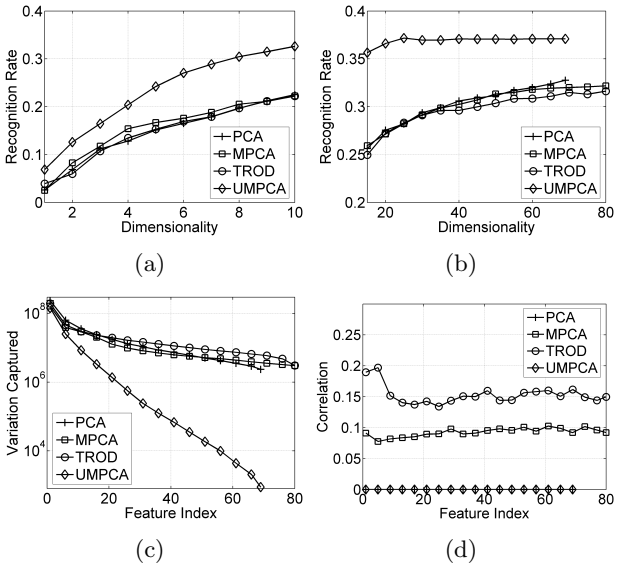

Figure 2. Detailed face recognition results on the FERET database for $L = 1$: (a) performance curves for the low-dimensional case, (b) performance curves for the high-dimensional case, (c) the variation captured by individual features and (d) the correlation among features.

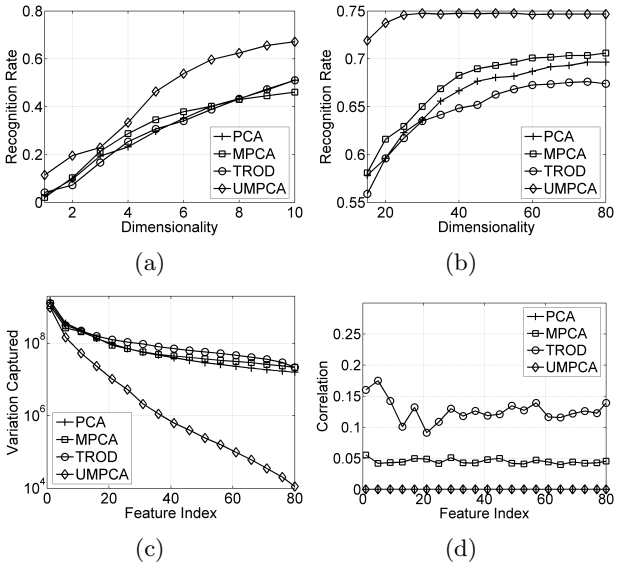

Figure 3. Detailed face recognition results on the FERET database for $L = 7$: (a) performance curves for the low-dimensional case, (b) performance curves for the high-dimensional case, (c) the variation captured by individual features and (d) the correlation among features.

cation. The figures also show that for UMPCA, the recognition rate saturates around $P = 30$, which can be explained by observing the variance captured by individual features as shown in Figs. 2(c) and 3(c) (in log scale). These figures show that the variance captured by UMPCA is considerably lower than those captured by the other methods, which is due to its constraints of zero-correlation and TVP. Despite capturing lower variance, UMPCA is superior in the recognition task performed. Nonetheless, when the variance captured is too low, those corresponding features are no longer descriptive enough to contribute in classification, leading to the saturation.

In addition, we also plot the average correlation of individual features with all the other features in Figs. 2(d) and 3(d). As supported by theoretical derivation, features extracted by PCA and UMPCA are uncorrelated. In contrast, features extracted by MPCA and TROD are correlated, with TROD features have higher correlation on average.

Table 2. Face recognition results on the FERET database: the recognition rates (in percentage) for various Ls and Ps.

The recognition results for $P = 1, 5, 10, 20, 50, 80$ are listed in Table 2 for $L = 2, 3, 4, 5, 6$, where the best recognition results among the four methods are shown in bold. More detailed results are omitted here to save space. From the table, UMPCA achieves superior recognition results in all cases except for $P = 80$ and $L = 2$, where the difference with the best results by MPCA is small (0.3%). In particular, for smaller P $(1, 5, 10, 20)$, UMPCA outperforms the other algorithms significantly, demonstrating its superior capability in classifying faces in low-dimensional spaces.

5. Conclusions

This paper proposes a novel uncorrelated multilinear PCA algorithm, where uncorrelated features are extracted directly from tensorial representation through a tensor-to-vector projection. The algorithm successively maximizes variance captured by each elementary projection while enforcing the zero-correlation constraint. The solution employs the alternating projection method and is iterative. Experiments on face recognition demonstrate that compared with other unsupervised learning algorithms including the PCA, MPCA and TROD, the UMPCA achieves the best results and it is particularly effective in low-dimensional spaces. Thus, face recognition through unsupervised learning benefits from the proposed UMPCA and in future research, it is worthwhile to investigate whether UMPCA can contribute in other unsupervised learning tasks, such as clustering.

Abstract

A good distance measure for time series needs to properly incorporate the temporal structure, and should be applicable to sequences with unequal lengths. In this paper, we propose a distance measure as a principled solution to the two requirements. Unlike the conventional feature vector representation, our approach represents each time series with a summarizing smooth curve in a reproducing kernel Hilbert space (RKHS), and therefore translate the distance between time series into distances between curves. Moreover we propose to learn the kernel of this RKHS from a population of time series with discrete observations using Gaussian process-based non-parametric mixed-effect models. Experiments on two vastly different real-world problems show that the proposed distance measure leads to improved classification accuracy over the conventional distance measures.

1. Introduction

Time series classification is a supervised learning problem aimed at labeling temporally structured sequences of variable length. The most common approach reduces time series classification to a static problem by suitably transforming the input sequences into vectors in Euclidean space. One can either summarize each time series with attributes pertinent to classification (called *feature extraction*)(Keogh & Pazzani, 1998), or use a properly sampled and aligned subsequence (called *sampling*)(Parra et al., 2003). Unfortunately, the feature extraction method is still more art than science, and the performance depends heavily on the designer's domain knowledge and the particular heuristic implemented. The sampling method, although preserving most of the information, is accused of ignoring the important temporal structure of the series. Indeed, the sampled sequences, if treated as vectors in Euclidean space, lead to the same classifiers after any permutation of the vector entries. Moreover, the sampling strategy does not apply to situations where we have only sparse observations that are made at irregular times.

In this paper, we propose a principled non-parametric distance measure for time series by representing each time series with a smooth curve in a reproducing kernel Hilbert space (RKHS) with a kernel learned from data. This new distance measure circumvents the limitations of the two above mentioned strategies.

Paper Roadmap In Section 2, we give the background of the Bregman divergence, and then generalize it to function space for a proper distance measure of smooth curves. In Section 3 we propose a family of new distance measures for time series with only discrete observations. Section 4 is devoted to the non-parametric mixed-effect model, which helps to further specify the proposed distance measure. In Section 5, we apply the proposed distance measure to two real-world time series classification problems. Finally we discuss the related work in Section 6.

2. Gaussian Processes and Functional Bregman Divergence

The Bregman divergence is a natural generalization of squared Euclidean distance and KL-divergence. A Bregman divergence corresponding to a strictly convex function $\phi(x)$ (called seed function) is defined as

$$d_\phi(x_1||x_2) = \phi(x_1) - \phi(x_2) - \langle \nabla\phi(x_2), x_1 - x_2 \rangle . \quad (1)$$

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Bregman divergence is closely connected to the exponential family (Banerjee et al., 2005). For any distribution in the exponential family

$$p(x;\theta) = \exp(\langle x,\theta\rangle - \Phi(\theta))p_0(x),$$

we know that the log likelihood can be re-written as

$$\log p(x;\theta) = -d_\phi(x||\mu(\theta)) + \phi(x) + \log p_0(x), \quad (2)$$

where ϕ is the conjugate function of Φ

$$\phi(x) = \sup_\theta\{\langle x,\theta\rangle - \Phi(\theta)\} \quad (3)$$

and $\mu(\theta) = \nabla\Phi(\theta)$ is the expectation parameter corresponding to θ. We go one step further to argue that $d_\phi(x_1||x_2)$ should be a proper model-weighted divergence measure between any x_1 and x_2. It is straightforward to show that for multi-variate Gaussian distribution $\mathcal{N}(a,\Sigma)$, the corresponding Bregman divergence is given by

$$d_\phi(x_1||x_2) = \frac{1}{2}(x_1-x_2)^T\Sigma^{-1}(x_1-x_2), \quad (4)$$

which is also suggested in (Tipping, 1999) as a model-weighted distance for Gaussian distribution.

2.1. Extension to Function Space

We generalize our discussion on the Bregman divergence and the exponential family to function spaces. To facilitate our discussion, we adopt the language of functional integral, which, although allegedly not rigorously defined, provides a powerful technique for describing the probability on functions (Simon, 1979).

Gaussian processes (GPs) (Rasmussen & Williams, 2006) generalize the multivariate Gaussian distribution to function space, which model any function f with the following probability [1]

$$p[f] \propto \exp(-\frac{1}{2}||f-f_0||^2_{\mathcal{H}}), \quad (5)$$

with f_0 being the *mean function* and $||\cdot||_{\mathcal{H}}$ the norm for the reproducing kernel Hilbert space (RKHS) $\mathcal{H}$. We use K to denote the reproducing kernel, which will also be noted as the covariance function for the Gaussian process expressed in Eq.(5) (Seeger, 2004). In regularization theory, the norm $||\cdot||_{\mathcal{H}}$ is often related to a particular type of smoothness of function, with large (even infinite) $||f||_{\mathcal{H}}$ for non-smooth function f.

After generalizing Eq.(1) to the functional case (Frigyik et al., 2006), we get the Bregman divergence between function f_1 and f_2, with a seed functional $g[\cdot]$

$$d_g(f_1||f_2) = g[f_1] - g[f_2] - \int Dg[f_2](f_1(t)-f_2(t))dt.$$

where $Dg[f]$ is the Fréchet derivative. The Gaussian process expressed in Eq.(5) can be viewed as a member of the exponential family extended to distributions on functions (Altun et al., 2004). Then a direct generalization of Eq.(3) leads to $g[f] = \frac{1}{2}||f||^2_{\mathcal{H}}$, which gives a GP-related divergence for smooth functions

$$d_{\mathcal{H}}(f_1||f_2) = \frac{1}{2}||f_1-f_2||^2_{\mathcal{H}}. \quad (6)$$

3. Distance for Time Series

We consider k time series, using $\mathbf{y}_i$ to denote the N_i observations from the i^{th} time series made at times $\mathbf{t}_i$

$$\mathbf{y}_i \doteq [y_{i1},\cdots,y_{iN_i}]^T, \quad \mathbf{t}_i \doteq [t_{i1},\cdots,t_{iN_i}]^T.$$

The subscript i on $\mathbf{t}_i$ and N_i indicates that the observation times and even the number of observations are generally different for each individual. The time series are called *synchronized* if all the $\mathbf{t}_i$ are the same.

We can define a distance measure for such time series by associating the observations $\{\mathbf{t}_i,\mathbf{y}_i\}$ with a (smooth) curve. We assume the observations for each individual i is generated from a independent Gaussian process f_i with the same covariance function K (and therefore $\mathcal{H}$) and mean f_0. The observation is modeled as

$$y_{in} = f_i(t_{in}) + \epsilon_{in}, \quad n = 1,2,\cdots,N_i, \quad (7)$$

where ϵ_{in} is a white observation noise with standard deviation σ for all i and n.

We choose to summarize each individual time series i with the expectation of $f_i(t)$ given the discrete noisy observation $\{\mathbf{t}_i,\mathbf{y}_i\}$.

$$\hat{f}_i(t) = E[f_i(t)|\mathbf{y}_i,f_0;\mathbf{t}_i,K] \quad (8)$$
$$= f_0 + K(t,\mathbf{t}_i)(K(\mathbf{t}_i,\mathbf{t}_i)+\sigma^2\mathbb{I})^{-1}(\mathbf{y}_i-\mathbf{f}_{0,i}) \quad (9)$$

where $\mathbf{f}_{0,i} \doteq [f_0(t_{i1}),f_0(t_{i2}),\cdots,f_0(t_{iN_i})]^T$ is the values of f_0 at times $\mathbf{t}_i$, and $K(\mathbf{t}_i,\mathbf{t}_i)$ is the $N_i\times N_i$ matrix with the (n,m) entry being $K(t_{in},t_{im})$. With a smooth f_0, we have $||\hat{f}_i||_{\mathcal{H}} < +\infty$, which can be loosely interpreted as that $\hat{f}_i$ is smooth according to K. In Fig.1, we give an example of using such a curve $\hat{f}$ to represent the noisy observations (black crosses).

We then use the distance between $\hat{f}_i$ and $\hat{f}_j$ as the distance between time series $\{\mathbf{t}_i,\mathbf{y}_i\}$ and $\{\mathbf{t}_j,\mathbf{y}_j\}$ [2],

[1] In the remainder of the paper, we use the square brackets [ ] to distinguish functionals from common functions.

[2] Although $E[||f_i-f_j||^2_{\mathcal{H}}|\mathbf{y}_i,\mathbf{y}_j;\mathbf{t}_i,\mathbf{t}_j]$ seems to be a reasonable measure of distance, it goes to infinity since with probability one a sample f from the a Gaussian process with covariance function K has $||f||_{\mathcal{H}} = \infty$ (Seeger, 2004).

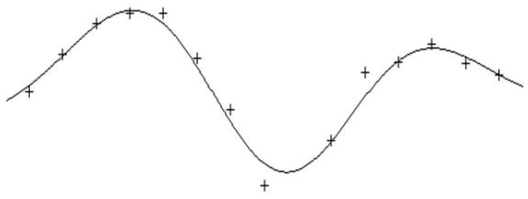

Figure 1. Using smooth curve to represent noisy discrete observations (black crosses). The smooth curve is obtained using Eq.(9) with K being a Gaussian kernel and $f_0 = 0$.

which is given by Eq.(6) as

$$d_{ij} = \frac{1}{2}||\hat{f}_i - \hat{f}_j||^2_{\mathcal{H}}. \tag{10}$$

Since $\mathcal{H}$ is the RKHS induced by the kernel K, this distance measure is well-defined

$$\begin{aligned} d_{ij} &= \frac{1}{2}||\hat{f}_i - \hat{f}_j||^2_{\mathcal{H}} = \frac{1}{2}\left\langle \hat{f}_i - \hat{f}_j, \hat{f}_i - \hat{f}_j \right\rangle_{\mathcal{H}} \\ &= \frac{1}{2}\langle K(t,\mathbf{t}_i)\mathbf{v}_i - K(t,\mathbf{t}_j)\mathbf{v}_j, K(t,\mathbf{t}_i)\mathbf{v}_i - K(t,\mathbf{t}_j)\mathbf{v}_j\rangle_{\mathcal{H}}, \end{aligned}$$

where $\mathbf{v}_i = (K(\mathbf{t}_i,\mathbf{t}_i) + \sigma^2\mathbb{I})^{-1}(\mathbf{y}_i - \mathbf{f}_{0,i})$. Using the reproducing kernel property

$$\forall\, t_n, t_m \quad \langle K(t_n,t), K(t_m,t)\rangle_{\mathcal{H}} = K(t_n,t_m),$$

the distance measurement can be simplified as

$$d_{ij} = \frac{1}{2}\mathbf{v}_i^T K(\mathbf{t}_i,\mathbf{t}_i)\mathbf{v}_i + \frac{1}{2}\mathbf{v}_j^T K(\mathbf{t}_i,\mathbf{t}_i)\mathbf{v}_j - \mathbf{v}_i^T K(\mathbf{t}_i,\mathbf{t}_j)\mathbf{v}_j. \tag{11}$$

It is important to note that this distance does not require all the time series to be synchronized, an advantage when sequences are of different lengths, or the observations are made at different times, as shown in our first experiment in Section 5. When the observations for all individuals are synchronized, we have $\mathbf{t}_i = \mathbf{t} = [t_1, t_2, \cdots, t_N]^T$ with N as the total number of observations for each individual. Letting $\mathbf{K} = K(\mathbf{t},\mathbf{t})$, we can re-write d_{ij} as

$$\begin{aligned} d_{ij} &= \mathbf{v}_i^T\mathbf{K}\mathbf{v}_i + \mathbf{v}_j^T\mathbf{K}\mathbf{v}_j - 2\mathbf{v}_i^T\mathbf{K}\mathbf{v}_j & (12)\\ &= (\mathbf{v}_i - \mathbf{v}_j)^T\mathbf{K}(\mathbf{v}_i - \mathbf{v}_j) & (13)\\ &= (\mathbf{y}_i - \mathbf{y}_j)^T(\mathbf{K} + \sigma^2\mathbb{I})^{-1}\mathbf{K}(\mathbf{K} + \sigma^2\mathbb{I})^{-1}(\mathbf{y}_i - \mathbf{y}_j). & (14) \end{aligned}$$

Temporal Structure In Eq.(11)-(14), the temporal regularity is incorporated in the distance via the kernel K. It is most clear when we notice that K models the correlation of f value at different time

$$K(\mathbf{t}_i,\mathbf{t}_j) = E[(f(\mathbf{t}_i) - f_0(\mathbf{t}_i))^T(f(\mathbf{t}_j) - f_0(\mathbf{t}_j))].$$

The norm $||f_i - f_j||_{\mathcal{H}}$ measures the irregularity defined by K, in contrast to the Euclidean distance $\int(f_i(t) - f_j(t))^2 dt$ which only concerns about the point wise difference between f_i and f_j. It is also important to notice the particular temporal structure incorporated varies greatly with the choice of K. For example, the widely used Matérn (including Gaussian) kernel or rational quadratic kernel promote different types and level of smoothness. On the other hand, the temporal structure is often problem specific and hard to determine beforehand. In the next section, we will discuss learning this temporal structure from the data.

4. Non-parametric Mixed-effect Model

In Section 3, we assume a Gaussian process with known mean and covariance function. However in practice it is often not the case. Instead we may want to learn the characteristic of Gaussian process from examples. One situation of interest to us is when a population of similar time series are available. This prior learning scheme is known in statistics as the empirical Bayesian or the hierarchial Beyesian (Gelman, 2004). Particularly, the model is called mixed-effect model when the hyper-prior is a Gaussian, on which the maximum likelihood (ML) solution can be found with Expectation-Maximization (EM) algorithm.

Traditional mixed-effect models are parametric, which assume a θ-parameterized regression model for each individual. Since the model parameters vary across individuals, it is natural to consider them generated by the sum of a fixed and a random piece $\theta = \alpha + \beta_i$, where α is called the *fixed effect*, and β_i, called *random effect*, is assumed distributed $\mathcal{N}(0,\mathbf{D})$ with unknown covariance $\mathbf{D}$. The fitting of mixed-effect model is to find α, $\mathbf{D}$, and the variance of observation noise.

In non-parametric mixed-effect models, the individual regression models do not take a parametric form. Instead, we assume the observations are generated by k smooth curves $\{f_1, f_2, \cdots, f_k\}$ fluctuating around a mean (fixed-effect) function f_0. We use $\widetilde{f}_i = f_i - f_0$ to denote the deviation of f_i from f_0 (random effect). The prior of both f_0 and $\widetilde{f}_i$ can be summarized with the following equations:

$$\begin{aligned} p_0[f_0] &\propto \exp(-\frac{1}{2}||f_0||^2_{\mathcal{H}_0}) & (15)\\ p_f[\widetilde{f}_i] &\propto \exp(-\frac{1}{2}||\widetilde{f}_i||^2_{\mathcal{H}}) \;\; i = 1,2,\cdots,k, & (16) \end{aligned}$$

where $\mathcal{H}$ and $\mathcal{H}_0$ are generally different Hilbert spaces, with the corresponding reproducing kernel denoted as K and K_0. Also we assume the observation noise to be

white Gaussian with variance σ^2, from which follows

$$p(\mathbf{y}_i|\widetilde{f}_i, f_0; \mathbf{t}_i) \propto \prod_{j=1}^{n_i} \exp(-\frac{(y_{in} - \widetilde{f}_i(t_{in}) - f_0(t_{in}))^2}{2\sigma^2}).$$

We assume $\mathcal{H}_0$ (and thus the form of $p_0[\cdot]$) is predetermined, while the fixed effect f_0 is to be decided. Also unknown are the noise variance σ^2 and the Hilbert space $\mathcal{H}$ for random effects (or equivalently K). Our learning task is therefore to jointly optimize over $\{f_0, K, \sigma\}$ by maximizing the following probability of $\mathbf{Y} = \{\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_k\}$.

$$p(\mathbf{Y}|f_0; K, \sigma)p_0[f_0] = p_0[f_0] \prod_{i=1}^{k} \int Df_i \{p(\mathbf{y}_i|\widetilde{f}_i, f_0; \sigma)p_f[\widetilde{f}_i]\}, \quad (17)$$

where the integral $\int D\omega\, g[\omega]$ is a functional integral over ω (Simon, 1979). Using the Gaussian property, Eq.(17) can be further reduced to a standard integral

$$p(\mathbf{Y}|f_0; K, \sigma)p_0[f_0] = p_0[f_0] \prod_{i=1}^{k} \int d\mathbf{f}_i \{p(\mathbf{y}_i|\mathbf{f}_i, f_0; \sigma)p(\mathbf{f}_i; K)\}. \quad (18)$$

where $\mathbf{f}_i = [\widetilde{f}_i(t_{i1}), \widetilde{f}_i(t_{i2}), \cdots, \widetilde{f}_i(t_{iN_i})]^T$ collects the values of f_i on times $\mathbf{t}_i$ and $p(\mathbf{f}_i; K)$ is a standard multivariate Gaussian

$$p(\mathbf{f}_i; K) = \frac{1}{\sqrt{(2\pi)^{N_i}|K(\mathbf{t}_i, \mathbf{t}_i)|}} \exp(-\frac{1}{2}\mathbf{f}_i^T K(\mathbf{t}_i, \mathbf{t}_i)^{-1}\mathbf{f}_i). \quad (19)$$

In general, there is no unique solution of K that maximizes $p(\mathbf{Y}|f_0; K, \sigma)p_0[f_0]$. Indeed, it is easy to verify that if $K(t_{in}, t_{im}) = K'(t_{in}, t_{im})$ for any individual i and time index (n, m), we will have

$$p(\mathbf{Y}|f_0; K, \sigma)p_0[f_0] = p(\mathbf{Y}|f_0; K', \sigma)p_0[f_0].$$

This situation can be circumvented in two ways. First we can restrain K in a particular parametric family, such as the widely used Gaussian kernel. Second, we can instead optimize *only* over the entry $K(t_{in}, t_{im})$ for all individual i, and time index (n, m). Both strategies will be addressed in this paper.

4.1. Optimization with the EM Algorithm

The task is to find the set $\mathcal{M} = \{f_0, K, \sigma\}$ that maximizes the probability $p(\mathbf{Y}|f_0; K, \sigma)p_0[f_0]$. As shown in Eq.(18), we can rewrite the data likelihood $p(\mathbf{y}_i|f_0; K, \sigma)$ using the $\{\mathbf{f}_1, \mathbf{f}_2, \cdots, \mathbf{f}_k\}$ as the latent variables

$$p(\mathbf{y}_i|f_0; K, \sigma) = \int d\mathbf{f}_i p(\mathbf{y}_i|\mathbf{f}_i, f_0, \sigma)p(\mathbf{f}_i; K), \quad (20)$$

which enables us to employ the EM algorithm in finding $\mathcal{M}$. In the following, we will give the results of the expectation step (E-step) and the maximization step (M-step).

E-step: In each EM iteration:

$$Q(\mathcal{M}, \mathcal{M}^g) = E_{\{\mathbf{f}_i|\mathbf{Y};\mathcal{M}^g\}}[\log\{p(\mathbf{Y}, \{\mathbf{f}_i\}; \mathcal{M})p_0[f_0]\}] = \sum_{i=1}^{k} \int d\mathbf{f}_i \log p(\mathbf{y}_i, \mathbf{f}_i; \mathcal{M})p(\mathbf{f}_i|\mathbf{y}_i; \mathcal{M}^g) + \log p[\mathbf{f}_0],$$

where $\mathcal{M}^g$ stands for the parameters from the last iteration. After some algebra, we can re-arrange $Q(\mathcal{M}, \mathcal{M}^g)$ into the following form

$$Q(\mathcal{M}, \mathcal{M}^g) = -\frac{1}{2}||f_0||^2_{\mathcal{H}_0} - n\log\sigma - \frac{1}{2\sigma^2}\sum_{i=1}^{k}\sum_{j=1}^{n_i} E_{\{\mathbf{f}_i|\mathbf{Y};\mathcal{M}^g\}}[(y_{ij} - \widetilde{f}_i(t_{ij}) - f_0(t_{ij}))^2] + \sum_{i=1}^{k} \int d\mathbf{f}_i \log p(\mathbf{f}_i; \mathcal{M})p(\mathbf{f}_i|\mathbf{y}_i; \mathcal{M}^g). \quad (21)$$

M-step: In M-step, we find the

$$\mathcal{M}^* = \arg\max_{\mathcal{M}} Q(\mathcal{M}, \mathcal{M}^g), \quad (22)$$

and use $\mathcal{M}^*$ to update the model parameters. The optimization in Eq.(22) can be divided into two separate parts. The first three terms on the left hand side of Eq.(21) is a function of only (f_0, σ); The last (fourth) term is a function of only K. To find the solution of f_0 and σ, we need to solve the following optimization problem:

$$(\sigma^*, f_0^*) = \arg\min_{\sigma, f_0} \{\frac{1}{2}||f_0||^2_{\mathcal{H}_0} + N\log\sigma + \frac{1}{2\sigma^2}\sum_{i=1}^{k}\sum_{j=1}^{n_i} E_{\{\mathbf{f}_i|\mathbf{Y};\mathcal{M}^g\}}[(y_{ij} - \widetilde{f}_i(t_{ij}) - f_0(t_{ij}))^2]. \quad (23)$$

Particularly, with any fixed σ, maximizing $Q(\mathcal{M}, \mathcal{M}^g)$ over f_0 becomes a regularized regression problem

$$f_0^* = \arg\min_{f_0} \frac{1}{2}||f_0||^2_{\mathcal{H}_0} + \frac{1}{2\sigma^2}\sum_{i=1}^{N}\sum_{j=1}^{n_i}\{(y_{ij} - E_{\{\mathbf{f}_i|\mathbf{y}_i,\mathcal{M}^g\}}[\widetilde{f}_i(t_{ij})] - f_0(t_{ij}))^2\}.$$

The optimization over K is

$$K = \arg\max_{K\in\mathcal{K}} \sum_{i=1}^{k} \int d\mathbf{f}_i \log p(\mathbf{f}_i; K)p(\mathbf{f}_i|\mathbf{y}_i; K^g) \quad (24)$$

$$= \arg\max_{K\in\mathcal{K}} -\sum_{i=1}^{k}\{\frac{1}{2}\log|K(\mathbf{t}_i,\mathbf{t}_i)| + \frac{1}{2}tr(K(\mathbf{t}_i,\mathbf{t}_i)^{-1}(\mathbf{C}_i^g+\mu_i^g(\mu_i^g)^T))\}, \quad (25)$$

where $\mathcal{K}$ is the set of feasible K, and μ_i is the posterior mean $E[\mathbf{f}_i|\mathbf{y}_i;\mathcal{M}]$ that can be calculated as

$$\mu_i = K(\mathbf{t}_i,\mathbf{t}_i)(K(\mathbf{t}_i,\mathbf{t}_i)+\sigma^2\mathbb{I})^{-1}(\mathbf{y}_i-\mathbf{f}_{0,i})$$

and $\mathbf{C}_i$ is the posterior covariance of $\mathbf{f}_i$

$$\mathbf{C}_i = K(\mathbf{t}_i,\mathbf{t}_i) - K(\mathbf{t}_i,\mathbf{t}_i)(K(\mathbf{t}_i,\mathbf{t}_i)+\sigma^2\mathbb{I})^{-1}K(\mathbf{t}_i,\mathbf{t}_i).$$

4.2. Parametric Covariance Estimation

We assume the covariance function K is of the parametric form $K(x,y;\theta)$. For example, the Gaussian kernel with scale a and kernel width s

$$K(x,y;\{a,s\}) = a\exp(-\frac{||x-y||^2}{2s^2}),$$

or as suggested in (Lanckriet et al., 2004) a convex combination of a set of kernels $\{K_1,K_2,\cdots,K_M\}$

$$K(x,y;\lambda) = \lambda_1K_1(x,y)+\lambda_2K_2(x,y)+\cdots+\lambda_MK_M(x,y).$$

In this case, the optimization of K in the M-step can be reduced to the following parameter estimation

$$\theta^* = \arg\max_{\theta} -\sum_{i=1}^{k}\{\frac{1}{2}\log|K(\mathbf{t}_i,\mathbf{t}_i;\theta)| + \frac{1}{2}tr(K(\mathbf{t}_i,\mathbf{t}_i;\theta)^{-1}(\mathbf{C}_i^g+\mu_i^g(\mu_i^g)^T))\}, \quad (26)$$

where $p(\mathbf{f}_i;\theta) = p(\mathbf{f}_i;K(\mathbf{t}_i,\mathbf{t}_i;\theta))$. This parametric form of K is appealing in either one of the following two situations:

- when the observation are sparse, since the parametric K is generally less prone to overfitting compared to the non-parametric estimation, as will be discussed in Section 4.3.
- when the time series are not synchronized (as in Section 5.1) since the parametric K allows the out-of-sample extension.

4.3. Non-parametric Covariance Estimation

When all the time series all synchronized, we have $\mathbf{t}_i = \mathbf{t}, i = 1,2,\cdots,k$. We can replace $K(\mathbf{t}_i,\mathbf{t}_i)$ in Eq.(25) with $\mathbf{K}\equiv K(\mathbf{t},\mathbf{t})$, and rewrite the optimization into the matrix form

$$\mathbf{K} = \arg\max_{\mathbf{K}\in\mathcal{P}} -\sum_{i=1}^{N}\{\frac{1}{2}\log|\mathbf{K}| + \frac{1}{2}tr(\mathbf{K}^{-1}(\mathbf{C}_i^g+\mu_i^g(\mu_i^g)^T))\}. \quad (27)$$

If we let $\mathcal{P}$ be the set of positive definite matrix, the solution of Eq.(27) is simple

$$\mathbf{K} = \frac{1}{k}\sum_{i=1}^{k}(\mathbf{C}_i^g+\mu_i^g(\mu_i^g)^T). \quad (28)$$

The non-parametric fitting of kernel matrix $\mathbf{K}$ is appealing since it does not assume a particular form for the covariance matrix and thus can fully exploit the information in the samples. However it can only be used when the time series are synchronized. One example of this modeling choice is given in Section 5.2.

5. Experiments

We tested the proposed distance measure on two real-world applications. The first one is an algorithm for cognitive decline detection based on longitudinal clinical observations of motor ability. The second one is an target identifier system based on electroencephalograph (EEG) signal.

In each experiment, we employ support vector machine (SVM) (Burges, 1998) with Gaussian kernel defined as follows

$$\mathbf{G}_{ij} = \exp(-\frac{d_{ij}}{2r^2}) \quad (29)$$

where d_{ij} is the squared distance between the time series i and j and the kernel width r is usually obtained using cross-validation. It is easy to see the $\mathbf{G}$ is a Mercer kernel.

5.1. Cognitive Decline Detection Based on Longitudinal Data

Research by our group and others show that motor changes, such as in walking and finger tapping rates, can effectively predict cognitive decline several years before impairment is manifest (Camicioli et al., 1998). It would be useful to build a system to detect cognitive decline (at least partially) from motor behavior, since they can be obtained by unintrusive in-home assessment (Hayes et al., 2004). Our research focuses on using clinical motor behavior and data from the Oregon Brain Aging Study (OBAS) (Green et al., 2000). All 143 subjects in the cohort were healthy at entry, and when the data were drawn 46 of them had developed into mild cognitive impairment, while 97 remained cognitively healthy. We divide all the subjects into the impaired group and the normal group according to their state when the data were drawn from the database. [3] We intend to predict whether a subject

[3] This grouping is potentially inaccurate due to the possibility that those cognitively healthy subjects can later develop into dementia, which is known as right censoring in survival analysis.

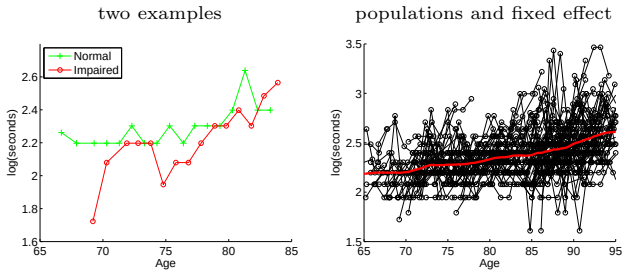

Figure 2. Left panel: sample spaghetti plots of seconds from two groups. Right panel: the population of seconds data and the fit fixed effect model (red line).

would develop into cognitive impairment based on his or her motor behavior before a clinical diagnosis (if any). In this experiment, this task reduces to predicting the group membership for each subject. This classification is difficult due to the fact that motor observations are sparse and noisy, as shown in Fig.2(left panel). We examined four motor behaviors summarized in Table 1. Usually as the subjects age or become impaired, the seconds and steps increase, while tappingD and tappingN decrease.

seconds	# of seconds the subject takes to walk 9 m
steps	# of steps the subject takes to walk 9 m
tappingD	# of the tappings the subject does in 10 seconds with the dominant hand
tappingN	# of the tappings the subject does in 10 seconds with the non-dominant hand

Table 1. Description of data.

We fit the non-parametric mixed-effect model to each motor behavior with the parameterized kernel

$$K_0(t_1,t_2) = \exp(\frac{||t_1-t_2||^2}{2s_0^2}),$$
$$K(t_1,t_2;\{a,s\}) = a\exp(\frac{||t_1-t_2||^2}{2s^2}),$$

where s_0 is predetermined and $\{a,s\}$ are to be learnt. The right panel of Fig.2 shows the seconds time series from the 143 subjects (black $-\circ-$) and the fit fixed effect (red line). Once the model is fit, the distance between any two subjects i and j is calculated as in Eq.(11).

For comparison, we also examined a parametric feature based on the least-square (LSQ) fit coefficients for linear regression: $\mathbf{x}_i = \arg\min_{\mathbf{x}} \sum_{j=1}^{N_i}(x_0 + x_1 t_{ij} - y_{ij})^2$ with $\mathbf{x} = [x_0, x_1]^T$. This feature extraction is justified by the observation that the intercept and the slope of the motor behavior trajectory are predictor of future cognitive decline and dementia (Marquis et al., 2002). Based on the LSQ feature we get another distance measure $d_{ij} = ||\mathbf{x}_i - \mathbf{x}_j||^2$. We employ a SVM as the classifier with kernels calculated with Eq.(29). Fig.3 compares the ROC curves using the proposed distance measure and the Euclidean distance between the LSQ features. It is clear that SVM with proposed distance measure outperforms the SVM with the LSQ features in terms of the area under curve (AUC). There are two reasons for the superiority of the proposed distance over the LSQ feature:

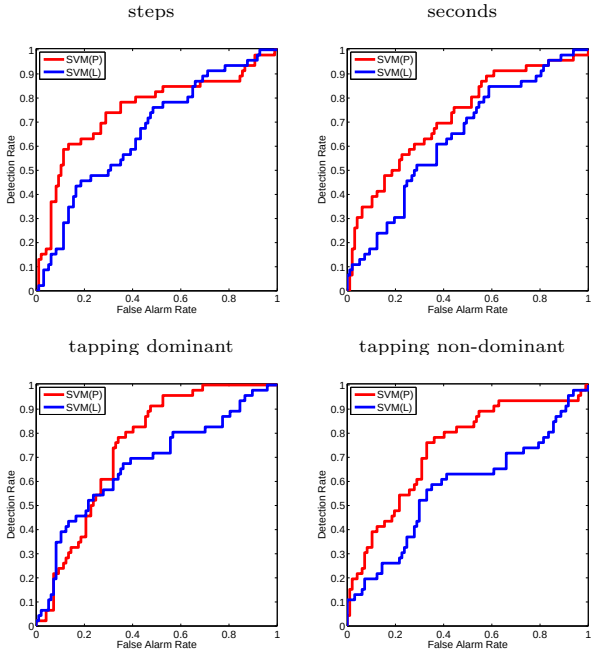

Figure 3. The ROC curve of SVM with two distance measures. SVM(P): SVM with proposed distance. SVM(L): SVM with least-square features.

- The simple heuristic features such as the intercept and the slope cannot capture enough information for the classification.
- The feature extraction is not robust enough for the sparse and noisy observations.

5.2. EEG-based Image Target Detection

The system reported here exploits the perceptual capabilities of expert humans for searching objects of interest (e.g., a golf course in a satellite image) within large image sets. The technique uses event related potentials (ERPs), neural signals linked to critical events, such as interesting/novel visual stimuli. The basic idea of the ERP-based image triage system is to collect electroencephalograph (EEG) signals from a subject's scalp when he or she performs visual target detection, and then detect the ERPs associated with the target

stimuli. We focus on single-trial ERP detection using 32 EEG sensors, which is challenging due to the low signal-to-noise ratio.

This detection task is then boiled down to classifying the EEG segments into target-associated EPRs and distractors. After proper alignment and sampling, the EEG segments are transformed into synchronized sequence of length 4128, which are denoted $\mathbf{y}_i$ for each individual trial i. In this experiment, we collected the EEG data from three human experts, each of them performed 1 training session and 7 test sessions. In each training session, the human expert was fed with ∼600 images with ∼50 targets among them. In each test session, there are 1-4 targets within ∼3000 distractors. Fig.4 (left panel) shows single-trial EEG signals associated with a target and a distractor stimulus.

Due to the high dimensionality, the EM algorithm will be fairly slow due to the extensive use of inverse of $\mathbf{K}$ (4128×4128). To keep the computation at a reasonable level, we simplify the model by assigning a flat prior to the fixed effect f_0, or equivalently letting $||f||_{\mathcal{H}_0} = 0$ for any f. This simplifying assumption instantly leads to the following results.

- The optimal solution of $\mathbf{f}_0$ is simply the data mean $\mathbf{f}_0 = \frac{1}{k}\sum_{i=1}^{k} \mathbf{y}_i$, as shown in Fig.4 (right panel).
- The data likelihood is independent of σ^2 as long as it is less than the smallest eigenvalue of $\hat{\mathbf{K}} = \frac{1}{k}\sum_{i=1}^{k}(\mathbf{y}_i - \mathbf{f}_0)(\mathbf{y}_i - \mathbf{f}_0)^T$.

Based on the above two results, we can pick a σ and then calculate the optimal covariance $\mathbf{K}$ with Eq.(28) in one iteration.

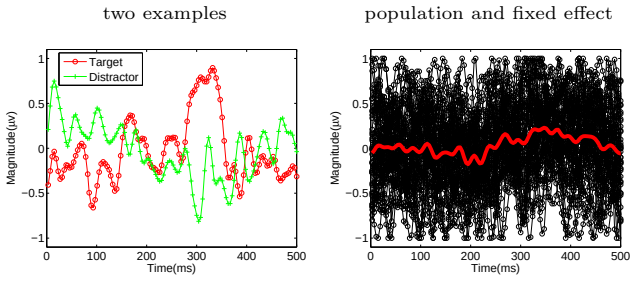

Figure 4. EEG data and the fit mixed-effect model. Left panel: Example of target-associated and distractor-associated EEG signals. Right panel: The population of EEG signals (black –○–) and the fit $\mathbf{f}_0$ (red curve).

Once the optimal $\mathbf{f}_0$ and $\mathbf{K}$ are obtained, the distance between any time series i and j can be calculated using Eq.(14). In addition to directly using the distance, we isometrically embed the time series $\{\mathbf{y}_i\}$ into Euclidean space while preserving the distance expressed in Eq.(14). The embedded vectors, called *ISO feature*, will then be used directly in linear classifiers. One obvious choice is the non-degenerated linear transformation

$$\mathbf{x}_i = \mathbf{K}^{1/2}(\mathbf{K} + \sigma^2\mathbb{I})^{-1}\mathbf{y}_i \tag{30}$$

where $\mathbf{K}^{\frac{1}{2}}$ could be any matrix $\mathbf{A} \in \mathbb{R}^{N\times N}$ with $\mathbf{A}\mathbf{A}^T = \mathbf{K}$. We tested both the proposed distance and the (squared) Euclidean distance [4] $||\mathbf{y}_i - \mathbf{y}_j||^2$ as the distance term d_{ij} in the Gaussian kernel $\mathbf{G}$ and compared the performance of the SVM with the two distance measures. In addition, we also tried a linear logistic classifier (LLC) with both the raw feature $\mathbf{y}_i$ and ISO feature $\mathbf{x}_i$ as the input. In our experiment, the SVM parameters and kernel width were selected using 10-fold cross validation.

Due to the extremely low probability of targets and the high cost of misdetection, we aim for zero-miss and minimum false alarm rate (MFAR), which is defined as the percentage of false alarms among all classifications while all targets are correctly detected. We test both SVM and LLC on the 21 ($=3 \times 7$) test sessions. Table 1 summarizes the detection results when different distance or features are used. The criteria of comparison include the average MFAR across the 21 sessions, the number of sessions with low MFAR ($\leq 10\%$)and very low MFAR ($\leq 2\%$). Clearly, the LLC with ISO features outperforms the LLC with raw feature by giving low average MFAR, more low MFAR sessions, and more very low MFAR sessions. The story is similar when using SVM as the classifier: the proposed distance outperforms the the Euclidean distance on all three criteria.

Clearly the temporal structure is important in describing the EEG signal, and thus plays a crucial role in deciding the distances between EEG time series. The proposed distance measure successfully incorporates the temporal structure information learnt with a rather simple algorithm, and yields significantly better classification than the Euclidean distance that simply adds the index-by-index differences.

6. Related Work

The connection between Bregman divergence and exponential family is first proposed by (Forster & Warmuth, 2000), and later used by several authors in deriving a proper distance measure for either clustering (Banerjee et al., 2005) or dimension reduction (Collins et al., 2001). Our work also depends heavily on the functional Bregman divergence, an idea first fully explored in (Frigyik et al., 2006). The non-parametric

[4] It would be fair to learn the covariance for a Mahalanobis distance. However, we have not performed this comparison for the sake of simplicity.

	Aver. MFAR	$\# \leq 2\%$	$\# \leq 10\%$
LLC(I)	8.99%	12	16
LLC(R)	18.18%	2	12
SVM(P)	4.91%	13	19
SVM(E)	6.31%	7	16

Table 2. The detection results with different classifier settings. *Columns*: AverMFAR: the average MFAR across 21 sessions; #≤ 2%: the number of sessions with MFAR≤ 2%; #≤ 10%:the number of sessions with MFAR≤ 10%. *Rows:* LLC(I): LLC with the ISO feature; LLC(R): LLC with raw feature; SVM(P): SVM with the proposed distance; SVM(E): SVM with Euclidean distance.

mixed-effect model is a natural generalization to the hierarchical Bayesian Gaussian process proposed by (Schwaighofer et al., 2005) to functional form where synchronized and non-synchronized time series can be treated in a unified framework.

This work can be viewed as a particular example of the functional data analysis (Ramsay & Silverman, 1997). Particularly, in an early effort towards the functional PCA (Ramsay & Dalzell, 1991), the authors suggested to map the discrete observations $(\mathbf{t}_i, \mathbf{y}_i)$ to a smooth function through the following regularized regression

$$\hat{f}_i(t) = \arg\min_f \frac{1}{2}\sum_{n=1}^{N_i}(y_{in} - f(t_{in}))^2 + \frac{1}{2}\lambda||\mathcal{D}f||^2, \quad (31)$$

where $\mathcal{D}$ is a linear operator. The solution to Eq.(31) is the expectation in Eq.(9) if we let $\lambda = \sigma^2$ and K be the Green's function of the operator $\mathcal{D}^*\mathcal{D}$. The difference, however, are that (1) our model also assumes a non-zero mean (fixed effect) f_0 and (2) the kernel K is learned from a population of time series.

Abstract

We present an algorithm for on-line, incremental discovery of temporal-difference (TD) networks. The key contribution is the establishment of three criteria to expand a node in TD network: a node is expanded when the node is well-known, independent, and has a prediction error that requires further explanation. Since none of these criteria requires centralized calculation operations, they are easily computed in a parallel and distributed manner, and scalable for bigger problems compared to other discovery methods of predictive state representations. Through computer experiments, we demonstrate the empirical effectiveness of our algorithm.

1. Introduction

Predictive representations (Littman et al., 2002; Jaeger, 2000) are a relatively new group of approaches for expressing and learning grounded knowledge about dynamical systems. These approaches represent the state of a dynamical system as a vector of predictions, based on the hypothesis that important knowledge about the world can be represented strictly in terms of relationships between predictions of observable quantities. In the *predictive state representations* (PSRs) introduced by Littman et al. (2002), each prediction is an estimate of the probability of *tests*, defined as some sequence of observations given a sequence of actions. Sutton and Tanner (2005) proposed another approach for predictive representations, namely Temporal-Difference (TD) networks. TD networks are developed as a generalization of PSRs: in TD networks, each prediction is an estimate of the probability or expected value of some function of future predictions, actions and observations. The predictions can be considered as "answers" to a set of "questions" represented in the TD network.

One important problem in the research of predictive representations is the *discovery problem*, that is, the problem of determining the set of questions (or *core tests*) so that the state of a dynamical system is correctly represented by the vector of predictions for these questions. Many of the existing studies on this problem (Rosencrantz et al., 2004; James & Singh, 2004; Wolfe et al., 2005) utilize off-line discovery and learning on PSRs, and therefore they are hardly applicable to both implementing live-interaction agents and finding corresponding activity in the human brain. There is an on-line discovery algorithm (McCracken & Bowling, 2006) for PSR core tests, but it requires complex operations on a large matrix, such as calculation of the maximum linear independent set, and is therefore not suitable for parallel and distributed computing. As far as we are aware, no algorithm has been proposed for discovery of questions in TD networks. Study of a TD-network discovery algorithm that is suitable for parallel distributed computing would contribute not only to research on predictive representations but also to research on cognitive science by providing a hypothesis for the algorithm actually used in the human brain.

In this study, we propose an algorithm for discovering the correct set of tests by incremental node expansion in a TD network. Our key contribution is in the criteria that we have developed for node expansion: a node is expanded when the node is well-known, independent, and has a prediction error that requires further explanation. To check these criteria, our algorithm maintains the average squared error and average variance for each node, and it introduces a dependency detection network. Since none of these criteria requires centralized operations such as calculation of linear independence in the whole representation matrix, they

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

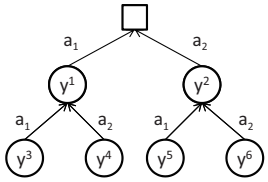

Figure 1. Example TD network we focus in this paper.

are easily computed in a parallel and distributed manner, which is an important property for seeking the algorithm used in the human brain. Although the algorithm has no theoretical guarantee to find the question network (indeed, it is known to be failed in some cases), our simulation experiments demonstrate the empirical effectiveness of our algorithm.

Section 2 reviews PSR and TD network that is necessary to understand our algorithm. Section 3 describes our incremental discovery algorithm. Experiments and results are shown in Section 4. After that, we discuss related work and future directions in Sections 5 and 6.

2. TD Networks

In this section, we make a brief review on TD network, based on the work by Tanner and Sutton (2005a).

The purpose of TD networks is to learn prediction of future observation obtained from the environment. Consider a partially observable environment, which changes its state according to an agent's action $a_t \in \mathcal{A}$ at every time step t, but the agent can only have a partial (and possibly noisy) observation $o_{t+1} \in \mathcal{O}$ of the state. Generally o_t can be a vector consisting of l bits, but in this paper, we consider the case that the observation is a single bit ($l = 1$).

A TD network consists of a set of nodes and links, and each node represents a single scalar prediction. A node has one or more links directed to other nodes or the observation from the environment, which denotes the targets for prediction of the node. A link may have a condition, which indicates that the node is a conditional prediction of the target. This set of nodes and links are called the *question network* since each node is some question about the environment.

As in the previous studies (Tanner & Sutton, 2005b; Tanner & Sutton, 2005a), we focus on a subset of TD networks, in which every node has a single target (hereafter, the parent node) and every link is conditioned with an action. Figure 1 is an example of such a TD network. The node y^1 predicts the observation at the next step if action a_1 is taken. The node y^4 predicts the value of the node y^1 at the next step if action a_2 is taken, and so on.

To provide an answer for the questions asked by the question network, each node in a TD network works also as a function approximator. The inputs to the function approximator of a node are defined by *answer network*, taking values from other nodes, available observations, and actions to be taken. These function approximators are trained so that the output of the nodes becomes the answers to the question asked by the question network. However, to provide an accurate answer, the set of nodes have to be a sufficient representation for the environmental state; in other words, a correct set of questions have to be posed by the question network. The focus of this paper is the discovery of the question network, i.e., to find the structure of the question network that is sufficient for prediction.

Formally, we denote the prediction for node i at time step t as $y_t^i \in [0, 1]$, $i = 1, \ldots, n$. The prediction vector $\mathbf{y}_t = (y_t^1, \ldots, y_t^n)^T$ is given by the answer network:

$$\mathbf{y}_t = \sigma(\mathbf{W}_t \mathbf{x}_t) \quad , \tag{1}$$

where $\mathbf{x}_t \in \Re^m$ is a feature vector, $\mathbf{W}_t$ is a $n \times m$ matrix of modifiable weights, and σ is the S-shaped logistic function $\sigma(s) = (1 + e^{-x})^{-1}$.

The feature vector is a function of the preceding action, observation, and node values:

$$\mathbf{x}_t = \mathbf{x}(a_{t-1}, o_t, \mathbf{y}_{t-1}) \in \mathbb{R}^m \quad . \tag{2}$$

We used the similar form of feature vector as appeared in the work of Tanner and Sutton (2005a); in our experiments, where two actions (L and R) are possible,

$$\mathbf{x}(a, o, \mathbf{y}) = \begin{cases} (o, 1-o, y^1, \ldots, y^n, 0, \ldots, 0)^T & a = \mathrm{L} \\ (0, \ldots, 0, o, 1-o, y^1, \ldots, y^n)^T & a = \mathrm{R} \end{cases} \tag{3}$$

This is equivalent to separate W for each action.

The question network, which gives the target of predictions in terms of the node values at the next time steps, is represented by a $n \times (n + l)$ matrix Z^a and a vector c. Without eligibility traces, the vector of the target values is

$$\mathbf{z}_{t-1} = \mathbf{c}_t \odot \mathbf{Z} \begin{pmatrix} \mathbf{y}_t \\ o_t \end{pmatrix} + \bar{\mathbf{c}}_t \odot \mathbf{y}_{t-1} \quad , \tag{4}$$

where $\odot$ is element-by-element multiplication, and each element of $\mathbf{Z}$, $\mathbf{c}$ and $\bar{\mathbf{c}}$ is:

$$z^{ij} = \begin{cases} 1 & y^i \text{ is the parent node of } y^j \\ 0 & \text{otherwise} \end{cases} , \tag{5}$$

$$c_t^i = \begin{cases} 1 & a_t \text{ satisfies the node } y^i\text{'s condition} \\ 0 & \text{otherwise} \end{cases} , \tag{6}$$

$$\bar{c}_t^i = 1 - c_t^i \quad . \tag{7}$$

The elements of Z are assigned so that $z_{t-1}^i = y_t^{p(i)}$ for any i with $c_t^i = 1$, where $p(i)$ is the parent node of i.

On the other hand, if $c_t^i = 0$, $z_{t-1}^i = y_{t-1}^i$, and the TD error of the node becomes zero so that only the weights for the nodes that satisfy the condition are updated.

In this study we employ eligibility traces (Tanner & Sutton, 2005a), which is a technique to accelerate learning in TD-error learning by incorporating further prediction into the learning target. In a forward view,

$$\mathbf{z}_{t-1} = \mathbf{c}_t \odot \mathbf{Z}(\lambda \mathbf{z}_t + (1-\lambda)\mathbf{y}_t) + \bar{\mathbf{c}}_t \odot \mathbf{y}_{t-1} \quad , \quad (8)$$

where $\lambda \in [0,1]$ is a parameter that controls the balance of temporally distant results in the learning target. When $\lambda = 0$, eq. (8) is equivalent to eq. (4), and no eligibility traces are used.

However, this formula recursively contains future values of z, and it is not easy to be calculated on-line. Tanner and Sutton (2005a) proposes an algorithm that performs on-line update of the weight vector to make the equivalent update as (8). Then each component w_t^{ij} of $\mathbf{W}_t$ is updated by the learning rule:

$$\begin{aligned} w_{t+1}^{ij} &= w_t^{ij} + \alpha(z_t^i - y_t^i)\frac{\partial y_t^i}{\partial w_t^{ij}} \\ &= w_t^{ij} + \alpha(z_t^i - y_t^i)y_t^i(1-y_t^i)x_t^j \quad , \end{aligned} \quad (9)$$

in which the second line is derived from eq. (1).

Roughly, the operation of a TD network proceeds by repeating the following steps: (1) Choose an action a_{t-1} and receive an observation o_t from the environment. (2) Operate the answer network, i.e., calculate feature vector $\mathbf{x}_t = \mathbf{x}(a_{t-1}, o_t, \mathbf{y}_{t-1})$ and obtain the new predictions $\mathbf{y}_t = \sigma(\mathbf{W}_t\mathbf{x}_t)$. (3) Use the question network to obtain the target value for the previous predictions $\mathbf{z}_{t-1} = \mathbf{z}(\mathbf{y}_t, o_t)$, and update the weights W according to the TD error $\mathbf{z}_{t-1} - \mathbf{y}_{t-1}$. For details, readers should consult the original paper of the TD network (Sutton & Tanner, 2005) to see subtle points, such as the precise order of calculation.

3. On-line Discovery Algorithm

We propose an algorithm that performs on-line discovery of the question network. Our algorithm starts with the minimal network, which consists of the observation node and a set of prediction nodes for the observation nodes, one for each action. During learning, the algorithm grows the network by *expanding* leaf nodes by adding a set of prediction nodes for the node. Intuitively, a node is expanded when the following three criteria holds:

1. **The node is well-known**: The agent has sufficient experience to learn the node. This criterion prevents relatively unexplored nodes to be expanded.

2. **The node is independent**: The prediction of the node cannot be calculated in terms of other, formerly known node values. In terms of PSRs, the node represents a core test. This criterion avoids redundant expansion of the nodes.

3. **The node's error requires further explanation**: The node's prediction error is not smaller than expected from the prediction error of the node's parent node. This criterion chooses the node that has the best descriptive power for the error in the parent node, and stops expansion when unpredictability is solved.

In the following, we first describe the variables that our algorithm maintains to check these criteria, and we present more detailed conditions for the criteria.

3.1. Variables

3.1.1. Dependency Detection Network

Our algorithm uses a dependency detection network, which tries to represent a prediction of the node y^i in terms of observation o and values of the nodes with younger index y^j $(j < i)$. If the network succeeds to represent y^i with small error, we can see that y^i is dependent to the predictions with younger index (namely, not a core test of PSRs), and exclude it from the candidate of node expansion. Otherwise, we can assume that y^i is an independent node. Note that it corresponds to the core test in non-linear PSRs (Rudary & Singh, 2004) because the nodes in TD networks correspond to e-tests in non-linear PSRs (Sutton & Tanner, 2005) and we use sigmoidal function in the answer network.

Formally, the dependency detection network is represented by $\mathbf{D}_t$, a $n \times (n+l)$ matrix of modifiable weights. In the matrix d^{ij} is restricted to zero if $i \geq j - l$. The output of the network is $\mathbf{d}_t = \sigma(\mathbf{D}_t \binom{o_t}{\mathbf{y}_t})$. The network is trained so that $\mathbf{d}_t$ is close to $\mathbf{y}_t$; in other words, the network tries to represent a prediction of the node y^i in terms of observation o and predictions with nodes with smaller index y^j $(j < i)$. Since the indices of the nodes are numbered in order, newly expanded nodes are always given higher indices, and are not used by the dependency detection network for describing older nodes with lower indices.

Each component d_t^{ij} of $\mathbf{D}_t$ is updated by the learning rule similar to eq. 9:

$$d_{t+1}^{ij} = d_t^{ij} + \alpha_D(y_t^i - d_t^i)\frac{\partial d_t^i}{\partial d_t^{ij}} \quad (10)$$

$$= d_t^{ij} + \alpha_D(y_t^i - d_t^i)d_t^i(1-d_t^i)y_t^j \quad (11)$$

But the update is limited in the area $i < j - l$. We assign the learning rate of the dependency detection network α_D to be larger than that of the answer network α to allow the dependency detection network to track changes in the calculated node values during the learning of the answer network (as long as the values are dependent).

3.1.2. Average Errors

Our algorithm gathers statistical information about the prediction and error of the TD network and the dependency detection network. To allow on-line learning, the statistical variables are calculated in forms of exponential moving averages:

$$\mathbf{y}_{t+1}^{\mathrm{LERR}} = \rho_2 \mathbf{y}_t^{\mathrm{LERR}} + (1-\rho_2)((\mathbf{z}_t - \mathbf{y}_t) \odot (\mathbf{z}_t - \mathbf{y}_t)) \quad (12)$$

$$\mathbf{d}_{t+1}^{\mathrm{SERR}} = \rho_1 \mathbf{d}_t^{\mathrm{SERR}} + (1-\rho_1)((\mathbf{y}_t - \mathbf{d}_t) \odot (\mathbf{y}_t - \mathbf{d}_t)) \quad (13)$$

$$\mathbf{d}_{t+1}^{\mathrm{LERR}} = \rho_2 \mathbf{d}_t^{\mathrm{LERR}} + (1-\rho_2)((\mathbf{y}_t - \mathbf{d}_t) \odot (\mathbf{y}_t - \mathbf{d}_t)) \quad (14)$$

where $\mathbf{d}_t^{\mathrm{SERR}}$ is a short-term average of squared prediction errors, $\mathbf{d}_t^{\mathrm{LERR}}$ is a long-term average of squared prediction errors, and $0 < \rho_1 < \rho_2 < 1$ is a temporal factor. When a node y^i is added to the network, statistical variables are initialized as $y^{\mathrm{LERR}\ i} = d_t^{\mathrm{SERR}\ i} = d_t^{\mathrm{LERR}\ i} = 1.0$so that the variables show larger errors during the initial period of the node.

Without eligibility traces, the target variable $\mathbf{z}_t$ is available at time $t+1$, so these parameters are easily calculated on-line. However, since eq. (12) contains quadratic term for $\mathbf{z}_t$, on-line calculation technique with eligibility traces such as used in Tanner and Sutton's work (2005a) cannot be used directly. Our implementation keeps the record of last k steps of node values, where k is the maximum depth of the current question network, and calculates errors of $\mathbf{y}_t$ and $\mathbf{d}_t$ at time $t+k$.

3.2. Expansion Criteria

Using these variables, we check the criteria described in the beginning of Section 3 as follows. The criteria are checked for every time step. Since all criteria are described on exponential moving averages, the precise timing of criteria check and node expansion is not important; it should be inserted somewhere in the TD(λ) network learning algorithm (Tanner & Sutton, 2005a). The expansion criterion are designed to avoid redundant expansion as much as possible because no shrinking criterion is given.

3.2.1. The node is well-known

To avoid expanding relatively unexplored nodes, we use the following criteria to determine whether the node y^i is well-known.

- Learning error is not in a decreasing trend (we assume the error is always decreasing during initial learning phase).
- Learning error of the node gets smaller compared with that of its parent node.

In formal representation,

$$d_t^{\mathrm{SERR}\ i} \geq d_t^{\mathrm{LERR}\ i} \quad and \quad (15)$$

$$d_t^{\mathrm{LERR}\ i} \leq d_t^{\mathrm{LERR}\ p(i)} . \quad (16)$$

If $p(i)$ is the observation bit, then $d_t^{\mathrm{LERR}\ p(i)}$ is considered as 1 (the largest possible value).

Eq. 15 works because these variables, representing moving averages of errors, are initialized with the highest possible value (see Section 3.1.2). Thus it is expected that the short-term average error variables stay lower than the long-term ones until the end of the initial learning period, in which the learning error is constantly decreasing.

Eq. 16 is usually satisfied with a plenty amount of experience because the dependency network has no connection from a child node to a parent node. The parent node always has fewer inputs in the dependency network than the child node; if the child node has an unexplained dependency (large $d_t^{\mathrm{LERR}\ i}$), it is likely that the parent node also has an unexplained dependency.

3.2.2. The node is independent

To prevent dependent (non-core test) nodes to be expanded, we require that the learning error in the dependency detection network is not small.

$$d_t^{\mathrm{LERR}\ i} \geq \theta_1 \quad (17)$$

θ_1 is a threshold parameter that controls the requirement for independence.

When all the nodes that match this criterion are expanded, then all the leaf nodes in the question network becomes dependent nodes, and no further expansion occurs. Thus, this criterion is equivalent to the assumption that independent (core test) nodes does not exist as a child of dependent (non-core test) nodes.

3.2.3. The node's error requires further explanation

If the prediction error of a node is larger than expected from its parent node, it is reasonable to require further prediction on the node to reduce the error. Otherwise, we can infer that the error in the parent node has other causes (e.g. another prediction node with different action conditions has large prediction error), and further

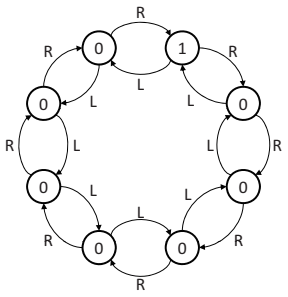

Figure 2. 8-state ring world. The digit in a node represents observation from the state, and edge labels denote actions.

Table 1. Tests for various θ_1 and θ_2 values in the 8-state ring world. Values are [final number of nodes] / [steps ($\times 10^4$) until learned (MSE reduces less than 10^{-4})].

$\theta_1 \backslash \theta_2$	0.005	0.0075	0.01	0.0125	0.015
0.001	18/47	20/46	16/49	6/–	6/–
0.002	18/49	18/48	18/51	6/–	6/–
0.003	18/53	18/55	16/55	6/–	6/–
0.004	18/54	18/57	16/58	6/–	6/–
0.005	18/59	18/59	16/60	6/–	6/–

prediction for the node is less important to reduce the error of the final prediction for the observation.

In case that the parent node $p(i)$ is purely probabilistic, error distribution of the $p(i)$'s child nodes is proportional to the probability that the conditions of the nodes are matched; the following condition checks that the error of the node is greater than that:

$$y_t^{\mathrm{LERR}\ i} \geq \gamma \frac{\#y^i}{\#y^{p(i)}} y_t^{\mathrm{LERR}\ p(i)} + \theta_2 \quad , \qquad (18)$$

where $\#y^i$ is the frequency that the conditions on the chain from the observation bit to node y^i is matched (thus, $\frac{\#y^i}{\#y^{p(i)}}$ is the relative probability that the condition of the node is matched). If $p(i)$ is the observation bit, then $y_t^{\mathrm{LERR}\ p(i)}$ is assumed to be zero. θ_2 is a threshold parameter that controls tolerance for noise.

4. Experiments

To test the efficiency of our algorithm, we conducted a series of computer experiments on n-state ring world ($n = 5, 8$) (Tanner & Sutton, 2005b). Figure 2 illustrates 8-state ring world. There are two observations, 0 or 1, and two actions, L and R.

Since the ring worlds contains only deterministic state transitions and observations, we also tested our algorithm on some standard probabilistic POMDP environments taken from repository (Cassandra, 1999). Among them, environments with one-bit observation are used, and adapted to non-reward situation (we followed a previous work that describe details; McCracken, 2005).

We generated a sequence of experience by a uniform random policy and applied our algorithm online. Through all experiments we used $\rho_1 = 0.99$, $\rho_2 = 0.999$, $\alpha_D = 0.2$, $\lambda = 0.9$, $\theta_1 = 0.0045$, and $\theta_2 = 0.0005$. α is initialized with 0.1, and after 800,000 steps, α is halved with every 100,000 step. We measured the error of the prediction for the selected action, compared to the oracle (observation probability calculated from the structure of the environment), and the mean squared errors for every 10,000 steps are plotted.

Figures 3(a) and 3(b) are the results in 5- and 8-state ring worlds. We can see that the number of nodes in the TD network increases as a result of node expansion until the prediction error decreases. This indicates that nodes in the TD-networks are expanded only when it is required.

We made additional tests with various parameters θ_1 and θ_2 on the 8-state ring world (Table 1). We found that θ_2 affects the final number of nodes. With larger θ_2, algorithm failed to make a required node expansion; with smaller θ_2, the algorithm made some spurious node expansions (though the learning was successful). On the other hand, θ_1 mainly affects the learning time, but less related to the number of nodes.

Figures 3(c) to 3(f) show the results of our algorithm in other well-known POMDP environments. Our algorithm has successfully learned predictions in all cases. However, we found that the initial form of the TD network without node expansion can learn equally well (compared to the case started with a large TD network, which is mechanically generated by expanding all nodes), due to the high generalization capacity of TD-network with sigmoid function. Thus these experiments are not helpful for evaluating our discovery algorithm. However, we see that some node expansions are occurred in these experiments. This indicates that our algorithm sometimes makes spurious node expansions, especially in these probabilistic environments.

We also evaluated the criteria we selected in terms of the discovered question network for the 8-state ring world. Figure 4 compares the mean square errors and the number of nodes in the discovered network with various settings of criteria (in these experiments α is kept constant to 0.1). Although the prediction error approaches to zero on all conditions, increase in the number of nodes is observed if any one of the criteria is removed.

Figure 5 further examines the difference of the discovered TD network. In the TD network discovered using all of the criteria (Figure 5(a)), all the expanded nodes

(f) Network

Figure 3. Results of experiments. X-axis shows time steps ($\times 10^5$)

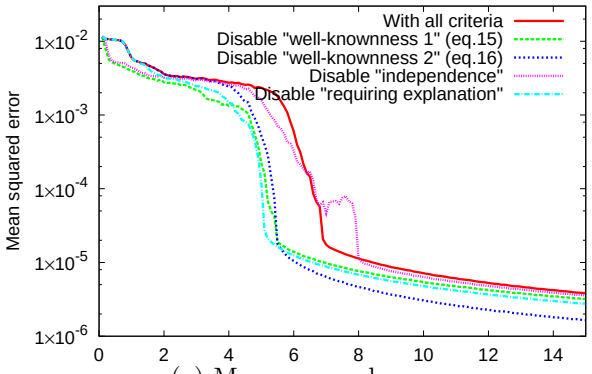
are independent of each other, thus the discovered network is the best network for the 8-state ring world that can be discovered by our algorithm. This shows clear contrast to TD network discovered solely by dependency detection network, shown in Figure 5(b). Although this network has correctly learned to predict the 8-state ring world, some spurious node expansions are observed. This indicates that the dependency detection network is not powerful enough to choose the right node to be expanded, and shows importance of other criteria in our algorithm.

5. Discussion

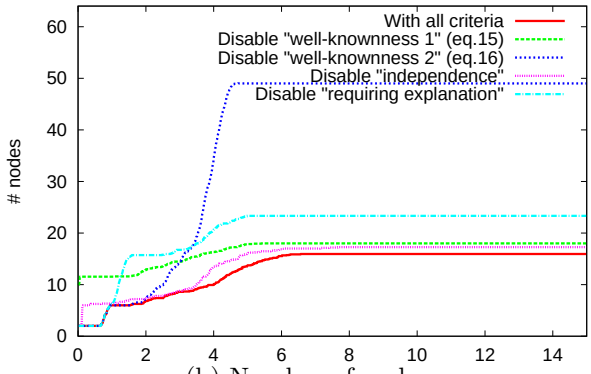
The algorithm we have presented has some limitations. It seems unavoidable because the algorithm has to make inference using an incomplete question network. In this section, we discuss some of the limitations that arose in our approach.

5.1. Deep Dependency

In our algorithm, Criterion 3 (requires more explanation) are devoted for distinguishing apparently unpredictable events, caused by an incomplete question net-

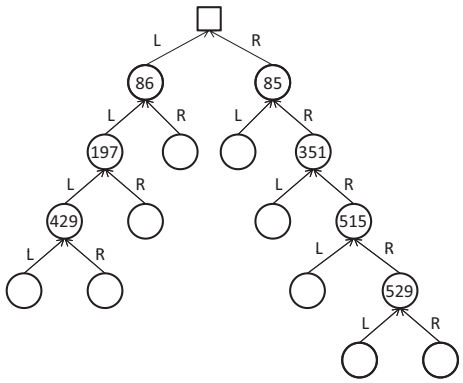


(a) Mean squared error

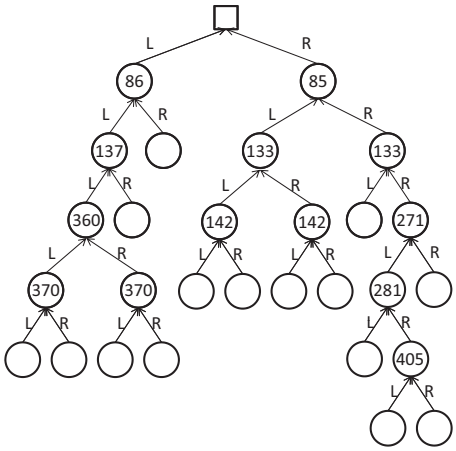


(b) Number of nodes

Figure 4. Results of experiments (average of 30 trials) on 8-state ring world with disabled criteria.



(a) With all criteria



(b) Without criterion "requires further explanation"

work, from inherently random events. However, we can imagine cases in which this criterion does not work well, especially when the observation depends only on the actions several steps before.

As an example, suppose an n-step delay world: $\mathcal{A} = \mathcal{O} = \{0, 1\}$, and the agent observes its own action with n-step delay. If the agent chooses actions randomly, then the observation is also random string. Moreover, unless the depth of the question network reaches n, the agent can predict nothing. For $n \geq 2$, the nodes in a question network are likely to fail satisfying Criterion 3, and as a result, the algorithm fails to achieve the correct test set for the environment.

A partial solution may be to introduce active learning (planned exploration). In the example above, if the agent could adopt some biased choice of actions for a while, one would observe informative result that might satisfy Criterion 3.

5.2. Selection of Expanding Node

The algorithm always expands the node that requires more explanation, but it is possible that the node is not the best one to be expanded. The algorithm depends on an assumption that, if there is a better node to be expanded, the node also satisfies the expansion criteria sooner or later. We need to work for some theoretical support for the assumption. However, if the assumption is correct, the algorithm may perform some spurious expansion due to its distributed-processing nature. A complete solution would require either centralized processing or node shrinking.

5.3. Parameter Selection

The algorithm depends on a number of parameters. Our selection of parameters seems working for the tested problems, but not guaranteed for others. In particular, the algorithm is sensitive to θ_2, a threshold value used in Criterion 3 for distinguishing apparently unpredictable events from inherently random events. Due to the limitation of our approach, it seems impossible to provide a universal parameter set for producing the minimum network for any environment; a better solution would be to use lower thresholds to overgen-

erate the question network and shrink it afterwards.

5.4. Handling Wider Observation

In this paper, we considered only the simple case with one observation bit ($l = 1$). When $l \geq 2$, it would be necessary to consider sets of nodes that share a common action conditions and associated to different observations, and to expand all nodes in a set simultaneously. In addition, it is necessary to extend our criteria have to handle the node sets.

6. Related Work

McCracken and Bowling (2006) proposes the on-line discovery and learning algorithm for predictive state representation. However, their algorithm has to keep substantially long (in their example, 1000 steps) history in memory and calculate linear independency, and requires quite complex efforts to normalize the probability in their representation. On the other hand, our algorithm requires only a small amount of memory (up to the size required for eligibility traces) and, thanks to the sigmoidal function used in the TD network, no effort is required to normalize the result. We argue that these differences cause larger difference in calculation costs in a complex environment.

7. Summary

We presented an algorithm for on-line, incremental discovery of temporal-difference (TD) networks. The key contribution is the establishment of criteria to expand a leaf node in TD network: the algorithm expands a node when the node is well-known, independent, and has a prediction error that requires further explanation. Since none of these criteria requires centralized calculation operations, they can be computed in a parallel and distributed manner. Through computer experiments on n-state ring worlds, we demonstrated the empirical effectiveness of our algorithm.

Among the future work the most important is to evaluate our algorithm on various environments for comparison with other discovery algorithms. Agent planning with TD network should be also studied to combine with our algorithm for developing an agent that explores environments (Bowling et al., 2006).

Abstract

Positive definite kernels on probability measures have been recently applied in structured data classification problems. Some of these kernels are related to classic information theoretic quantities, such as mutual information and the Jensen-Shannon divergence. Meanwhile, driven by recent advances in Tsallis statistics, nonextensive generalizations of Shannon's information theory have been proposed. This paper bridges these two trends. We introduce the *Jensen-Tsallis q-difference*, a generalization of the Jensen-Shannon divergence. We then define a new family of nonextensive mutual information kernels, which allow weights to be assigned to their arguments, and which includes the Boolean, Jensen-Shannon, and linear kernels as particular cases. We illustrate the performance of these kernels on text categorization tasks.

1. Introduction

There has been recent interest in kernels on probability distributions, to tackle several classification problems (Moreno *et al.*, 2003; Jebara *et al.*, 2004; Hein & Bousquet, 2005; Lafferty & Lebanon, 2005; Cuturi *et al.*, 2005). By mapping data points to fitted distributions in a parametric family where a kernel is defined, a kernel is automatically induced on the original input space. In text categorization, this appears as an alternative to the Euclidean geometry inherent to the usual bag-of-words vector representations. In fact, approaches that map data to a statistical manifold, where well-motivated non-Euclidean metrics may be defined (Lafferty & Lebanon, 2005), outperform SVM classifiers with linear kernels (Joachims, 1997). Some of these kernels have a natural information theoretic interpretation, creating a bridge between kernel methods and information theory (Cuturi *et al.*, 2005; Hein & Bousquet, 2005).

We reinforce that bridge by introducing a new class of kernels rooted in *nonextensive* (NE) information theory. The Shannon and Rényi entropies (Rényi, 1961) share the *extensivity* property: the joint entropy of a pair of independent random variables equals the sum of the individual entropies. Abandoning this property yields the so-called NE entropies (Havrda & Charvát, 1967; Tsallis, 1988), which have raised great interest among physicists in modeling certain phenomena (*e.g.*, long-range interactions and multifractals) and as generalizations of Boltzmann-Gibbs statistical mechanics (Abe, 2006). NE entropies have also been recently used in signal/image processing (Li *et al.*, 2006) and other areas (Gell-Mann & Tsallis, 2004).

The main contributions of this paper are:

- Based on the new concept of q-convexity and a related q-Jensen inequality, we introduce the *Jensen-Tsallis q-difference*, a NE generalization of the Jensen-Shannon (JS) divergence.
- We propose a broad family of positive definite (pd) kernels, which are interpretable as NE mutual information (MI) kernels. This family ranges from the Boolean to the linear kernels, and also includes the JS kernel (Hein & Bousquet, 2005).
- We extend results of Hein and Bousquet (2005) by proving positive definiteness of kernels based on the unbalanced JS divergence. As a side note, we

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

show that the parametrix approximation of the multinomial diffusion kernel introduced by Lafferty and Lebanon (2005) is *not* pd in general.

Our main purpose is to present new theoretical insights about kernels on measures by unifying some well-known instances into a common parametrized family. This family allows reinterpreting these kernels in light of NE information theory, a connection that to our knowledge had not been presented before. The fact that some members of this family are novel pd kernels leads us to include a set of text categorization experiments that illustrates their effectiveness.

The paper is organized as follows. Sec. 2 reviews NE entropies, while Jensen differences and divergences are discussed in Sec. 3. In Sec. 4, the concepts of q-differences and q-convexity are introduced and used to define the Jensen-Tsallis q-difference. Sec. 5 presents the new family of entropic kernels. Sec. 6 reports experiments on text categorization and Sec. 7 presents concluding remarks and future research directions.

Although, for simplicity, we focus on discrete distributions on finite sets, most results are valid in arbitrary measured spaces, as shown by Martins *et al.* (2008).

2. Nonextensive Information Theory

Let X denote a random variable (rv) taking values in a finite set $\mathcal{X} = \{x_1, \ldots, x_n\}$ according to a probability distribution P_X. An entropy function is said to be *extensive* if it is additive over independent variables. For example, the Shannon entropy (Cover & Thomas, 1991), $H(X) \triangleq -\mathbb{E}[\ln P_X]$, is extensive: if X and Y are independent, then $H(X,Y) = H(X)+H(Y)$. Another example is the family of Rényi entropies (Rényi, 1961), parameterized by $q \geq 0$,

$$R_q(X) \triangleq \frac{1}{1-q} \ln \sum_{i=1}^{n} P_X(x_i)^q, \tag{1}$$

which includes Shannon's entropy as a special case when $q \to 1$.

In classic information theory, extensivity is considered desirable, and is enforced axiomatically (Khinchin, 1957), to express the idea borrowed from thermodynamics that "independent systems add their entropies." In contrast, the *Tsallis entropies* abandon the extensivity requirement (Tsallis, 1988). These NE entropies, denoted $S_q(X)$, are defined as follows:

$$S_q(X) \triangleq -\mathbb{E}_q(\ln_q P_X) = \frac{1}{q-1}\left(1 - \sum_{i=1}^{n} P_X(x_i)^q\right), \tag{2}$$

where $\mathbb{E}_q(f) \triangleq \sum_{i=1}^{n} P(x_i)^q f(x_i)$ is the unnormalized *q-expectation*, and $\ln_q(y) \triangleq (y^{1-q}-1)/(1-q)$ is the so-called *q-logarithm*. It is noteworthy that when $q \to 1$, we get $\mathbb{E}_q \to \mathbb{E}$, $\ln_q \to \ln$, and $S_q \to H$; *i.e.*, the family of Tsallis entropies also includes Shannon's entropy. For the Tsallis family, when X and Y are independent, extensivity no longer holds; instead, we have

$$S_q(X,Y) = S_q(X) + S_q(Y) - (q-1)S_q(X)S_q(Y), \tag{3}$$

where the parameter $q \geq 0$ is called *entropic index*.

While statistical physics has been the main application of Tsallis entropies, some attempts have been made to produce NE generalizations of classic information theory results (Furuichi, 2006). As for the Shannon entropy, the Tsallis *joint* and *conditional* entropies are defined as $S_q(X,Y) \triangleq -\mathbb{E}_q[\ln_q P_{XY}]$ and $S_q(X|Y) \triangleq -\mathbb{E}_q[\ln_q P_{X|Y}]$, respectively, and follow a chain rule $S_q(X,Y) = S_q(X) + S_q(Y|X)$. Similarly, Furuichi (2006) defines the Tsallis MI as

$$I_q(X;Y) \triangleq S_q(X) - S_q(X|Y) = I_q(Y;X), \tag{4}$$

generalizing (for $q > 1$) Shannon's MI. This NE version of the MI underlies one of the central contributions of this paper: the Jensen-Tsallis q-difference (Sec. 4).

For reasons that will become clear in Sec. 5, it is convenient to extend the domain of Tsallis entropies to *unnormalized* measures, *i.e.*, in $\mathbb{R}^n_+ \triangleq \{\boldsymbol{\mu} \in \mathbb{R}^n \mid \forall i\ \mu_i \geq 0\}$, but not necessarily in the probability simplex $\mathbb{P}^{n-1} \triangleq \{\mathbf{p} \in \mathbb{R}^n \mid \sum_{i=1}^{n} p_i = 1,\ \forall i\ p_i \geq 0\}$. The Tsallis entropy of a measure $\boldsymbol{\mu}$ in $\mathbb{R}^n_+$ is[1]

$$S_q(\boldsymbol{\mu}) \triangleq -\sum_{i=1}^{n} \mu_i^q \ln_q \mu_i = \sum_{i=1}^{n} \varphi_q(\mu_i), \tag{5}$$

where $\varphi_q : \mathbb{R}_+ \to \mathbb{R}$ is given by

$$\varphi_q(y) = -y^q \ln_q y = \begin{cases} -y \ln y, & \text{if } q = 1, \\ (y - y^q)/(q-1), & \text{if } q \neq 1. \end{cases} \tag{6}$$

This extension does not add expressive power, since function (5) is completely determined by its values on $\mathbb{P}^{n-1}$, as shown by the following proposition (the proof is straightforward).

Proposition 1 *The following denormalization formula holds for any $c \geq 0$ and $\boldsymbol{\mu} \in \mathbb{R}^n_+$:*

$$S_q(c\boldsymbol{\mu}) = c^q S_q(\boldsymbol{\mu}) + \varphi_q(c)\|\boldsymbol{\mu}\|_1, \tag{7}$$

where $\|\boldsymbol{\mu}\|_1 \triangleq \sum_{i=1}^{n} \mu_i$ is the ℓ_1-norm of $\boldsymbol{\mu}$.

[1] In the following, we represent normalized and unnormalized measures as vectors in $\mathbb{R}^n$, and we use those as arguments of entropy functions, *e.g.*, we write $H(\boldsymbol{\pi})$ to denote $H(X)$ where $X \sim P(X)$, with $\pi_i = P(x_i)$.

This fact will be used in a constructive way in Sec. 5 to devise a family of pd NE entropic kernels.

3. Jensen Differences and Divergences

Jensen's inequality is at the heart of many important results in information theory. Let the rv Z take values on a finite set $\mathcal{Z}$. Jensen's inequality states that if f is a convex function defined on the convex hull of $\mathcal{Z}$, then $f(\mathbb{E}[Z]) \leq \mathbb{E}[f(Z)]$. The nonnegative quantity $\mathbb{E}[f(Z)] - f(\mathbb{E}[Z])$ is known as *Jensen difference* and has been studied by Burbea and Rao (1982) when $-f$ is some form of generalized entropy. Here, we are interested in the case where $Z \in \{\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_m\}$ is a *random measure*, where each $\boldsymbol{\mu}_j \in \mathbb{R}^n_+$, with probabilities $\boldsymbol{\pi} = (\pi_1, \ldots, \pi_m) \in \mathbb{P}^{m-1}$. The Jensen difference induced by a (concave) generalized entropy Ψ is

$$\begin{aligned} J^{\boldsymbol{\pi}}_{\Psi}(\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_m) &\triangleq \Psi\left(\sum_{j=1}^m \pi_j \boldsymbol{\mu}_j\right) - \sum_{j=1}^m \pi_j \Psi(\boldsymbol{\mu}_j) \\ &= \Psi\left(\mathbb{E}[Z]\right) - \mathbb{E}[\Psi(Z)], \end{aligned} \tag{8}$$

Below, we show examples of Jensen differences that have been applied in machine learning. In Sec. 4, we provide a NE generalization of the Jensen difference.

Jensen-Shannon (JS) Divergence Consider a classification problem with m classes, $Y \in \mathcal{Y} = \{1, \ldots, m\}$, with *a priori* probabilities $\boldsymbol{\pi} = (\pi_1, \ldots, \pi_m) \in \mathbb{P}^{m-1}$. Let $\mathbf{p}_j = (p_{j1}, \ldots, p_{jn}) \in \mathbb{P}^n$ for $j = 1, \ldots, m$, where $p_{ji} \triangleq P(X = x_i | Y = j)$, be the corresponding class-conditional distributions.

Letting Ψ in (8) be H, the Shannon entropy, the resulting Jensen difference $J^{\boldsymbol{\pi}}_H(\mathbf{p}_1, \ldots, \mathbf{p}_m)$ is known as the JS divergence of $\mathbf{p}_1, \ldots, \mathbf{p}_m$, with weights $\pi_1, \ldots, \pi_m$ (Burbea & Rao, 1982; Lin, 1991). In this instance of the Jensen difference,

$$J^{\boldsymbol{\pi}}_H(\mathbf{p}_1, \ldots, \mathbf{p}_m) = I(X; Y), \tag{9}$$

where $I(X;Y) = H(X) - H(X|Y)$ is the MI between X and Y (Banerjee *et al.*, 2005).

For $m = 2$ and $\boldsymbol{\pi} = (\frac{1}{2}, \frac{1}{2})$, we denote the ensuing $J_H^{(\frac{1}{2}, \frac{1}{2})}(\mathbf{p}_1, \mathbf{p}_2)$ as $JS(\mathbf{p}_1, \mathbf{p}_2)$:

$$JS(\mathbf{p}_1, \mathbf{p}_2) = H((\mathbf{p}_1 + \mathbf{p}_2)/2) - (H(\mathbf{p}_1) + H(\mathbf{p}_2))/2.$$

It can be shown that that $\sqrt{JS}$ satisfies the triangle inequality and is a *Hilbertian metric*[2] (Endres & Schindelin, 2003; Topsøe, 2000), which has motivated its use in kernel-based machine learning.

[2] A metric $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is Hilbertian if there is some Hilbert space $\mathcal{H}$ and an isometry $f : \mathcal{X} \to \mathcal{H}$ such that $d^2(x, y) = \langle f(x) - f(y), f(x) - f(y) \rangle_{\mathcal{H}}$ holds for any $x, y \in \mathcal{X}$ (Hein & Bousquet, 2005).

Jensen-Rényi (JR) Divergence Let $\Psi = R_q$, which is concave for $q \in [0, 1)$; then, (8) becomes

$$J^{\boldsymbol{\pi}}_{R_q}(\mathbf{p}_1, \ldots, \mathbf{p}_m) = R_q\left(\mathbb{E}[\mathbf{p}]\right) - \mathbb{E}[R_q(\mathbf{p})]. \tag{10}$$

We call $J^{\boldsymbol{\pi}}_{R_q}$ the JR divergence. When $m = 2$ and $\boldsymbol{\pi} = (1/2, 1/2)$, we write $J^{\boldsymbol{\pi}}_{R_q}(\mathbf{p}) = JR_q(\mathbf{p}_1, \mathbf{p}_2)$, where

$$JR_q(\mathbf{p}_1, \mathbf{p}_2) = R_q\left(\frac{\mathbf{p}_1 + \mathbf{p}_2}{2}\right) - \frac{R_q(\mathbf{p}_1) + R_q(\mathbf{p}_2)}{2}.$$

The JR divergence has been used in signal processing applications (Karakos *et al.*, 2007). We show in Sect. 5.3 that $\sqrt{JR_q}$ is also an Hilbertian metric.

Jensen-Tsallis (JT) Divergence Divergences of the form (8), with $\Psi = S_q$, are known as JT divergences (Burbea & Rao, 1982) and were recently used in image processing (Hamza, 2006). Unlike the JS divergence, the JT divergence lacks a MI interpretation; in Sec. 4, we introduce an alternative to the JT divergence, which is interpretable as a NE MI in the sense of Furuichi (2006).

4. Jensen q-Differences

We now introduce *Jensen q-differences*, a generalization of Jensen differences. As described shortly, a special case of the Jensen q-difference is the *Jensen-Tsallis q-difference*, which is an NE generalization of the JS divergence, and provides the building block for the NE entropic kernels to be introduced in Sec. 5. We begin by introducing the concept of "q-convexity", which satisfies a Jensen-type inequality.

Definition 1 *Let $q \in \mathbb{R}$ and $\mathcal{X}$ a convex set. A function $f : \mathcal{X} \to \mathbb{R}$ is* q-convex *if, for any $x, y \in \mathcal{X}$ and $\lambda \in [0, 1]$,*

$$f(\lambda x + (1 - \lambda) y) \leq \lambda^q f(x) + (1 - \lambda)^q f(y). \tag{11}$$

f is q-concave *if $-f$ is q-convex.*

Naturally, 1-convexity is the usual convexity. The next proposition states the q-Jensen inequality and is easily proved by induction, like the standard Jensen inequality (Cover & Thomas, 1991). It also states that the property of q-convexity gets stronger as q increases.

Proposition 2 *If $f : \mathcal{X} \to \mathbb{R}$ is q-convex and $f \geq 0$, then, for any $n \in \mathbb{N}$, $x_1, \ldots, x_n \in \mathcal{X}$ and $\boldsymbol{\pi} \in \mathbb{P}^{n-1}$:*

$$f\left(\sum_{i=1}^n \pi_i x_i\right) \leq \sum_{i=1}^n \pi_i^q f(x_i). \tag{12}$$

Moreover, if $q \geq r \geq 0$, we have:

$$f \text{ is } q\text{-convex} \quad \Rightarrow \quad f \text{ is } r\text{-convex} \tag{13}$$

$$f \text{ is } r\text{-concave} \quad \Rightarrow \quad f \text{ is } q\text{-concave.} \tag{14}$$

Based on the q-Jensen inequality, we can now consider *Jensen q-differences* of the form $\mathbb{E}_q[f(Z)] - f(\mathbb{E}[Z])$, which are nonnegative if f is q-convex. As in Sec. 3, we focus on the scenario where Z is a random measure and $-f = \Psi$ is an entropy function, yielding

$$\begin{aligned} T^{\boldsymbol{\pi}}_{q,\Psi}(\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_m) &\triangleq \Psi\left(\sum_{t=1}^m \pi_t\, \boldsymbol{\mu}_t\right) - \sum_{t=1}^m \pi_t^q \Psi(\boldsymbol{\mu}_t) \\ &= \Psi\left(\mathbb{E}[Z]\right) - \mathbb{E}_q[\Psi(Z)]. \end{aligned} \quad (15)$$

The Jensen q-difference is a deformation of the Jensen 1-difference (8), in which the second expectation is replaced by a q-expectation. We are now ready to introduce the class of Jensen-Tsallis q-differences.

Jensen-Tsallis q-Differences Consider again the classification problem used in the description of the JS divergence, but replacing the Jensen difference with the Jensen q-difference and the Shannon entropy with the Tsallis q-entropy, *i.e.*, letting $\Psi = S_q$ in (15). We obtain (writing $T^{\boldsymbol{\pi}}_{q,S_q}$ simply as $T^{\boldsymbol{\pi}}_q$):

$$T^{\boldsymbol{\pi}}_q(\mathbf{p}_1, \ldots, \mathbf{p}_m) = S_q(X) - S_q(X|Y) = I_q(X;Y), \quad (16)$$

where $S_q(X|Y)$ is the Tsallis conditional q-entropy, and $I_q(X;Y)$ is the Tsallis MI (cf. (4)). Note that (16) is an NE analogue of (9), *i.e.* the Jensen-Tsallis q-differences are NE mutual informations.

We call $T^{\boldsymbol{\pi}}_q(\mathbf{p}_1, \ldots, \mathbf{p}_m)$ the Jensen-Tsallis q-difference of $\mathbf{p}_1, \ldots, \mathbf{p}_m$ with weights $\pi_1, \ldots, \pi_m$.

When $m = 2$ and $\boldsymbol{\pi} = (1/2, 1/2)$, define $T_q \triangleq T^{(1/2,1/2)}_q$,

$$T_q(\mathbf{p}_1, \mathbf{p}_2) = S_q\left(\frac{\mathbf{p}_1 + \mathbf{p}_2}{2}\right) - \frac{S_q(\mathbf{p}_1) + S_q(\mathbf{p}_2)}{2^q}. \quad (17)$$

Three special cases are obtained for $q \in \{0, 1, 2\}$:

$$\begin{aligned} S_0(\mathbf{p}) &= -1 + \|\mathbf{p}\|_0; & T_0(\mathbf{p}_1, \mathbf{p}_2) &= 1 - \|\mathbf{p}_1 \odot \mathbf{p}_2\|_0 \\ S_1(\mathbf{p}) &= H(\mathbf{p}); & T_1(\mathbf{p}_1, \mathbf{p}_2) &= JS(\mathbf{p}_1, \mathbf{p}_2) \\ S_2(\mathbf{p}) &= 1 - \langle \mathbf{p}, \mathbf{p} \rangle; & T_2(\mathbf{p}_1, \mathbf{p}_2) &= \frac{1}{2} - \frac{1}{2}\, \langle \mathbf{p}_1, \mathbf{p}_2 \rangle \end{aligned}$$

where $\|\mathbf{x}\|_0$ is the number of nonzeros in $\mathbf{x}$, $\odot$ denotes the Hadamard-Schur (elementwise) product, and $\langle \cdot, \cdot \rangle$ is the inner product.

The JT q-difference is an NE generalization of the JS divergence, and some of the latter's properties are lost in general. Since Tsallis entropies are 1-concave, Prop. 2 guarantees q-concaveness only for $q \geq 1$. Therefore, nonnegativity is only guaranteed for JT q-differences when $q \geq 1$; for this reason some authors only consider this range of values (Furuichi, 2006). Moreover, unless $q = 1$ (the JS divergence), it is not generally true that $T^{\boldsymbol{\pi}}_q(\mathbf{p}, \ldots, \mathbf{p}) = 0$ or even that $T^{\boldsymbol{\pi}}_q(\mathbf{p}, \ldots, \mathbf{p}, \mathbf{p}') \geq T^{\boldsymbol{\pi}}_q(\mathbf{p}, \ldots, \mathbf{p}, \mathbf{p})$. For example,

$$\operatorname{argmin}_{\mathbf{p}_1 \in \mathbb{P}^{n-1}} T_q(\mathbf{p}_1, \mathbf{p}_2) \quad (18)$$

can be different from $\mathbf{p}_2$, unless $q = 1$. In general, the minimizer is closer to either the uniform distribution (if $q \in [0, 1)$) or a degenerate distribution[3] (for $q \in (1, 2]$). For these reasons, the term "divergence" is misleading and we use the term "difference." Other properties of JT q-differences (convexity, lower/upper bounds) are studied by Martins *et al.* (2008).

5. Nonextensive Entropic Kernels

Using the denormalization formula (7), we now introduce kernels based on the JS divergence and the JT q-difference, which allow weighting their arguments. In this section, $m = 2$ (kernels involve pairs of measures).

5.1. Background on Kernels

We begin with some basic results on kernels (Schölkopf & Smola, 2002). Below, $\mathcal{X}$ denotes a nonempty set; $\mathbb{R}_+$ denote the nonnegative reals, and $\mathbb{R}_{++} \triangleq \mathbb{R}_+ \setminus \{0\}$.

Definition 2 *Let $\varphi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a symmetric function, i.e., $\varphi(y, x) = \varphi(x, y)$, for all $x, y \in \mathcal{X}$. φ is called a pd kernel if and only if*

$$\sum_{i=1}^n \sum_{j=1}^n c_i\, c_j\, \varphi(x_i, x_j) \geq 0, \quad (19)$$

for any integer n, $x_i, \ldots, x_n \in \mathcal{X}$ and $c_i, \ldots, c_n \in \mathbb{R}$. A symmetric function $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is called a negative definite *(nd) kernel if and only if*

$$\sum_{i=1}^n \sum_{j=1}^n c_i\, c_j\, \psi(x_i, x_j) \leq 0, \quad (20)$$

for any integer n, $x_i, \ldots, x_n \in \mathcal{X}$ and $c_i, \ldots, c_n \in \mathbb{R}$, satisfying the additional constraint $\sum_i c_i = 0$. In this case, $-\psi$ is called conditionally *pd; obviously, positive definiteness implies conditional positive definiteness.*

Both the sets of pd and nd kernels are closed under pointwise sums/integrations, the former being also closed under pointwise products; moreover, both sets are closed under pointwise convergence. While pd kernels correspond to inner products via embedding in a Hilbert space, nd kernels that vanish on the diagonal and are positive anywhere else, correspond to squared Hilbertian distances. These facts, and the following ones, are shown by Berg *et al.* (1984).

[3] Notice that $T_2(\mathbf{p}_1, \mathbf{p}_2) = \frac{1}{2} - \frac{1}{2}\langle \mathbf{p}_1, \mathbf{p}_2 \rangle$; in this case, (18) becomes a linear program, and the solution is $\mathbf{p}_1^* = \mathbf{e}_j$, where $j = \operatorname{argmax}_i p_{2i}$.

Proposition 3 *Let $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a symmetric function, and $x_0 \in \mathcal{X}$. Let $\varphi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be*

$$\varphi(x, y) = \psi(x, x_0) + \psi(y, x_0) - \psi(x, y) - \psi(x_0, x_0).$$

Then, φ is pd if and only if ψ is nd.

Proposition 4 *The function $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a nd kernel if and only if $\exp(-t\psi)$ is pd for all $t > 0$.*

Proposition 5 *The function $\psi : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+$ is a nd kernel if and only if $(t + \psi)^{-1}$ is pd for all $t > 0$.*

Proposition 6 *If ψ is nd and $\psi(x, x) \geq 0$, for all $x \in \mathcal{X}$, then so are ψ^α, for $\alpha \in [0,\, 1]$, and $\ln(1 + \psi)$.*

Proposition 7 *If $f : \mathcal{X} \to \mathbb{R}$ satisfies $f \geq 0$, then, for $\alpha \in [1, 2]$, the function $-(f(x) + f(y))^\alpha$ is a nd kernel.*

5.2. Jensen-Shannon and Tsallis Kernels

The basic result that allows deriving pd kernels based on the JS divergence and, more generally, on the JT q-difference, is the fact that the denormalized Tsallis q-entropies are nd functions[4] on $\mathbb{R}^n_+$, for $q \in [0, 2]$. Of course, this includes the denormalized Shannon entropy as a particular case, corresponding to $q = 1$. Partial proofs are given by Berg *et al.* (1984), Topsøe (2000), and Cuturi *et al.* (2005); we present here a complete proof.

Proposition 8 *For $q \in [0, 2]$, the denormalized Tsallis q-entropy S_q is an nd function on $\mathbb{R}^n_+$.*

Proof: Since nd kernels are closed under pointwise summation, it suffices to prove that φ_q (see (6)) is nd on $\mathbb{R}_+$. For $q \neq 1$, $\varphi_q(y) = (q-1)^{-1}(y - y^q)$. If $q \in [0, 1)$, φ_q equals $-\iota + \iota^q$ times a positive constant, where ι is the identity ($\iota(y) = y$) on $\mathbb{R}_+$. Since the set of nd functions is closed under sums, we only need to show that both $-\iota$ and ι^q are nd, which is easily seen from the definition; besides, since ι is nd and nonnegative, Prop. 6 implies that ι^q is also nd. For $q \in (1, 2]$, φ_q equals $\iota - \iota^q$ times a positive constant. It remains to show that $-\iota^q$ is nd for $q \in (1, 2]$; since $k(x, y) = -(x+y)^q$ is nd (Prop. 7), so is ι^q. For $q = 1$, since the set of nd functions is closed under limits,

$$\varphi_1(x) = \varphi_H(x) = -x \ln x = \lim_{q \to 1} -x^q \ln_q x = \lim_{q \to 1} \varphi_q(x),$$

it follows that φ_1 is nd. □

The following proposition, proved by Berg *et al.* (1984), will also be used below.

[4] A function $f : \mathcal{X} \to \mathbb{R}$ is called pd (resp. nd) if $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, defined as $k(x, y) = f(x + y)$, is a pd (resp. nd) kernel (Berg *et al.*, 1984).

Proposition 9 *The function $\zeta_q : \mathbb{R}_{++} \to \mathbb{R}$, defined as $\zeta_q(y) = y^{-q}$ is pd, for $q \in [0, 1]$.*

We now present the main contribution of this section, the family of *weighted JT kernels*, generalizing the JS divergence kernels in two ways: **(i)** they apply to unnormalized measures (equivalently, they allow weighting the arguments differently); **(ii)** they extend the MI nature of the JS divergence kernel to the NE case.

Definition 3 (weighted Jensen-Tsallis kernels) *The kernel $\widetilde{k}_q : (\mathbb{R}^n_+)^2 \to \mathbb{R}$ is defined as*

$$\begin{aligned} \widetilde{k}_q(\boldsymbol{\mu}_1, \boldsymbol{\mu}_2) &= \widetilde{k}_q(\omega_1 \mathbf{p}_1, \omega_2 \mathbf{p}_2) \\ &\triangleq \left[S_q(\boldsymbol{\pi}) - T_q^{\boldsymbol{\pi}}(\mathbf{p}_1, \mathbf{p}_2)\right](\omega_1 + \omega_2)^q, \end{aligned}$$

where $\mathbf{p}_1 = \boldsymbol{\mu}_1/\omega_1$ and $\mathbf{p}_2 = \boldsymbol{\mu}_2/\omega_2$ are the normalized counterparts of $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, with corresponding weights $\omega_1, \omega_2 \in \mathbb{R}_+$, and $\boldsymbol{\pi} = (\omega_1/(\omega_1 + \omega_2), \omega_2/(\omega_1 + \omega_2))$.

The kernel $k_q : (\mathbb{R}^n_{++})^2 \to \mathbb{R}$ is defined as

$$k_q(\boldsymbol{\mu}_1, \boldsymbol{\mu}_2) = k_q(\omega_1 \mathbf{p}_1, \omega_2 \mathbf{p}_2) \triangleq S_q(\boldsymbol{\pi}) - T_q^{\boldsymbol{\pi}}(\mathbf{p}_1, \mathbf{p}_2).$$

Recalling (16), notice $S_q(Y) - I_q(X; Y) = S_q(Y|X)$ can be interpreted as the *Tsallis posterior conditional entropy*. Hence, k_q can be seen (in Bayesian classification terms) as a NE expected measure of uncertainty in correctly identifying the class given the prior $\boldsymbol{\pi} = (\pi_1, \pi_2)$ and a random sample from the mixture distribution $\pi_1 \mathbf{p}_1 + \pi_2 \mathbf{p}_2$. The more similar the two distributions are, the greater this uncertainty.

Proposition 10 *The kernel $\widetilde{k}_q$ is pd, for $q \in [0, 2]$. The kernel k_q is pd, for $q \in [0, 1]$.*

Proof: With $\boldsymbol{\mu}_1 = \omega_1 \mathbf{p}_1$ and $\boldsymbol{\mu}_2 = \omega_2 \mathbf{p}_2$ and using the denormalization formula (7), we obtain $\widetilde{k}_q(\boldsymbol{\mu}_1, \boldsymbol{\mu}_2) = -S_q(\boldsymbol{\mu}_1 + \boldsymbol{\mu}_2) + S_q(\boldsymbol{\mu}_1) + S_q(\boldsymbol{\mu}_2)$. Now invoke Prop. 3 with $\psi = S_q$ (which is nd by Prop. 8), $x = \boldsymbol{\mu}_1$, $y = \boldsymbol{\mu}_2$, and $x_0 = \mathbf{0}$ (the null measure). Observe now that $k_q(\boldsymbol{\mu}_1, \boldsymbol{\mu}_2) = \widetilde{k}_q(\boldsymbol{\mu}_1, \boldsymbol{\mu}_2)(\omega_1 + \omega_2)^{-q}$. Since the product of two pd kernels is a pd kernel and (Prop. 9) $(\omega_1 + \omega_2)^{-q}$ is a pd kernel, for $q \in [0, 1]$, k_q is pd. □

As we can see, the weighted JT kernels have two inherent properties: they are parameterized by the entropic index q and they allow their arguments to be unbalanced, *i.e.*, to have different weights ω_i. We now mention some instances of kernels where each of these degrees of freedom is suppressed.

Weighted JS Kernel Setting $q = 1$, we obtain an extensive subfamily that contains unbalanced versions of the JS kernel (Hein & Bousquet, 2005). Namely, we

get the pd kernels:

$$\begin{aligned}\widetilde{k}_1(\boldsymbol{\mu}_1,\boldsymbol{\mu}_2) &= [H(\boldsymbol{\pi})-J^{\boldsymbol{\pi}}(\mathbf{p}_1,\mathbf{p}_2)]\,(\omega_1+\omega_2),\\ k_1(\boldsymbol{\mu}_1,\boldsymbol{\mu}_2) &= H(\boldsymbol{\pi})-J^{\boldsymbol{\pi}}(\mathbf{p}_1,\mathbf{p}_2).\end{aligned} \quad (21)$$

Exponentiated Weighted JS Kernel Using Prop. 4, we have that exponentiated weighted JS kernel $k_{EWJS}:\mathbb{R}^n_+\to\mathbb{R}$,

$$\begin{aligned}k_{EWJS}(\boldsymbol{\mu}_1,\boldsymbol{\mu}_2) &\triangleq \exp[t\,k_1(\boldsymbol{\mu}_1,\boldsymbol{\mu}_2)]\\ &= \exp(t\,H(\boldsymbol{\pi}))\exp\left[-tJ^{\boldsymbol{\pi}}(\mathbf{p}_1,\mathbf{p}_2)\right]\end{aligned} \quad (22)$$

is also pd for any $t>0$. This generalizes the exponentiated JS kernel $k_{EJS}(\mathbf{p}_1,\mathbf{p}_2)\triangleq\exp\left[-t\,JS\left(\mathbf{p}_1,\mathbf{p}_2\right)\right]$ (Cuturi *et al.*, 2005).

We now keep $q\in[0,2]$ but consider the weighted JT kernel family restricted to normalized measures, $k_q|_{(\mathbb{P}^{n-1})^2}$. This corresponds to setting uniform weights ($\omega_1=\omega_2=1/2$); note that in this case $\widetilde{k}_q$ and k_q collapse into the same kernel,

$$\widetilde{k}_q(\mathbf{p}_1,\mathbf{p}_2)=k_q(\mathbf{p}_1,\mathbf{p}_2)=\ln_q(2)-T_q(\mathbf{p}_1,\mathbf{p}_2). \quad (23)$$

Prop. 10 tells us that these kernels are pd for $q\in[0,2]$. Remarkably, we recover three well-known particular cases for $q\in\{0,1,2\}$.

Jensen-Shannon kernel (JSK) For $q=1$, we obtain the JS kernel, $k_{JS}:(\mathbb{P}^{n-1})^2\to\mathbb{R}$,

$$k_{JS}(\mathbf{p}_1,\mathbf{p}_2)=\ln(2)-JS(\mathbf{p}_1,\mathbf{p}_2), \quad (24)$$

introduced and shown pd by Hein and Bousquet (2005).

Boolean kernel For $q=0$, we obtain the kernel $k_0=k_{Bool}:(\mathbb{P}^{n-1})^2\to\mathbb{R}$,

$$k_{Bool}(\mathbf{p}_1,\mathbf{p}_2)=\|\mathbf{p}_1\odot\mathbf{p}_2\|_0. \quad (25)$$

Linear kernel For $q=2$, we obtain the kernel $k_2=k_{lin}:(\mathbb{P}^{n-1})^2\to\mathbb{R}$,

$$k_{lin}(\mathbf{p}_1,\mathbf{p}_2)=\frac{1}{2}\,\langle\mathbf{p}_1,\mathbf{p}_2\rangle. \quad (26)$$

Summarizing, Boolean, JS, and linear kernels, are members of the much wider family of Tsallis kernels, continuously parameterized by $q\in[0,2]$. Furthermore, Tsallis kernels are a particular subfamily of the even wider set of weighted Tsallis kernels.

A key feature of our generalization is that the kernels are defined on unnormalized measures. This is relevant for empirical measures (*e.g.*, term counts, image histograms); instead of the usual normalization (Hein & Bousquet, 2005), these empirical measures may be left unnormalized, allowing objects of different sizes to have different weights. Another possibility is the explicit inclusion of weights (ω_i): given an input set of normalized measures, each can be multiplied by an arbitrary (positive) weight before computing the kernel.

5.3. Other Kernels Based on Jensen Differences

Other pd kernels may be devised inspired by Jensen-Rényi and Jensen-Tsallis divergences (Section 3). For example, it is a direct consequence of Prop. 6 that, for $q\in[0,1]$, $(\mathbf{p}_1,\mathbf{p}_2)\mapsto R_q\big(\frac{\mathbf{p}_1+\mathbf{p}_2}{2}\big)$, and therefore JR_q, are nd kernels on $(\mathbb{P}^{n-1})^2$. We can then make use of Prop. 4 to derive pd kernels via exponentiation; for example, the *exponentiated Jensen-Rényi kernel* (pd for $q\in[0,1]$ and $t\geq 0$):

$$\begin{aligned}k_{EJR}(\mathbf{p}_1,\mathbf{p}_2) &\triangleq \exp(-t\,J_{R_q}(\mathbf{p}_1,\mathbf{p}_2))\\ &= \left(\frac{\sum_i\left(\frac{p_{1i}+p_{2i}}{2}\right)^q}{\sqrt{\sum_i p_{1i}^q\sum_i p_{2i}^q}}\right)^{-\frac{t}{1-q}}.\end{aligned} \quad (27)$$

However, these kernels are no longer interpretable as MIs, and arbitrary weights are not allowed. Martins *et al.* (2008) also show that a related family of pd kernels for probability measures introduced by Hein and Bousquet (2005) can be written as differences between JT-type divergences.

5.4. The Heat Kernel Approximation

The diffusion kernel for statistical manifolds, recently proposed by Lafferty and Lebanon (2005), is grounded in information geometry. It models the diffusion of "information" over the manifold through the heat equation. Since in the case of the multinomial manifold the diffusion kernel has no closed form, the authors adopt the so-called "first-order parametrix expansion," which resembles the Gaussian kernel replacing the Euclidean distance by the geodesic distance induced by the Fisher information metric. The resulting heat kernel approximation is

$$k_{\,heat}(\mathbf{p}_1,\mathbf{p}_2)=(4\pi\tau)^{-\frac{n}{2}}\exp\left(-\frac{1}{4t}\,d_g^2(\mathbf{p}_1,\mathbf{p}_2)\right), \quad (28)$$

where $\tau>0$ and $d_g(\mathbf{p}_1,\mathbf{p}_2)=2\arccos\left(\sum_i\sqrt{p_{1i}p_{2i}}\right)$. Whether $k_{\,heat}$ is pd has been an open problem (Hein *et al.*, 2004; Zhang *et al.*, 2005).

Proposition 11 *Let $n\geq 2$. For sufficiently large τ, the kernel k_{heat} is* not *pd.*

Proof: From Prop. 4, k_{heat} is pd, for all $\tau > 0$, if and only if d_g^2 is nd. We provide a counterexample, using the following four points in $\mathbb{P}^2$: $\mathbf{p}_1 = (1, 0, 0)$, $\mathbf{p}_2 = (0, 1, 0)$, $\mathbf{p}_3 = (0, 0, 1)$ and $\mathbf{p}_4 = (1/2, 1/2, 0)$. The squared distance matrix $[D_{ij}] = [d_g^2(\mathbf{p}_i, \mathbf{p}_j)]$ is

$$D = \frac{\pi^2}{4} \cdot \begin{bmatrix} 0 & 4 & 4 & 1 \\ 4 & 0 & 4 & 1 \\ 4 & 4 & 0 & 4 \\ 1 & 1 & 4 & 0 \end{bmatrix}. \tag{29}$$

Taking $\mathbf{c} = (-4, -4, 1, 7)$ we have $\mathbf{c}^T D \mathbf{c} = 2\pi^2 > 0$, showing that D is not nd. Although $\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3, \mathbf{p}_4$ lie on the boundary of $\mathbb{P}^2$, continuity of d_g^2 implies that it is not nd. The case $n > 2$ follows easily, by appending zeros to the four vectors above. □

6. Experiments

We illustrate the performance of the proposed NE kernels, in comparison with common kernels, for SVM text classification. We performed experiments in two standard datasets: *Reuters-21578* and *WebKB*.[5] Since our objective was to evaluate the kernels, we considered a simple binary classification task that tries to discriminate among the two largest categories of each dataset; this led us to the *earn-vs-acq* classification task for the first dataset, and *stud-vs-fac* (student *vs.* faculty webpages) in the second dataset.

After the usual preprocessing steps of stemming and stop-word removal, we mapped text documents into probability distributions over words using the bag-of-words model and maximum likelihood estimation (which corresponds to normalizing term frequency using the ℓ_1-norm), which we denote by *tf*. We also used the *tf-idf* measure, which penalizes terms that occur in many documents. To weight the documents for the Tsallis kernels, we tried four strategies: uniform weighting, word counts, square root of the word counts, and one plus the logarithm of the word counts; however, for both tasks, uniform weighting revealed the best strategy, which may be due to the fact that documents in both collections are usually short and do not differ much in size.

As baselines, we used the linear kernel with ℓ_2 normalization, commonly used for this task, and the heat kernel approximation (28) (Lafferty & Lebanon, 2005), which is known to outperform the former, albeit not being guaranteed to be pd for an arbitrary choice of τ (see 28), as shown above. This parameter and the SVM C parameter were tuned with cross-validation over the training set. The SVM-Light package (`http://svmlight.joachims.org/`) was used to solve the SVM quadratic optimization problem.

Figs. 1–2 summarize the results. We report the performance of the Tsallis kernels as a function of the entropic index. For comparison, we also plot the performance of an instance of a Tsallis kernel with q tuned through cross-validation. For the first task, this kernel and the two baselines exhibit similar performance for both the *tf* and the *tf-idf* representations; differences are not statiscally significant. In the second task, the Tsallis kernel outperformed the ℓ_2-normalized linear kernel for both representations, and the heat kernel for *tf-idf*; the differences are statistically significant (using the unpaired t test at the 0.05 level). Regarding the influence of the entropic index, we observe that in both tasks, the optimum value of q is usually higher for *tf-idf* than for *tf*.

The results on these two problems are representative of the typical relative performance of the kernels considered: in almost all tested cases, both the heat kernel and the Tsallis kernels (for a suitable value of q) outperform the ℓ_2-normalized linear kernel; the Tsallis kernels are competitive with the heat kernel.

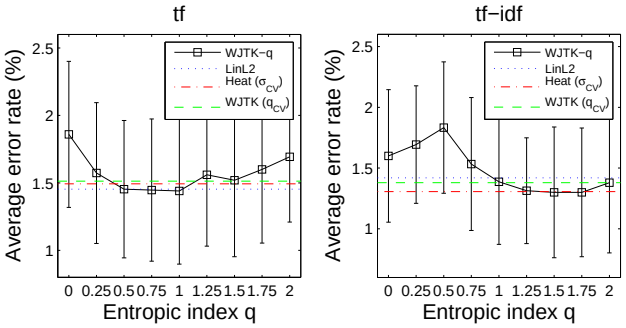

Figure 1. Results for *earn-vs-acq* using *tf* and *tf-idf* representations. The error bars represent ±1 standard deviation on 30 runs. Training (resp. testing) with 200 (resp. 250) samples per class.

7. Conclusion

We have introduced a new family of positive definite kernels between measures, which contains some well-known kernels as particular cases. These kernels are defined on unnormalized measures, which makes them suitable for use on empirical measures (*e.g.*, word counts or pixel intensity histograms), allowing objects of different sizes to be weighted differently. The family is parameterized by the entropic index, a key concept in Tsallis statistics, and includes as extreme cases the Boolean and the linear kernels. The new kernels, and

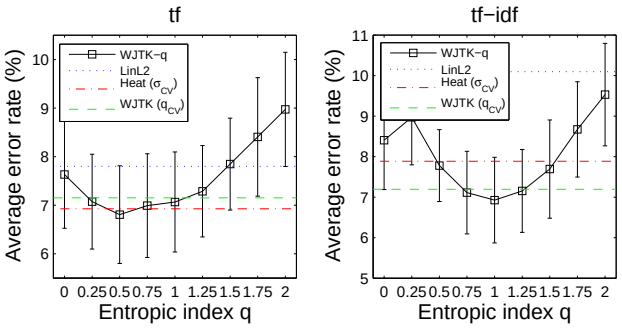

Figure 2. Results for *stud-vs-fac*.

the proofs of positive definiteness, are supported by the other contributions of this paper: the new concept of q-convexity, the underlying Jensen q-inequality, and the concept of *Jensen-Tsallis q-difference*, a nonextensive generalization of the Jensen-Shannon divergence. Experimentally, kernels in this family outperformed the linear kernel in the task of text classification and achieved similar results to the first-order approximation of the multinomial diffusion kernel. They have the advantage, however, of being pd, which fails to happen with the latter kernel, as also shown in this paper.

Future research will concern applying Jensen-Tsallis q-differences to other learning problems, like clustering, possibly exploiting the fact that they accept more than two arguments.

Acknowledgments

Abstract

We present an algorithm, HI-MAT (Hierarchy Induction via Models And Trajectories), that discovers MAXQ task hierarchies by applying dynamic Bayesian network models to a successful trajectory from a source reinforcement learning task. HI-MAT discovers subtasks by analyzing the causal and temporal relationships among the actions in the trajectory. Under appropriate assumptions, HI-MAT induces hierarchies that are consistent with the observed trajectory and have compact value-function tables employing safe state abstractions. We demonstrate empirically that HI-MAT constructs compact hierarchies that are comparable to manually-engineered hierarchies and facilitate significant speedup in learning when transferred to a target task.

1. Introduction

Scaling up reinforcement learning (RL) to large domains requires leveraging the structure in these domains. Hierarchical reinforcement learning (HRL) provides mechanisms through which domain structure can be exploited to constrain the value function and policy space of the learner, and hence speed up learning (Sutton et al., 1999; Dietterich, 2000; Andre & Russell, 2002). In the MAXQ framework, a task hierarchy is defined (along with relevant state variables) for representing the value function of the overall task. This allows for decomposed subtask-specific value functions that are easier to learn than the global value function.

Automated discovery of such task hierarchies is compelling for at least two reasons. First, it avoids the significant human effort in engineering the task-subtask structural decomposition, along with the associated state abstractions and subtask goals. Second, if the same hierarchy is useful in multiple domains, it leads to significant transfer of learned structural knowledge from one domain to the other. The cost of learning can be amortized over several domains. Several researchers have focused on the problem of automatically inducing temporally extended actions and task hierarchies (Thrun & Schwartz, 1995; McGovern & Barto, 2001; Menache et al., 2001; Pickett & Barto, 2002; Hengst, 2002; Şimşek & Barto, 2004; Jonsson & Barto, 2006).

In this paper, we focus on the *asymmetric knowledge transfer* setting where we are given access to solved source RL problems. The objective is to derive useful biases from these solutions that could speed up learning in target problems. We present and evaluate our approach, HI-MAT, for learning MAXQ hierarchies from a solved RL problem. HI-MAT applies dynamic Bayesian network (DBN) models to a single successful trajectory from the source problem to construct a *causally annotated trajectory* (CAT). Guided by the causal and temporal associations between actions in the CAT, HI-MAT recursively parses it and defines MAXQ subtasks based on each discovered partition of the CAT.

We analyze our approach both theoretically and empirically. Our theoretical results show that, under appropriate conditions, the task hierarchies induced by HI-MAT are consistent with the observed trajectory, and possess compact value-function tables that are safe with respect to state abstraction. Empirically, we show that (1) using a successful trajectory can result in more compact task decompositions than when using only DBNs, (2) our induced hierarchies are comparable to manually-engineered hierarchies on target RL tasks, and MAXQ-learning converges significantly faster than flat Q-learning on those tasks, and

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

(3) transferring hierarchical structure from a source task can speed up learning in target RL tasks where transferring value functions cannot.

2. Background and Related Work

We briefly review the MAXQ framework (Dietterich, 2000). This framework facilitates learning separate value functions for subtasks which can be composed to compute the value function for the overall semi-Markov Decision Process (SMDP) with state space $\mathcal{S}$ and action space $\mathcal{A}$. The task hierarchy $\mathcal{H}$ is represented as a directed acyclic graph called the *task graph*, and reflects the task-subtask relationships. Leaf nodes are the primitive subtasks corresponding to $\mathcal{A}$. Each composite subtask T_i defines an SMDP with parameters $\langle X_i, S_i, G_i, C_i \rangle$, where X_i is the set of relevant state variables, $S_i \subseteq \mathcal{S}$ is the set of admissible states, G_i is the termination/goal predicate, and C_i is the set of child tasks of T_i. T_0 represents the root task. T_i can be invoked in any state $s \in S_i$, it terminates when $s' \in G_i$, and (s, a) is called an *exit* if $\Pr(s'|s, a) > 0$.

The set S_i is defined using a projection function that maps a world state to an abstract state defined by a subset of the state variables. A *safe* abstraction function only merges world states that have identical values. The local policy for a subtask T_i is a mapping $\pi_i : S_i \mapsto C_i$. A hierarchical policy π for the overall task is an assignment of a local policy to each T_i. A *hierarchically optimal policy* for a given MAXQ graph is a hierarchical policy that has the best possible expected total reward. A hierarchical policy is *recursively optimal* if the local policy for each subtask is optimal given that all its child tasks are in turn recursively optimal.

HEXQ (Hengst, 2002) and VISA (Jonsson & Barto, 2006) are two existing approaches to learning task hierarchies. These methods define subtasks based on the changing values of state variables. HEXQ employs a heuristic that orders state variables based on the frequencies of change in their values to induce an *exit-option* hierarchy. The most frequently-changing variable is associated with the lowest-level subtask, and the least frequently-changing variable with the root. VISA uses DBNs to analyze the influence of state variables on one another. The variables are partitioned such that there is an acyclic influence relationship between the variables in different clusters (strongly-connected components). Here, state variables that influence others are associated with lower-level subtasks. VISA provides a more principled rationale for HEXQ's heuristic – a variable used to satisfy a precondition for setting another variable through an action typically changes more frequently than the other variable. A key difference between VISA and HI-MAT is the use of a successful trajectory in addition to the DBNs. In Section 5.1, we provide empirical evidence that this allows HI-MAT to learn hierarchies that are exponentially more compact than those of VISA.

The algorithm developed by Marthi et al. (2007) takes a search-based approach to generating hierarchies. Flat Q-value functions are learned for the source domain, and are used to sample trajectories. A greedy top-down search is conducted for the best-scoring hierarchy that fits the trajectories. The set of relevant state variables for each task is determined through statistical tests on the Q values of different states with differing values of the variables. In contrast to this approach, HI-MAT relies less on direct search through the hierarchy space, and more on the causal analysis of a trajectory based on DBN models.

3. Discovering MAXQ Hierarchies

In this work, we consider MDPs where the agent is solving a known conjunctive goal. This is a subset of the class of stochastic shortest-path MDPs. In such MDPs, there is a goal state (or a set of goal states), and the optimal policy for the agent is to reach such a state as quickly as possible. We assume that we are given factored DBN models for the source MDP where the conditional probability distributions are represented as trees (CPTs). Further, we are given a successful trajectory that reaches the goal in the source MDP. With this in hand, our objective is to automatically induce a MAXQ hierarchy that can suitably constrain the policy space when solving a related target problem, and therefore achieve faster convergence in the target problem. This is achieved via recursive partitioning of the given trajectory into subtasks using a top-down parse guided by backward chaining from the goal. We use the DBNs along with the trajectory to define the termination predicate, the set of subtasks, and the relevant abstraction for each MAXQ subtask.

We use the Taxi domain (Dietterich, 2000) to illustrate our procedure. Here, a taxi has to transport a passenger from a source location to a destination location within a 5×5 grid-world. The *pass.dest* variable is restricted to one of four special locations on the grid denoted by R, G, B, Y; the *pass.loc* could be set to R, G, B, Y or in-taxi; *taxi.loc* could be one of the 25 cells. The goal of *pass.loc* = *pass.dest* is achieved by taking the passenger to its intended destination. Besides the four navigation actions, a successful Pickup changes *pass.loc* to in-taxi, and a successful Putdown changes *pass.loc* from in-taxi to the value of *pass.dest*.

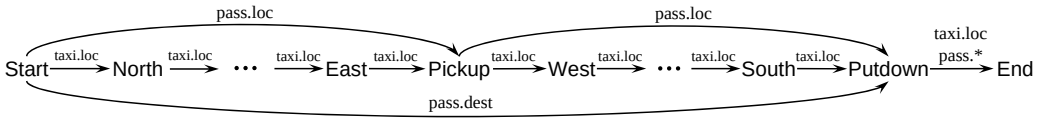

Figure 1. A sample CAT for the Taxi domain.

3.1. Definitions and Notation

We say that a variable v is *relevant* to an action a if the reward and transition dynamics for a either check or change v; it is *irrelevant* otherwise. The set of *trajectory-relevant* (t-relevant) variables of a, a subset of the relevant variables, are the variables that were actually checked or changed when a was executed in the trajectory. A *causal* edge $a \xrightarrow{v} b$ connects a to another action b (b following a in the trajectory) iff v is t-relevant to both a and b, and irrelevant to all actions in between. A *sink* edge, $a \xrightarrow{v} \mathsf{End}$ connects a with a dummy End action iff v is relevant to a and irrelevant to all actions before the final goal state; this holds analogously for a *source* edge $\mathsf{Start} \xrightarrow{v} a$. A *causally annotated trajectory* (CAT) is the original trajectory annotated with all the causal, source, and sink edges. Moreover, the CAT is preprocessed to remove any cycles present in the original trajectory (failed actions, such as an unsuccessful Pickup, introduce cycles of unit length). A sample CAT for Taxi is shown in Figure 1.

Given $a \xrightarrow{v} b$, the phrase "literal on a causal edge" refers to a formula of the form $v = \mathsf{V}$ where V is the value taken by v in the state before b is executed. We define `DBN-closure(`v`)` as the set of variables that influence v recursively as follows. From the action DBNs, add all variables that appear in internal nodes in the CPTs for the dynamics of v. Next, for each added variable u, union `DBN-closure(`u`)` with this set, repeating until no new variables are added. Similarly, the set `DBN-closure(`*reward*`)` contains all variables that influence the reward function of the MDP. The set `DBN-closure(`$fluent$`)` is the union of the `DBN-closure`s of all variables in the fluent. For example, `DBN-closure(`*goal*`)` is the set of all variables that influence the goal fluent. The CAT ignores all variables $v \notin$ `DBN-closure(`*goal*`)`, namely, those variables that never affect the goal conjunction.

3.2. The HI-MAT Algorithm

Given a CAT and the MDP's goal predicate (or recursively, the current subtask's goal predicate), the main loop of the hierarchy induction procedure is illustrated in Algorithm 1. The algorithm first checks if two stopping criteria are satisfied (lines 2 & 4): either the trajectory contains only a single primitive action, or it consists of actions whose relevances are identical. (In the latter case, any further partitioning would yield subtasks with the same abstraction as the parent.) Otherwise, it first initializes the set of "unsolved" goals to the set of literals in the goal conjunction (line 9). It then selects any unsolved goal u, and finds the corresponding subtask (line 12). Algorithm 2 returns indices i, j marking the boundaries of the subtask in the CAT. If this CAT segment is nontrivial (neither just the initial state nor the whole trajectory), it is stored (line 17), and the literals on causal edges that enter it (from earlier in the trajectory) are added to the unsolved goals (line 18). This ensures that the algorithm parses the entire trajectory barring redundant actions. If the trajectory segment is equal to the entire trajectory, this implies that the trajectory achieves only the literal u after the ultimate action. In this case, the trajectory is split into two segments: one segment contains the prefix of the ultimate action a_n with the preconditions of a_n forming the goal literals for this segment (line 14); the other segment contains only the ultimate action a_n (line 15). CAT scanning is repeated until all subgoal literals are accounted for.

The only way trajectory segments can overlap is if they have identical boundaries, and the ultimate action achieves the literals of all these segments. In this case, the segments are merged (line 23). Merging replaces the duplicative segments with one that is assigned a conjunction of the subgoal literals.

The HI-MAT algorithm partitions the CAT into unique segments, each achieving a single literal or a conjunction of literals due to merging. It is called recursively on each element of the partition (line 27). It can be proved that the set of subtasks output by the algorithm is independent of the order in which the literal u is picked (line 11).

3.2.1. Subtask Detection

Given a literal, a subtask is determined by finding the set of temporally contiguous actions that are closed with respect to the causal edges in the CAT such that the final action achieves the literal. The idea is to group all actions that contribute to achieving the specific literal being considered. This procedure is shown in Algorithm 2.

Algorithm 1 HI-MAT
Input: CAT Ω, Goal predicate G.
Output: Task $\langle X, S, G, C\rangle$; X is the set of relevant variables, S is the set of non-terminal states, G is the goal predicate, C is the set of child actions.

1: $n \leftarrow$ Number of actions in Ω excluding Start and End
2: **if** $n = 1$ **then** // Single action
3: **return** $\langle \textsc{RelVars}(\Omega), \mathcal{S}, \text{true}, a_1\rangle$
4: **else if** CheckRelVars(Ω) **then** // Same relevance
5: $S \leftarrow$ All states that reach G via $\textsc{Actions}(\Omega)$
6: **return** $\langle \textsc{RelVars}(\Omega), S, G, \textsc{Actions}(\Omega)\rangle$
7: **end if**
8: $\Psi \leftarrow \emptyset$ // Trajectory segments
9: $U \leftarrow \textsc{Literals}(G)$
10: **while** $U \neq \emptyset$ **do**
11: Pick $u \in U$
12: $(i, j, u) \leftarrow$ CAT-Scan(Ω, u)
13: **if** $i = 1 \wedge j = n$ **then**
14: $\Psi \leftarrow \Psi \cup \{(1, n-1, v) : v \in \textsc{Precondition}(a_n)\}$
15: $\Psi \leftarrow \Psi \cup \{(n, n, \emptyset)\}$
16: **else if** $j > 0$ **then** // Last segment action $\neq$ Start
17: $\Psi \leftarrow \Psi \cup \{(i, j, u)\}$
18: $U \leftarrow U \cup \{v : \exists k < i \; \exists l \; a_k \xrightarrow{v} a_l \in \Omega, i \leq l \leq j\}$
19: **end if**
20: $U \leftarrow U - \{u\}$
21: **end while**
22: **while** $\exists (i, j, u_1), (i, j, u_2) \in \Psi$ **do**
23: $\Psi \leftarrow (\Psi - \{(i, j, u_1), (i, j, u_2)\}) \cup \{(i, j, u_1 \wedge u_2)\}$
24: **end while**
25: $C \leftarrow \emptyset$
26: **for** $t \in \Psi$ **do**
27: $\langle X_t, S_t, G_t, C_t\rangle \leftarrow$ HI-MAT($\textsc{Extract}(\Omega, t_i, t_j), t_u$)
28: $C \leftarrow C \cup \{\langle X_t, S_t, G_t, C_t\rangle\}$
29: **end for**
30: $X \leftarrow \textsc{RelVars}(\Omega) \cup \textsc{Variables}(G)$
31: $S \leftarrow$ All states that reach G via C
32: **return** $\langle X, S, G, C\rangle$

Algorithm 2 CAT-Scan
Input: CAT Ω, literal u.
Output: (i, j, u); i is the start index, j is the end index.

1: Set j such that $a_j \xrightarrow{u}$ End $\in \Omega$
2: $i \leftarrow j - 1$
3: **while** $i > 0$ **and** $\forall v \; \exists k \; a_i \xrightarrow{v} a_k \implies k \leq j$ **do**
4: $i \leftarrow i - 1$
5: **end while**
6: **return** $(i + 1, j, u)$

As before, when considering causal edges in line 3, we can ignore all causal edges that are labeled with variables not in the `DBN-closure` of any variable in the current unsolved goal list. Because of the way we construct the CAT, we can show that this procedure will always stop before adding an action which has a relevant variable that is not relevant to the last action in the partition. Note that the temporal contiguity of the actions we assign to a subtask is required by the MAXQ-style execution of a policy. A hierarchical MAXQ policy cannot interrupt an unterminated subtask, start executing a sibling subtask, and then return to executing the interrupted subtask.

3.2.2. Termination Predicate

After finding the partition that constitutes a subtask, we assign a set of child tasks and a termination predicate to it. To assign the termination condition to a subtask, we consider the relational test(s) t_u in the action and reward DBNs involving the variable u on the causal edge leaving the subtask (line 27 of Algorithm 1). When a subtask's relational termination condition involves other variables not already in the abstraction, these variables are added to the state abstraction (line 30), effectively creating a parameterized subtask. For example, consider the navigation subtask that terminates when $taxi.loc = pass.dest$ in the Taxi domain. The abstraction for this subtask already involves $taxi.loc$. However, $pass.dest$ in the relational test implies that $pass.dest$ behaves like a parameter for this subtask.

3.2.3. Action Generalization

To determine if the set of primitive actions available to any subtask should be expanded, we follow a bottom-up procedure (not shown in Algorithm 1). We start with subtasks that have only primitive actions as children. We create a *merged* DBN structure for such a subtask T using the incorporated primitive actions. The merged DBN represents possible variable effects after any sequence of these primitive actions. Next, for each primitive action that we did not see in this trajectory, we consider the subgraph of its DBN that only involves the variables relevant to T. If this is a subgraph of the merged DBN of T, we add this action to the set of actions available to T. The rationale here is that the added action has similar effects to the actions we observed in the trajectory, and it does not increase the set of relevant variables for T. For example, if the navigation actions used on the observed trajectory consisted only of North and East actions, this procedure would also add South and West to the available actions for this subtask. When considering subtasks that have non-primitive children, we only consider adding actions that have not been added to any of the non-primitive children.

Given the termination predicate and the generalized set of actions, the set of relevant variables for a subtask is the union of the set of relevant variables of the merged DBN (described above) and the variables appearing in the termination predicate (line 30). Computing the relevant variables is similar to explanation-based reinforcement learning (Tadepalli & Dietterich,

1997) except that here we care only about the set of relevant variables and not their values. Moreover, the relevant variables are computed over a set rather than a sequence of actions.

4. Theoretical Analysis

In this section, we establish certain theoretical properties of the hierarchies induced by the HI-MAT algorithm. We consider a factored SMDP state-space $\mathcal{S} = D_{x_1} \times \ldots \times D_{x_k}$, where each D_{x_i} is the domain of variable x_i. We assume that our DBN models have the following property.

Definition 1 *A DBN model is maximally sparse if for any $y \in Y$ where Y is the set of parents of some node x (which represents either a state variable or the reward node), and $Y' = Y - \{y\}$,*

$$\exists y_1, y_2 \in D_y \quad \Pr(x|Y', y = y_1) \neq \Pr(x|Y', y = y_2).$$

Maximal sparseness implies that the parents of a variable have non-trivial influences on it; no parent can be removed without affecting the next-state distribution.

A task hierarchy $\mathcal{H} = \langle V, E \rangle$, is a directed acyclic graph, where V is a set of task nodes, and E represents the task-subtask edges of the graph. Each task node $T_i \in V$ is defined as in Section 2.

A trajectory-task pair $\langle \Omega, T_i \rangle$, where $\Omega = \langle s_1, a_1, \ldots, s_n, a_n, s_{n+1} \rangle$ and $T_i = \langle X_i, S_i, G_i, C_i \rangle$, is consistent with $\mathcal{H}$ if $T_i \in V$, and $\{s_1, \ldots, s_n\} \subseteq S_i$. If T_i is a primitive subtask then $n = 1$, and $C_i = a_1$. If T_i is not primitive then $\{s_1, \ldots, s_n\} \cap G_i = \emptyset$, $s_{n+1} \in G_i$, and there exist trajectory-task pairs $\langle \Omega_j, T_j \rangle$ consistent with $\mathcal{H}$ where Ω is a concatenation of $\Omega_1, \ldots, \Omega_p$ and $T_1, \ldots, T_p \in C_i$.

A trajectory Ω is consistent with a hierarchy $\mathcal{H}$ if $\langle \Omega, T_0 \rangle$ is consistent with $\mathcal{H}$.

Definition 2 *A trajectory $\langle s_1, a_1, \ldots, s_n, a_n, s_{n+1} \rangle$ is non-redundant if no subsequence of the action sequence in the trajectory, $a_1, \ldots, a_n$, can be removed such that the remaining sequence still achieves the goal starting from s_1.*

Theorem 1 *If a trajectory Ω is non-redundant then HI-MAT produces a task hierarchy $\mathcal{H}$ such that Ω is consistent with $\mathcal{H}$.*

Proof sketch: Let $\Omega = \langle s_1, a_1, \ldots, s_n, a_n, s_{n+1} \rangle$ be the trajectory. The algorithm extracts the conjunction of literals that are true in s_{n+1} (and not before), and assigns it to the goal, G_i. Such literals must exist since, otherwise, some suffix of the trajectory can be removed while the rest still achieves the goal, violating the property of non-redundancy. Since the set S_i is set to all states that do not satisfy G_i, the condition that all states $s_1, \ldots, s_n$ are in S_i is satisfied.

Whenever the trajectory is partitioned into a sequence of sub-trajectories, each sub-trajectory is associated with a conjunction of goal literals achieved by that sub-trajectory. Hence, the above argument applies recursively to each such sub-trajectory. □

Definition 3 *A hierarchy $\mathcal{H}$ is safe with respect to the DBN models M if for any trajectory-task pair $\langle \Omega, T_i \rangle$ consistent with $\mathcal{H}$, where $T_i = \langle X_i, S_i, G_i, C_i \rangle$, the total expected reward during the trajectory is only a function of the values of $x \in X_i$ in the starting state of Ω.*

The above definition says that the state variables in each task are sufficient to capture the value of any trajectory consistent with the sub-hierarchy rooted at that task node.

Theorem 2 *If the procedure HI-MAT produces a task hierarchy $\mathcal{H}$ from Ω and the DBN models M then $\mathcal{H}$ is safe with respect to M. Further, if the DBN models are maximally sparse, for any hierarchy $\mathcal{H}'$ which is consistent with Ω and safe with respect to M, and $T_i = \langle X_i, S_i, G_i, C_i \rangle$ in $\mathcal{H}$, there exists $T'_i = \langle X'_i, S'_i, G'_i, C'_i \rangle$ in $\mathcal{H}'$ such that $X_i \subseteq X'_i$.*

Proof sketch: By the construction procedure, in any segment of trajectory Ω composed of primitive actions under a subtask T_i, all primitive actions check or set only the variables in X_i. Thus, changing any other variables in the initial state s of Ω yielding s' does not change the effects of these actions according to the DBN models. Similarly, all immediate rewards in the trajectory are also functions of the variables in X_i. Hence, the total accumulated reward and the probability of the trajectory only depend on X_i, and the hierarchy produced is safe with respect to M.

Suppose that $\mathcal{H}'$ is a consistent hierarchy which is safe with respect to M. Let a_i be the last action in the trajectory Ω_i corresponding to the subtask T_i in $\mathcal{H}$. By consistency, there must be some task T'_i in $\mathcal{H}'$ that matches up with a_i. Recall that X_i includes only those variables checked and set by a_i to achieve the goal G_i. We claim that the abstraction variables X'_i of T'_i must include X_i. If this is not the case then, by maximal sparseness, there is a variable y in $X_i - X'_i$ and some values y_1 and y_2 such that the probabilities of the next state or reward are different based on whether $y = y_1$ or $y = y_2$. Hence, $\mathcal{H}'$ would not be safe, leading to a contradiction. □

Corollary 1 *If the DBN models are maximally sparse then the maximum size of the value function table for any task in the hierarchy produced by HI-MAT is the smallest over all safe hierarchies which are consistent with the trajectory.*

Proof: Direct consequence of part 2 of the previous theorem. □

The significance of the above corollary lies in the fact that the size of the value-function table is exponential in the number of variables $n_i = |X_i|$ in the abstraction of task T_i. If all features are binary and there are t tasks then the total number of values for the value-function tables is $O(t\,2^{n_{\max}})$. Since the hierarchy is a tree with the primitive actions at the leaves, the number of subtasks is bounded by $2l$ where l is the length of the trajectory. Hence, we can claim that the number of parameters needed to fully specify the value-function tables in our hierarchy is at most $O(l)$ times that of the best possible.

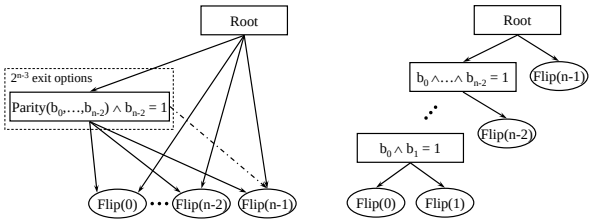
Our analysis does not address state abstractions arising from the so-called *funnel* property of subtasks where many starting states result in a few terminal states. Funnel abstractions permit the parent task to ignore variables that, while relevant inside the child task, do not affect the terminal state. Nevertheless, our analysis captures some of the key properties of our algorithm including consistency with the trajectory, safety, minimality, and sheds some light on its effectiveness.

5. Empirical Evaluation

We test three hypotheses. First, we expect that employing a successful trajectory along with the action models will allow the HI-MAT algorithm to induce task hierarchies that are much more compact than (or at least as compact as) just using the action models. Second, in a transfer setting, we expect that the hierarchies induced by HI-MAT will speed up convergence to the optimal policy in related target problems. Finally, we expect that the HI-MAT hierarchies will be applicable to and speed up learning in RL problems which are different enough from the source problems such that value functions either do not transfer or lead to poor transfer.

5.1. Contribution of the Trajectory

To highlight our first hypothesis, a modified Bitflip domain (Diuk et al., 2006) is designed as follows. The state is represented by n bits, $b_0 b_1 \ldots b_{n-1}$. There are n actions denoted by Flip(i). Flip(i) toggles b_i if both



(a) VISA hierarchy. Task labels are the exit conditions; dash-dot arrows indicate exit options.

(b) HI-MAT hierarchy. Task labels are the termination conditions.

Figure 2. Task hierarchies for the modified Bitflip domain.

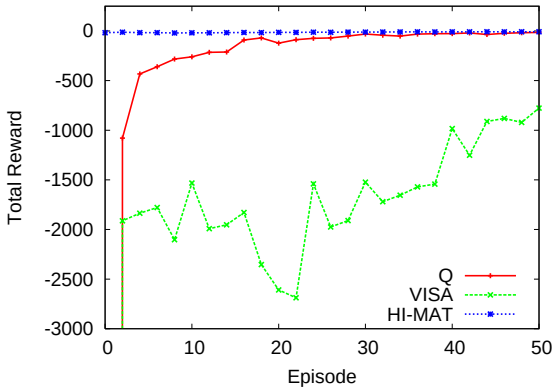


Figure 3. Performance of Q, VISA, and HI-MAT in the 7-bit modified Bitflip domain (averaged over 20 runs).

b_{i-1} is set and the parity across bits $b_0, \ldots, b_{i-1}$ is even when i is even (odd otherwise); if not, it resets the bits $b_0, \ldots, b_i$. All bits are reset at the initial state, and the goal is to set all bits.

We ran both VISA and HI-MAT in this domain with $n = 7$, and compared the induced hierarchies (Figure 2). We observe that VISA constructs an exponentially sized hierarchy even with subtask merging activated within VISA. There are two reasons for this. First, VISA relies on the full action set to construct its causal graph, and does not take advantage of any context-specific independence among its variables that may arise when the agent acts according to certain policies. Specifically, for this domain, the causal graph constructed from DBN analysis has only two strongly connected components (SCCs): one partition has $\{b_0, \ldots, b_{n-2}\}$, and the other has $\{b_{n-1}\}$. This SCC cannot be further decomposed using only information from the DBNs. Second, VISA creates exit options for all strongly connected components that transitively influence the reward function, whereas only a few of these may actually be necessary to solve the problem. Specifically, for this problem, VISA creates

an exit condition for any instantiation that satisfies $\mathsf{parity}(b_0, \ldots, b_{n-2}) \wedge b_{n-2} = 1$, resulting in exponential number of subtasks shown in Figure 2(a). The successful trajectory provided to HI-MAT achieves the goal by setting the bits going from left to right, and results in the hierarchy in Figure 2(b). The performance results are shown in Figure 3. VISA's hierarchy converges even slower than the basic Q learner because the root has $O(2^n)$ children as opposed to $O(n)$.

This domain has been engineered to highlight the case when access to a successful trajectory allows for significantly more compact hierarchies than without. We expect that access to a solved instance will usually improve the compactness of the resulting hierarchy.

5.2. Transfer of the Task Hierarchy

To test our remaining hypotheses, we apply the transfer setting to two domains: Taxi and the real-time strategy game Wargus. The Taxi domain has been described in Section 3. The source and target problems in Taxi differ only in the wall configurations; the passenger sources and destinations are the same. This is engineered to allow value-function transfer to occur. For Wargus, we consider the *resource collection* problem. Here, the agent has units called peasants that can harvest gold and wood from goldmines and forests respectively, and deposit them at a townhall. The goal is to reach a predetermined quota of gold and wood. Since the HI-MAT approach does not currently generalize to termination conditions involving numeric predicates, the state representation of the domain replaces the actual quota variables with Boolean variables that are set when the requisite quotas of gold and wood are met. We consider target problems whose specifications are scaled up from that of the source problems, including the number of peasants, goldmines, forests, and the size of the map. In this domain, coordination does not affect the policy significantly. Thus, in the target maps, we learn a hierarchical policy for the peasants using a shared hierarchy structure without coordination (Mehta & Tadepalli, 2005). In each case, we report the total reward received as a function of the number of episodes, averaged over multiple trials.

We compare three basic approaches: (1) non-hierarchical Q-learning (Q), (2) MAXQ-learning applied to a hierarchy manually engineered for each domain (Manual), and (3) MAXQ-learning applied to the HI-MAT hierarchy induced for each domain (HI-MAT). The HI-MAT algorithm first solves the source problem using flat Q-learning, and generates a successful trajectory from it. In Taxi, we also show the performance of initializing the value-function tables with values learned from the source problem – these curves are suffixed with the phrase "with value". In Wargus, we include the performance of VISA. The results of these experiments are shown in Figures 4 and 5.

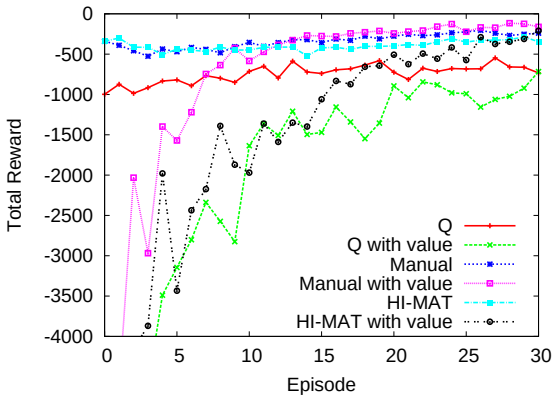

Figure 4. Performance in the Taxi domain (averaged over 20 runs). Source and target problems differ only in the configuration of the grid walls.

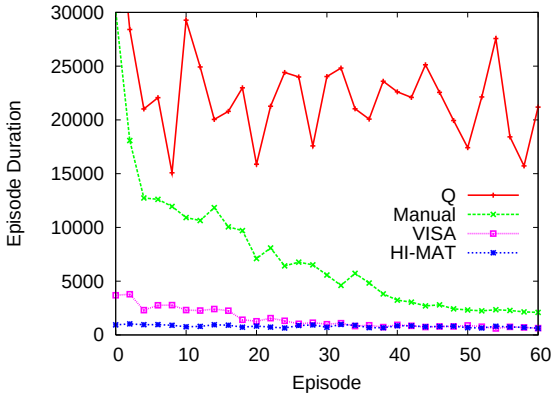

Figure 5. Performance in the Wargus domain (averaged over 10 runs). Source: 25×25 grid, 1 peasant, 2 goldmines, 2 forests, 1 townhall, 100 units of gold, 100 units of wood. Target: 50×50 grid, 3 peasants, 3 goldmines, 3 forests, 1 townhall, 300 units of gold, 300 units of wood.

Although the target problems in Taxi allow value-function transfer to occur, the target problems are still different enough that the agent has to "unlearn" the old policy. This leads to negative transfer evidenced in the fact that transferring value functions leads to worse rates of convergence to the optimal policy than transferring just the hierarchy structure with uninitialized policies. This indicates that transferring structural knowledge via the task-subtask decomposition can be superior to transferring value functions especially when the target problem differs significantly in terms of its optimal policy. In Wargus, the difference

between the source and target problems renders direct value-function transfer impossible even though the hierarchy structure still transfers.

In Taxi, we observe that MAXQ-learning on HI-MAT's hierarchy converges to the optimal policy at a rate comparable to that of the manually-engineered hierarchy. However, in Wargus, HI-MAT's hierarchy is faster to converge than the manually-engineered one because, by analyzing the solved source problem, it is able to find stricter termination conditions for each subtask. Consequently, reducing the policy space in the target problem leads to a greater speed-up in learning than reducing the number of value parameters via subtask sharing as in the manually-engineered hierarchy. The improved rate of convergence is in spite of the fact that HI-MAT does not currently merge subtly different instantiations of the same subtask so there is room for further improvement. VISA's performance suffers initially due to a large branching factor at the root option (which directly includes all the navigation actions).

6. Conclusion

We have presented an approach to automatically inducing MAXQ hierarchies from solved RL problems. Given DBN models and an observed successful trajectory, our method analyzes the causal and temporal relationships between actions, and partitions the trajectory recursively into subtasks as long as the state abstraction improves. We show that the learned hierarchies are consistent, safe, and have compact value-function tables. Our empirical results indicate that using the observed trajectory can allow us to learn more compact hierarchies. Further, in a transfer setting, our hierarchies perform comparably to manually-engineered hierarchies, and improve the rate of convergence where direct policy transfer does not help.

We are currently working on extending the approach to handle disjunctive goals. Further, in order to ensure hierarchical optimality, we may need to deal with non-zero pseudo-rewards. In related work, we are also investigating methods that learn compact DBN models of the MDP. Finally, an important challenge for the future is to investigate the transfer scenario where the induced hierarchy may need to be altered structurally in order to apply effectively to the target problem.

Abstract

Minimum rank problems arise frequently in machine learning applications and are notoriously difficult to solve due to the non-convex nature of the rank objective. In this paper, we present the first online learning approach for the problem of rank minimization of matrices over polyhedral sets. In particular, we present two online learning algorithms for rank minimization - our first algorithm is a multiplicative update method based on a generalized experts framework, while our second algorithm is a novel application of the online convex programming framework (Zinkevich, 2003). In the latter, we flip the role of the decision maker by making the decision maker search over the constraint space instead of feasible points, as is usually the case in online convex programming. A salient feature of our online learning approach is that it allows us to give provable approximation guarantees for the rank minimization problem over polyhedral sets. We demonstrate the effectiveness of our methods on synthetic examples, and on the real-life application of low-rank kernel learning.

1. Introduction

Minimizing the rank of matrices restricted to a convex set is an important problem in the field of optimization with numerous applications in machine learning. For instance, many important problems like low-rank kernel learning, feature efficient linear classification, semi-definite embedding (SDE), non-negative matrix approximation (NNMA), etc., can be viewed as rank minimization problems over a polyhedron with additional convex constraints such as a Frobenius norm constraint and/or a semi-definiteness constraint. Even though there has been extensive work on the specific problems mentioned above, the general problem of rank minimization over polyhedral sets is not well understood. In this paper we address the problem of rank minimization when there are a large number of trace constraints along with a few convex constraints that are relatively "easy" in a precise sense defined below.

We now formulate the rank minimization problem we study. Let $A_1, \ldots, A_m \in \mathbb{R}^{n \times n}$, $b_1, \ldots, b_m \in \mathbb{R}$ and let $\mathcal{C} \subseteq \mathbb{R}^{n \times n}$ be a convex set of matrices. Then, consider the following optimization problem which we refer to as RMP (for Rank Minimization over Polyhedron):

$$\begin{aligned} \min \quad & \text{rank}(X) \\ \text{s.t} \quad & \text{Tr}(A_i X) \geq b_i, \quad 1 \leq i \leq m \\ & X \in \mathcal{C}. \end{aligned} \tag{RMP}$$

The set $\mathcal{C}$ will represent the "easy" constraints in the sense that for such a set $\mathcal{C}$, we assume that RMP with a single trace constraint can be solved efficiently. This holds for many typical convex sets $\mathcal{C}$, e.g., the unit ball under any L_p or Frobenius norm, the semi-definite cone, and the intersection of the unit ball with the p.s.d. cone. Furthermore, low-rank kernel learning, SDE and NNMA can all be seen as instantiations of the above general formulation.

The general RMP problem as stated above is non-convex, NP-hard and, as we prove, cannot be approximated well unless $P = NP$. Due to the computational hardness of the problem, much of the previous work has concentrated on providing heuristics, with no guarantees on the quality of the solution. We remark that the recent trace-norm based approach of (Recht et al., 2007) does guarantee an optimal solution for a simplified instance of RMP where only well-conditioned linear equality constraints are allowed. However, it is not clear how to extend their guarantees to the more general RMP problem.

We now list the main contributions of this paper:

- We show that for the RMP problem, the minimum feasible rank cannot be approximated well unless $P =$

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

NP (see Theorem 3.1). To get over this hurdle we introduce a relaxed notion of approximation, where along with approximating the optimal rank we also allow small violations in the constraints. In practice, this relaxed notion is as meaningful as the standard notion of approximation since almost all real-life problems have noisy measurements.

- We provide an algorithm for RMP based on the Multiplicative Weights Update framework of (Plotkin et al., 1991; Arora et al., 2005b) and under the relaxed notion of approximation, we prove approximation guarantees for the algorithm.
- We provide an algorithm for RMP based on the framework of online convex programming (OCP) introduced by (Zinkevich, 2003). We use the OCP framework in a novel way by changing the role of the decision maker to search over the constraints instead of the feasible points, as is usually the case. We prove that under the relaxed notion of approximation, the algorithm provides approximation guarantees. The guarantees obtained using the OCP framework are better than those obtained using the Multiplicative Weights Update framework by a logarithmic factor.
- For a practical application, we apply our methods to the problem of low-rank kernel learning which can be seen as a specific instance of general RMP.

We empirically evaluate our methods on synthetic instances of RMP, where the constraints are chosen randomly. We compare them with the trace-norm heuristic of (Fazel et al., 2001; Recht et al., 2007) and the log-det heuristic of (Fazel et al., 2003), and our experimental results indicate that our methods are significantly faster and give comparable rank solutions to existing methods. We also evaluate the performance of our methods for low-rank kernel learning on UCI datasets. On all the datasets, our algorithms improve the accuracy of the baseline kernel while also significantly decreasing the rank.

2. Related Work and Background

Most existing methods for rank minimization over convex sets are based on relaxing the non-convex rank function to a convex function, e.g., the trace-norm (Fazel et al., 2001; Recht et al., 2007) or the logarithm of the determinant (Fazel et al., 2003). Unfortunately, these heuristics do not have any guarantees on the quality of the solution in general. A notable exception is the work of (Recht et al., 2007), which extends the techniques of (Candès & Tao, 2005) for compressed sensing to rank minimization. (Recht et al., 2007) show that minimizing the trace-norm guarantees an optimal rank solution to a special class of RMP where only well-conditioned linear equalities are allowed. Thus their approach is limited in its applicability and it is not clear how to extend it to general RMP. We also remark that minimizing the trace-norm is computationally expensive, which further limits its applicability.

(Barvinok, 2002) (Chapter V) describes an approximation algorithm for RMP based on random projections and a generalization of the Johnson-Lindenstrauss Lemma, with an approximation guarantee similar to the one provided by our MW algorithm (Section 4.1). However, this approach works only for a special case of RMP where only linear equalities described by p.s.d. matrices are allowed. Furthermore, this approach needs to solve the relaxed RMP problem without the rank constraint which involves solving a large semi-definite programming problem. This maybe undesirable for various real-world applications such as the low-rank kernel learning problem. In contrast, our approaches can be used for a larger class of convex sets $\mathcal{C}$ and are considerably more scalable.

Several specific instances of the general RMP problem have been widely researched in the machine learning community. Examples include low-rank kernel learning, SDE, sparse PCA and NNMA. Most methods for these problems can be broadly grouped into the following two categories: a) methods which drop the rank constraint and use the top k eigenvectors of the solution to the relaxed optimization problem e.g., (Weinberger et al., 2004); b) methods which factor the matrix X in RMP into AB^T and optimize the resultant non-convex problem e.g., (Lee & Seung, 2000; Kim et al., 2007). However, typically these methods do not have any provable guarantees.

We apply our algorithms for the general RMP problem to the low-rank kernel learning problem(Bach & Jordan, 2005; Kulis et al., 2006). Existing methods for this problem do not provide any provable guarantees on the solution and/or assume that the initial kernel has a small rank to begin with. In contrast, a straight forward application of our general RMP framework gives algorithms with provable guarantees on the rank of the learned kernel. Furthermore, we demonstrate that our algorithms can be used to initialize existing methods to obtain better solutions.

Our approaches to RMP are based on two online learning methods - the generalized experts framework as abstracted in (Arora et al., 2005b) and the online convex programming (Zinkevich, 2003), which we now review briefly.

2.1. Multiplicative Weights Update Algorithm

The Multiplicative Weights Update algorithm (MW algorithm) is an adaptation of the Winnow algorithm (Littlestone & Warmuth, 1989) for a generalized experts framework as described in (Freund & Schapire, 1997). This framework was implicitly used by (Plotkin et al., 1991) for solving several fractional packing and covering problems and was formalized and extended to semi-definite programs

in (Arora et al., 2005a). Throughout this work we will follow the presentation of the generalized experts framework as abstracted in (Arora et al., 2005b).

In the generalized experts (GE) framework there is a set of n experts, a set of events $\mathcal{E}$, and a penalty matrix M such that the i-th expert incurs a penalty of $M(i,j)$ for an event $j \in \mathcal{E}$. The penalties are assumed to be bounded and lie in the interval $[-\rho, \rho]$ for a fixed $\rho > 0$. At each time step $t = 1, 2, \ldots,$ an adversary chooses an event $j^t \in \mathcal{E}$ so that the i-th expert incurs a penalty of $M(i, j^t)$. The goal in the GE framework is to formulate a *prediction algorithm* that chooses a distribution $\mathcal{D}^t = (p_1^t, \ldots, p_n^t)$ on the experts at time step t, so that the total expected loss incurred by the prediction algorithm is not much worse than the total loss incurred by the best expert. Formally, the goal of the prediction algorithm is to minimize

$$\sum_{t=1}^{T}\sum_{l=1}^{n} p_l^t M(l, j^t) - \min_i \sum_{t=1}^{T} M(i, j^t).$$

Note that the distribution in round t, $\mathcal{D}^t$, must be chosen without knowledge of the event j^t chosen at time step t. At every step t, the MW algorithm has a weight w_i^t assigned to expert i, and sets the distribution $\mathcal{D}^t = (p_1^t, \ldots, p_n^t)$, where $p_i^t = w_i^t / \sum_j w_j^t$. The MW algorithm then proceeds analogously to the Winnow algorithm and updates the weights at time step $t+1$ to $w_i^{t+1} = w_i^t(1-\delta)^{M(i,j^t)/\rho}$ if $M(i,j^t) \geq 0$ and $w_i^{t+1} = w_i^t(1+\delta)^{M(i,j^t)/\rho}$ if $M(i,j^t) < 0$, where δ is a parameter provided to the algorithm. For our analysis we will use the following theorem.

Theorem 2.1 (Corollary 4 of (Arora et al., 2005b))**.** *Suppose that for all i and $j \in \mathcal{E}$, $M(i,j) \in [-\rho, \rho]$. Let $\epsilon > 0$ be an error parameter and let $\delta = \min\{\frac{\epsilon}{4\rho}, \frac{1}{2}\}$, and $T = \frac{16\rho^2 \ln n}{\epsilon^2}$. Then, the following bound holds for the average expected loss of the MW algorithm*

$$\frac{\sum_{t=1}^{T}\sum_{l=1}^{n} p_l^t M(l, j^t)}{T} \leq \epsilon + \frac{\sum_t M(k, j^t)}{T}, \ \forall k.$$

2.2. Online Convex Programming

The online convex programming (OCP) framework (Zinkevich, 2003; Kalai & Vempala, 2005; Hazan et al., 2006) models various useful online learning problems like industrial production and network routing. The OCP framework involves a fixed convex set K and a sequence of unknown cost functions $f_1, f_2, \ldots : K \to \mathbb{R}$. At each time step t, a decision maker must choose a point $z_t \in K$ and incurs a cost $f_t(z_t)$. However, the choice of z_t must be made with the knowledge of $z_1, \ldots, z_{t-1}$ and $f_1, \ldots, f_{t-1}$ alone i.e., without knowing f_t. The total cost incurred by the algorithm after T steps equals $\sum_t f_t(z_t)$. The objective in OCP is to minimize the *regret* as defined below:

$$R(T) = \sum_{t=1}^{T} f_t(z_t) - \min_{z \in K} \sum_{t=1}^{T} f_t(z). \tag{1}$$

(Zinkevich, 2003) has shown that in the case when the functions f_t are convex and differentiable with bounded gradient, one can achieve a regret of $O(\sqrt{T})$. Let $\|K\| = \max_{z_1, z_2 \in K} \|z_1 - z_2\|$ and $G = \max_{z \in K, t \in \{1,\ldots\}} \| \bigtriangledown f^t(z)\|$, where $\|\cdot\|$ denotes the Euclidean norm (or Frobenius norm if the set K is defined over matrices). Also, assume that $\bigtriangledown f^t$ can be evaluated efficiently at any given point z. Under the above assumptions (Zinkevich, 2003) proposed a Generalized Infinitesimal Gradient Ascent algorithm which achieves a regret of $O((G^2 + \|K\|^2)\sqrt{T})$. The function GIGA in Algorithm 2 describes a slightly modified version of (Zinkevich, 2003)'s algorithm that achieves the following improved regret bound.

Theorem 2.2 (Adaptation of Theorem 1 of (Zinkevich, 2003))**.** *The following bound holds for the regret of the GIGA sub-routine of Algorithm 2 after T rounds,*

$$R(T) \leq G \cdot \|K\| \sqrt{T} \tag{2}$$

Proof sketch: Using the modified step-size in Algorithm 2, the theorem follows from Zinkevich's original proof. □

3. Computational Complexity

As was mentioned in the introduction, RMP is NP-hard in general. Further, by a reduction to the problem of support minimization over convex sets, and using hardness of approximation results from (Amaldi & Kann, 1998) we prove the following hardness result for RMP. A full proof of the following theorem appears in (Meka et al., 2008).

Theorem 3.1. *There exists no polynomial time algorithm for approximating* RMP *within a logarithmic factor unless $P = NP$. Further, assuming $NP \nsubseteq DTIME(n^{poly \log n})$,* RMP *is not approximable within a factor of $2^{\log^{1-\delta} n}$ for every $\delta > 0$; and* RMP *is not approximable within a factor of $2^{\log^{1-\delta} \Delta}$ for every $\delta > 0$, where $\Delta = \max\{\|A_i\|_F + |b_i| : 1 \leq i \leq m\}$* [1].

In view of the above hardness result we introduce a weaker notion of approximation. We believe the relaxed notion of approximation to be of equal use, if not more, as the standard notion of approximation in practice. For an instance of RMP, let $\mathbb{F}(A_1, \ldots, A_m, \boldsymbol{b}, \mathcal{C})$ denote the feasible region, where $\boldsymbol{b} = (b_1, \ldots, b_m)$:

$$\mathbb{F}(A_1, \ldots, A_m, \boldsymbol{b}, \mathcal{C}) = \{X : X \in \mathcal{C}, \mathrm{Tr}(A_i X) \geq b_i, \forall i\}. \tag{3}$$

[1] This hardness result holds even when $\mathcal{C}$ is fixed to be the unit ball under an L_p or Frobenius norm or many other common sets.

Definition 3.1. *Given a function $c : \mathbb{R} \to \mathbb{R}_+$, we say that a matrix $\overline{X}$ is a $(c(\epsilon), \epsilon)$-approximate solution to* RMP *if the following hold:*

$\bar{X} \in \mathbb{F}(A_1, \ldots, A_m, \boldsymbol{b} - \epsilon\mathbf{1}, \mathcal{C})$

$\textit{rank}(\bar{X}) \leq c(\epsilon) \min\{\textit{rank}(X) : X \in \mathbb{F}(A_1, .., A_m, \boldsymbol{b}, \mathcal{C})\}$.

Further, we say that RMP *is $(c(\epsilon), \epsilon)$-approximable, if there exists a polynomial time algorithm that given inputs $A_1, \ldots, A_m, \boldsymbol{b}, \epsilon$, outputs a $(c(\epsilon), \epsilon)$-approximate solution to* RMP.

Thus, along with approximating the minimum feasible rank we also allow a small violation, quantified by ϵ, of the constraints. Note that for $\epsilon = 0$, we recover the normal notion of approximation with an approximation factor of $c(0)$.

4. Methodology

Our approaches to RMP rely on the fact that even though RMP is hard in general, it is efficiently solvable for certain convex sets $\mathcal{C}$ when there is a single trace constraint. For instance, when $\mathcal{C} = \{X : \|X\|_F \leq 1\}$, a RMP problem with a single trace constraint can be solved efficiently using a singular value decomposition of the constraint matrix.

In our approach, we assume the existence of an oracle $\mathcal{O}$ that solves the following RMP problem with a single trace constraint, and returns an optimal X or declares the problem infeasible:

$$\mathcal{O}: \quad \min \text{ rank}(X) \text{ s.t. } \text{Tr}(AX) \geq b, X \in \mathcal{C}. \quad (4)$$

As discussed above, for certain convex sets $\mathcal{C}$, oracle $\mathcal{O}$ solves a non-convex problem. In both our approaches, we exploit this fact by making several queries to the oracle where the trace constraint $\text{Tr}(AX) \geq b$ is obtained by a weighted combination of the original trace constraints. The trick then is to choose the combinations in such a way that after a small number of iterations, we can find a low-rank X that satisfies all the constraints with at most an ϵ-violation.

Based on the above intuition, we give two approaches to solve the RMP problem - one based on the Multiplicative Weights Update algorithm and the other based on online convex programming.

Before we describe our algorithms, we need to introduce additional notation. For an instance of RMP specified by matrices $A_1, \ldots, A_m$, scalars $b_1, \ldots, b_m$ and convex set $\mathcal{C}$, let $D = \max\{\|X\|_F : X \in \mathcal{C}\}$. We assume, without loss of generality, that $D \geq 1$. Recall that $\mathbb{F}((A_1, \ldots, A_m), \boldsymbol{b}, \mathcal{C})$ and $\mathbb{F}((A_1, \ldots, A_m), \boldsymbol{b} - \epsilon\mathbf{1}, \mathcal{C})$ denote the feasibility sets as defined in (3) and $\Delta = \max\{\|A_i\|_F + |b_i| : 1 \leq i \leq m\}$. Further, let k^* be the rank of the optimal solution to RMP. That is,

$$k^* = \min\{\text{rank}(X) : X \in \mathbb{F}((A_1, \ldots, A_m), \boldsymbol{b}, \mathcal{C})\}.$$

Algorithm 1 RMP-MW (Multiplicative Updates)

Require: Constraints (A_i, b_i), $1 \leq i \leq m$, ϵ
Require: Oracle $\mathcal{O}(A, b)$ which solves $\min \text{ rank}(X) \quad s.t. \quad \text{Tr}(AX) \geq b,\ X \in \mathcal{C}$
Initialize: $w_i^1 = 1,\ \forall i$ and $t = 1$
repeat
  Set $(A^t, b^t) = \sum_i w_i^t (A_i, b_i)$
  if Oracle $\mathcal{O}(A^t, b^t)$ declares infeasibility **then**
    return Problem is infeasible
  else
    Obtain X^t using Oracle $\mathcal{O}(A^t, b^t)$
    Set $M(i, X^t) = \text{Tr}(A_i X^t) - b_i$
    Set $\rho = \max_i M(i, X^t)$
    Set $\boldsymbol{w}^{t+1}$=MultUpdate($\boldsymbol{w}^t, M, \rho, \epsilon$)
  end if
  Set $t = t + 1$
until $t > T$
return $\overline{X} = \sum_t X^t / T$

function $\boldsymbol{w}^{t+1}$=MultUpdate($\boldsymbol{w}^t, M, \rho, \epsilon$)
Set $\delta = \min\{\frac{\epsilon}{4\rho}, \frac{1}{2}\}$
for all $1 \leq i \leq m$ **do**
  if $M(i, X^t) \geq 0$ **then**
    $w_i^{t+1} = w_i^t (1 - \delta)^{M(i, X^t)/\rho}$
  else
    $w_i^{t+1} = w_i^t (1 + \delta)^{-M(i, X^t)/\rho}$
  end if
end for

4.1. Rank Minimization via Multiplicative Weights Update

In this section we present an approach to RMP based on the generalized experts (GE) framework described in Section 2.1. To adapt the GE framework for the RMP problem, we first need to select a set of experts, a set of events and the associated penalties. We associate each RMP constraint $\text{Tr}(A_i X) \geq b_i$ with an expert and let the events correspond to elements of $\mathcal{C}$. The penalty for expert i corresponding to the i-th constraint and event X is then given by $\text{Tr}(A_i X) - b_i$. Note that rather than rewarding a satisfied constraint, we penalize it. This strategy is motivated by the work of (Plotkin et al., 1991; Arora et al., 2005a) and is similar to boosting, where a distribution is skewed towards an example for which the current hypothesis made an incorrect prediction.

We assign weight w_i^t to the i-th expert in the t-th iteration, and initialize the weights $w_i^1 = 1$, for all i. In the t-th iteration we query the oracle $\mathcal{O}$ with $(A^t, b^t) = \sum_i w_i^t (A_i, b_i)$ to obtain a solution $X^{t+1} \in \mathcal{C}$. We then use the Multiplicative Weights Update algorithm as described in function MultUpdate of Algorithm 1 to compute the weights

w_i^{t+1} for the $(t+1)$-st iteration. Algorithm 1 describes our multiplicative update based algorithm for RMP. In the following theorem we prove approximation guarantees for the solution output by Algorithm 1.

Theorem 4.1. *Given the existence of an oracle $\mathcal{O}$ to solve the problem* (4)*, Algorithm 1 outputs an $(O(\frac{\Delta^2 D^2 \log n}{\epsilon^2}), \epsilon)$-approximate solution to* RMP.

Proof. Observe that, if the oracle declares infeasibility at any time step t, the original problem is also infeasible. Hence, we assume that the oracle returns a feasible point X^t at time-step t, for all $1 \leq t \leq T$.

Now, $|\text{Tr}(A_i X) - b_i| \leq \|A_i\|_F \|X\|_F + |b_i| \leq \Delta D$. Thus, the penalties $\text{Tr}(A_i X) - b_i$ lie in the interval $[-\Delta D, \Delta D]$. Since Algorithm 1 uses multiplicative updates to update the weights[2] as in Theorem 2.1, for $T = 16(\Delta D)^2 \log n/\epsilon^2$, we have

$$\frac{\sum_t \sum_j p_j^t [A_j X^t - b_j]}{T} \leq \epsilon + \frac{\sum_t [A_i X^t - b_i]}{T}, \ \forall i,$$

where $p_j^t = w_j^t / \sum_l w_l^t$. Since $\text{Tr}(A^t X^t) \geq b^t), \ \forall t$, the $LHS \geq 0$. Thus, for $\overline{X} = \sum_t X^t/T$ we have

$$\text{Tr}(A_i \overline{X}) \geq b_i - \epsilon, \quad \forall i. \tag{5}$$

We now bound the rank of $\overline{X}$ compared to the optimal value. Let t be such that X_t has the highest rank, say k, among $X_1, \ldots, X_T$. Then, $k^* \geq k$, as for a particular convex combination of (A_i, b_i) the minimum rank possible was k. Thus, $\text{rank}(\overline{X}) \leq kT = O(\frac{(\Delta^2 \cdot D^2 \log n) k^*}{\epsilon^2})$. Using (5) we have that $\overline{X} \in \mathbb{F}((A_1, \ldots, A_m), b - \epsilon \mathbf{1}, \mathcal{C})$. Thus, by Definition 3.1 $\overline{X}$ is an $(O(\frac{\Delta^2 D^2 \log n}{\epsilon^2}), \epsilon)$-approximate solution to RMP. □

The running time of Algorithm 1 is $O(\frac{\Delta^2 D^2 \log n}{\epsilon^2}(T_{\mathcal{O}} + mn^2))$, where $T_{\mathcal{O}}$ denotes the oracle's running time.

4.2. Rank Minimization via OCP

In this section, we present a novel application of online convex programming described in Section 2.2 to obtain an approximate solution to RMP. The intuition behind this approach is similar to that of Section 4.1; in fact this approach can be viewed as a generalization of the approach of Section 4.1.

In the OCP framework one generally associates the convex set K with a feasible region and the cost functions with penalty functions. In our application of OCP to RMP we flip this view and choose K to be the space of convex combinations of the constraints and associate cost functions with feasible points of RMP. In particular, we set $K \subseteq \mathbb{R}^{n \times n} \times \mathbb{R}$ to be the convex hull of $(A_1, b_1), \ldots, (A_m, b_m)$, i.e.,

$$K = \left\{ \sum_i \lambda_i (A_i, b_i) : \sum_i \lambda_i = 1, \lambda_i \geq 0 \ \forall i \right\}.$$

Given a matrix X, we define a cost function $f_X : K \to \mathbb{R}$ by $f_X(A, b) = \text{Tr}(AX) - b$.

We initialize $A^1 = \sum_i A_i/m$ and $b^1 = \sum_i b_i/m$. Given $(A^t, b^t) \in K$ for the t-th iteration, we query the oracle $\mathcal{O}$ with $(A, b) = (A^t, b^t)$ to obtain a solution $X^t \in \mathcal{C}$. We then set the cost function $f^t(A, b) = f_{X^t}(A, b) = \text{Tr}(AX^t) - b$ and use the OCP algorithm (Zinkevich, 2003) as described in function GIGA of Algorithm 2 to compute (A^{t+1}, b^{t+1}) for the $(t+1)$-st iteration. Algorithm 2 describes our OCP based algorithm for RMP. In the following theorem we prove approximation guarantees for the output of Algorithm 2.

Algorithm 2 RMP-OCP (Online Convex Programming)

Require: Constraints (A_i, b_i), $1 \leq i \leq m$, ϵ
Require: Oracle $\mathcal{O}(A, b)$ which solves $\min \text{rank}(X) \quad s.t. \quad \text{Tr}(AX) \geq b, \ X \in \mathcal{C}$
Initialize: $A^1 = \frac{\sum_i A_i}{m}$ and $b^1 = \frac{\sum_i b_i}{m}$, $t = 1$
Set $K = \{\sum_i \lambda_i (A_i, b_i) : \sum_i \lambda_i = 1, \lambda_i \geq 0 \ \forall i\}$
repeat
  if Oracle $O(A^t, b^t)$ declares infeasibility **then**
    return Problem is infeasible
  else
    Obtain X^t using Oracle $\mathcal{O}(A^t, b^t)$
    Define function $f^t(A, b) = \text{Tr}(AX^t) - b$
    Set (A^{t+1}, b^{t+1})=GIGA($(A^t, b^t), f^t(A, b), K, t$)
  end if
  Set $t = t + 1$
until $t > T$
return $\overline{X} = \sum_t X^t/T$

function $\boldsymbol{z^{t+1}}$=GIGA($\boldsymbol{z^t}, f^t(\boldsymbol{z}), K, t$)
Set $\eta_t = \frac{\Delta}{2D\sqrt{t}}$
Set $\boldsymbol{z^{t+1}} = \Pi_K \left(\boldsymbol{z^t} - \eta_t \nabla f^t(\boldsymbol{z^t}) \right)$, where Π_K represents the orthogonal projection onto K

Theorem 4.2. *Given the existence of an oracle $\mathcal{O}$ to solve the problem* (4)*, Algorithm 2 outputs an $(O(\frac{\Delta^2 D^2}{\epsilon^2}), \epsilon)$-approximate solution to* RMP.

Proof. As in Theorem 4.1 we assume that the oracle returns a feasible point at all time steps. Note that using the terminology of Theorem 2.2, $G = \max_{z \in K, t \in \{1, \ldots\}} \| \bigtriangledown$

[2] Our updates are slightly different from those of (Arora et al., 2005b) in that we adaptively choose the width parameter ρ. However, the analysis of (Arora et al., 2005b) is applicable for these updates as well.

$f^t(z)\| \leq D$ and $\|K\| \leq \Delta$. Thus, using Theorem 2.2 we have

$$\sum_{t=1}^{T}(\text{Tr}(A^tX^t)-b^t) \leq \min_{(A,b)\in K}\sum_{t=1}^{T}(\text{Tr}(AX^t)-b)+\Delta D\sqrt{T}.$$

Note that the above LHS ≥ 0 since oracle returns a feasible $X^t,\ \forall t$. Thus, for $T = \Delta^2D^2/\epsilon^2$ and $\overline{X} = \sum_t X^t/T$,

$$\text{Tr}(A\overline{X}) \geq b - \epsilon, \tag{6}$$

for all $(A, b) \in K$. In particular, we have for every i, $\text{Tr}(A_i\overline{X}) \geq b_i - \epsilon$. We now bound the rank of $\overline{X}$ compared to the optimal value. Let t be such that X_t has the highest rank, say k, among $X_1, \ldots, X_T$. Then, we must have $k^* \geq k$, and so we have $\text{rank}(\overline{X}) \leq kT \leq O((\Delta D)^2k^*/\epsilon^2)$. Also, from (6) we have that $\overline{X} \in \mathbb{F}((A_1, \ldots, A_m), b - \epsilon\mathbf{1}, \mathcal{C})$. Thus by Definition 3.1, $\overline{X}$ is a $(O((\Delta^2D^2)/\epsilon^2), \epsilon)$-approximate solution to RMP. □

The running time of Algorithm 2 is $O(\frac{\Delta^2D^2}{\epsilon^2}(T_{\mathcal{O}}+T_{OCP}+mn^2))$, where $T_{\mathcal{O}}$ denotes the running time of the oracle, and T_{OCP} denotes the time taken in each round by the GIGA algorithm of Theorem 2.2.

4.3. Discussion

Oracle: The oracle for solving problem (4) plays a crucial role in both our approaches. As discussed previously, for typical cases of $\mathcal{C}$, like the unit ball under an L_p or Frobenius norm etc., (4) can be solved by the singular value decomposition of A. Further, in the case when the set $\mathcal{C}$ involves a quadratic or ellipsoid constraint we can use the S-procedure (Rockafellar, 1970) to solve (4).

Comparison of the approaches: Our approach to RMP based on Multiplicative Weights Update has a slightly weaker guarantee than the approach based on OCP. This is also confirmed by our experiments where OCP gives better results than the MW approach. However, the MW approach is computationally less intensive as the approach based on OCP involves a projection onto the convex set K. Thus, MW can be used for large scale problems.

Limitations: A drawback of our methods is the dependence on Δ, ϵ in the bounds of Theorems 4.1 and 4.2. This limits the applicability of our methods to problems, such as NNMA, with a large number of non-negativity constraints where the ratio $\frac{\Delta}{\epsilon}$ is typically large. However, our algorithms can be used as a heuristic for such problems and can be used to initialize other methods which require a good low-rank solution for initialization. Also, the lower bounds for the experts framework and boosting suggest that the dependence on Δ, ϵ in our bounds may be optimal for the general RMP problem (Arora et al., 2005b).

5. Low-rank Kernel Learning

In this section we apply both our rank minimization algorithms to the problem of low-rank kernel learning, which involves finding a low-rank positive semi-definite (p.s.d.) matrix that satisfies linear constraints typically derived from labeled data. Due to the rank constraint, this problem is non-convex and is in general hard to solve. As described below, both our online learning approaches can be applied naturally to this problem. We provide provable guarantees on the rank of the obtained kernel.

Formally, the low-rank kernel learning problem can be cast as the following optimization problem:

$$\begin{aligned} \min_K \quad & \|K - K_0\|_F \\ \text{s.t.} \quad & \text{Tr}(S_iK) \leq \ell, \quad \forall\ 1 \leq i \leq |\mathcal{S}|, \\ & \text{Tr}(D_jK) \geq u, \quad \forall\ 1 \leq j \leq |\mathcal{D}|, \\ & \text{rank}(K) \leq r, \quad K \succeq 0, \end{aligned} \tag{7}$$

where $\mathcal{S}$ is a set of pairs of points from the same class that are constrained to have distance less than ℓ. Similarly, $\mathcal{D}$ is a set of pairs of points from different classes that are constrained to have distance greater than u, with $\ell \ll u$. For a similarity constraint matrix S_i, $S_i(i_1, i_1) = S_i(i_2, i_2) = 1$, $S_i(i_1, i_2) = S_i(i_2, i_1) = -1$ and all other entries 0. The dissimilarity constraint matrices D_j can be constructed similarly. Assuming $\|K_0\|_F = 1$, (7) can be reformulated as:

$$\begin{aligned} \min_K \quad & \text{rank}(K) \\ \text{s.t.} \quad & \text{Tr}(S_iK) \leq \ell\ \forall i, \quad \text{Tr}(D_jK) \geq u\ \forall j, \\ & \text{Tr}(KK_0) \geq \beta, \quad \|K\|_F \leq 1, \quad K \succeq 0, \end{aligned} \tag{8}$$

where β is a function of r and can be computed using binary search. Note that (8) is a special case of RMP with the convex set $\mathcal{C}$ being the intersection of the p.s.d. cone and the unit Frobenius ball. Hence, we can use RMP-MW and RMP-OCP to solve (8). Given (A, b) the oracle for both the methods solves:

$$\min_K \text{rank}(K) :\ \text{Tr}(AK) \geq b, \|K\|_F \leq 1,\ K \succeq 0. \tag{9}$$

Let $A = U\Sigma U^T$ be the eigenvalue decomposition of A, and let Λ be a diagonal matrix with just the positive entries of Σ. Then the minimum k s.t. $\sqrt{\sum_{i=1}^{k}\Lambda(i,i)^2} \geq b$ is the solution to (9). This follows from elementary linear algebra. Note that for the oracle solving (9), $T_{\mathcal{O}} = O(n^3)$.

Now, $D = 1$ and $\Delta = O(1 + l^2 + u^2)$ as $\|S_i\|_F = \|D_j\|_F = 2$. Using Theorem 4.1, the RMP-MW algorithm obtains a solution with rank $r \leq O(\frac{1+u^2+l^2}{\epsilon^2}\log n)r^*$ where r^* is the optimal rank. Similarly, RMP-OCP obtains an $\left(O(\frac{1+u^2+l^2}{\epsilon^2}), \epsilon\right)$-approximate solution. In Section 6.2, we present empirical results for RMP-MW and RMP-OCP algorithms on some standard UCI datasets.

6. Experimental Results

We empirically evaluate and compare our algorithms to existing methods for general RMP as well as low-rank kernel learning. For general RMP, we use synthetic examples to compare our methods against the trace-norm heuristic (Recht et al., 2007) and the log-det heuristic (Fazel et al., 2001). The trace-norm heuristic relaxes the rank objective to the trace-norm of the matrix, which is given by the sum of its singular values. Note that the trace-norm of a matrix is a convex function. The log-det heuristic relaxes the rank objective to the log of the determinant of the matrix. For the application of RMP to low-rank kernel learning, we use standard UCI datasets. All the presented results represent the average over 20 runs.

6.1. Synthetic Datasets

First we use synthetic datasets by generating random matrices $A_i \in \mathbb{S}_n$, where $\mathbb{S}_n$ is the set of $n \times n$ symmetric matrices. We also generate a random positive semi-definite matrix $X_0 \in \mathbb{S}_n$ with $\|X_0\|_F \leq 1$, and use the obtained X_0 to generate constraints $\text{Tr}(A_i X) \geq b_i = \text{Tr}(A_i X_0)$. The convex set $\mathcal{C}$ is fixed to be the intersection of the p.s.d cone and the unit ball under the Frobenius norm. We fix the number of constraints to be 200 and the tolerance ϵ for RMP-MW and RMP-OCP to be 5%. We use SeDuMi to implement the trace-norm and log-det heuristics.

In Table 1, we compare the ranks of the solutions obtained by our algorithms against the ones obtained by the trace-norm and log-det heuristics. For small n, both trace-norm and log-det heuristic perform better than RMP-MW and RMP-OCP. Note that since the constraint matrices A_i are random, they satisfy (with high probability) the restricted isometry property used in the analysis of (Recht et al., 2007). However, RMP-OCP outperforms trace-norm heuristic for large n (Table 1, $n = 100$) and RMP-MW performs comparably. We attribute this phenomenon to the Frobenius norm constraint for which the theoretical guarantees of (Recht et al., 2007) are not applicable. Also, both trace-norm and log-det heuristic scale poorly with the problem size and fail to obtain a result in reasonable time even for moderately large n. In contrast, both our algorithms scale well with n, with RMP-MW in particular able to solve problems of sizes up to $n = 5000$.

6.2. Low-rank Kernel Learning

We evaluate the performance of our methods applied to the problem of low-rank kernel learning, as described in Section 5, for k-NN classification on standard UCI datasets. We use two-fold cross validation with $k = 5$. The lower and upper bounds for the similarity and dissimilarity constraints (l, u) are set using the 30-th and 70-th percentiles of the observed distribution of distances between pairs of points. We randomly select a set of $40c^2$ pairs of points for constraints, where c is the number of classes in the dataset. We run both RMP-MW and RMP-OCP for $T = 50$ iterations. Empirically our algorithms significantly outperform the theoretical rank guarantees of Theorems (4.1) and (4.2).

Method\n	50	75	100	200	300
RMP-MW	23.25	11.25	7.3	2	2
RMP-OCP	12.8	7.5	5.3	2	2
Trace-norm	6.8	6.7	6.5	-	-
LogDet	5	4.2	4.0	-	-

Table 1. Rank of the matrices obtained by different RMP methods for varying size of the constraint matrices (n). The number of constraints generated (m) is fixed to be 200. A "-" represents that the method could not find a solution within 3 hours on a 2.6GHz Pentium 4 machine. Note that for large problem sizes, both the trace-norm and the log-det heuristics are not computationally viable. Both our approaches outperform the trace-norm heuristic as the problem size increases.

Dataset\Method	GK	MW	OCP	BK
Musk	80.80 (476)	93.11 (44.1)	**98.15** (61.2)	81.51 (61.2)

Table 2. Accuracies for 5-Nearest Neighbor classification using kernels obtained by different methods. Numbers in parentheses represent the rank of the obtained solution. GK represents Gaussian Kernel ($\sigma = 0.1$), MW represents RMP-MW, OCP represents RMP-OCP and BK represents BurgKernel(Kulis et al., 2006). Overall, RMP-OCP obtains the best accuracy.

Table 2 shows the accuracies achieved by the baseline Gaussian kernel (with $\sigma = 0.1$), RMP-MW, RMP-OCP and the Burg divergence (also called as LogDet divergence) based low-rank kernel learning algorithm (BurgKernel) of (Kulis et al., 2006). It can be seen from the table that both RMP-MW and RMP-OCP obtain a significantly lower rank kernel than the baseline Gaussian kernel. Further, RMP-MW and RMP-OCP achieve a substantially higher accuracy than the Gaussian kernel. Our algorithms also achieve a substantial improvement in accuracy over the BurgKernel method. Note that we iterate our algorithms for fewer iterations compared to the ones suggested by the theoretical bounds, hence few of the constraints maybe unsatisfied. This suggests that these unsatisfied constraints maybe noisy constraints and have small effect on the generalization error. We leave further investigation into gener-

alization error of our methods as a topic for future research.

Note that the BurgKernel method needs to be initialized with a low-rank kernel. Typically, a few top eigenvectors of the baseline kernel are used for this initialization. However, selecting only a few top eigenvectors can lead to a poor initial kernel, especially if the rank of the initial kernel is high. This can further lead to poor accuracy for the BurgKernel method, as indicated by our experiments. Instead, the kernels obtained by our algorithms could be used to *initialize* the BurgKernel algorithm. For example, for the case of the Heart dataset, initialization of BurgKernel algorithm with the low-rank solution obtained by RMP-OCP method achieves an accuracy of 94.29 compared to 83.91 achieved when initialized with the top eigenvectors of the baseline Gaussian kernel. Note that this also improves upon the accuracy achieved by RMP-MW and RMP-OCP.

7. Conclusion

In this paper, we address the general problem of rank minimization over polyhedral sets and in particular the problem of low-rank kernel learning. We show that the problem is hard to approximate within a factor of $2^{\log^{1-\epsilon}\Delta}$ (see Theorem 3.1). Further, we introduce a relaxed notion of approximation and present two novel approaches for solving RMP with provable guarantees. Our first approach is based on the multiplicative weights update framework and provides an $(O(\frac{\Delta^2 D^2}{\epsilon^2}\log n), \epsilon)$-approximate solution. Our second approach is based on online convex programming and provides a tighter bound of $O(\frac{\Delta^2 D^2}{\epsilon^2})$ for the rank of the obtained matrix.

For future work, it would be interesting to see if the hardness of approximation factor of Theorem 3.1 can be improved; we believe it can be improved to $O(\Delta^2)$. Another question of interest is whether the dependence on ϵ in the bounds of Theorems 4.1 and 4.2 can be improved.

The regret bounds of (Zinkevich, 2003) were improved in (Hazan et al., 2006). However, the algorithms of (Hazan et al., 2006) require stronger convexity properties which are not satisfied in our application of OCP to RMP. It would be interesting to see if the linear constraints in RMP can be perturbed to satisfy the strong convexity properties, so that the improved regret bounds of (Hazan et al., 2006) can be used to achieve better bounds for RMP.

Our algorithms to RMP are motivated from an online learning perspective. However, for an optimization problem such as RMP an understanding of the algorithms from an optimization perspective would be highly desirable. In particular, intuitively there seems to be a correspondence between our methods and a primal-dual approach but we were unable to obtain a rigorous connection. We believe that such an understanding would be of importance in obtaining new applications of the online learning approach to solving optimization problems.

Abstract

We address the problem of computing the optimal Q-function in Markov decision problems with infinite state-space. We analyze the convergence properties of several variations of Q-learning when combined with function approximation, extending the analysis of TD-learning in (Tsitsiklis & Van Roy, 1996a) to stochastic control settings. We identify conditions under which such approximate methods converge with probability 1. We conclude with a brief discussion on the general applicability of our results and compare them with several related works.

1. Introduction

Convergence of Q-learning with function approximation has been a long standing open question in reinforcement learning (Sutton, 1999). In general, value-based reinforcement learning (RL) methods for optimal control behave poorly when combined with function approximation (Baird, 1995; Tsitsiklis & Van Roy, 1996a). In this paper, we address this problem by analyzing the convergence of Q-learning when combined with linear function approximation. We identify a set of conditions that imply the convergence of this approximation method with probability 1 (w.p.1), when a fixed learning policy is used, and provide an interpretation of the resulting approximation as the fixed point of a Bellman-like operator. This motivates the analysis of several variations of Q-learning when combined with linear function approximation. In particular, we study a variation of Q-learning using importance sampling and an on-policy variant of Q-learning (SARSA).

The paper is organized as follows. We start in Section 2 by describing Markov decision problems. We proceed with our analysis of the Q-learning algorithm and its variants, and produce our main results in Section 3. We also compare our results with other related works in the RL literature. We conclude with some further discussion in Section 4.

2. Markov Decision Problems

Let $(\mathcal{X}, \mathcal{A}, \mathsf{P}, r, \gamma)$ be a Markov decision problem (MDP) with a compact state-space $\mathcal{X} \subset \mathbb{R}^p$ and a finite action set $\mathcal{A}$. The action-dependent kernel P_a defines the transition probabilities for the underlying controlled Markov chain $\{X_t\}$ as

$$\mathbb{P}\left[X_{t+1} \in U \mid X_t = x, A_t = a\right] = \mathsf{P}_a(x, U),$$

where U is any measurable subset of $\mathcal{X}$. The $\mathcal{A}$-valued process $\{A_t\}$ represents the control process: A_t is the control action at time instant t.[1] Solving the MDP consists in determining the control process $\{A_t\}$ maximizing the expected total discounted reward

$$V\big(\{A_t\}, x\big) = \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R(X_t, A_t) \mid X_0 = x\right],$$

where $0 \leq \gamma < 1$ is a discount-factor and $R(x, a)$ represents a random "reward" received for taking action $a \in \mathcal{A}$ in state $x \in \mathcal{X}$. For simplicity of notation, we consider a bounded deterministic function $r : \mathcal{X} \times \mathcal{A} \times \mathcal{X} \longrightarrow \mathbb{R}$ assigning a reward $r(x, a, y)$ every time a transition from x to y occurs after taking

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] We take the control process $\{A_t\}$ to be adapted to the σ-algebra induced by $\{X_t\}$.

action a. This means that

$$\mathbb{E}\left[R(x,a)\right] = \int_{\mathcal{X}} r(x,a,y)\mathsf{P}_a(x,dy).$$

The *optimal value function* V^* is defined for each state $x \in \mathcal{X}$ as

$$V^*(x) = \max_{\{A_t\}} V\big(\{A_t\}, x\big) = \\ = \max_{\{A_t\}} \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R(X_t, A_t) \mid X_0 = x\right]$$

and verifies the Bellman optimality equation

$$V^*(x) = \max_{a\in\mathcal{A}} \int_{\mathcal{X}} \big[r(x,a,y) + \gamma V^*(y)\big]\mathsf{P}_a(x,dy). \quad (1)$$

$V^*(x)$ represents the expected total discounted reward received along an optimal trajectory starting at state x. We can also define the optimal Q-function Q^* as

$$Q^*(x,a) = \int_{\mathcal{X}} \big[r(x,a,y) + \gamma V^*(y)\big]\mathsf{P}_a(x,dy), \quad (2)$$

representing the expected total discounted reward along a trajectory starting at state x obtained by choosing a as the first action and following the optimal policy thereafter. The control process $\{A_t\}$ defined as

$$A_t = \arg\max_{a\in\mathcal{A}} Q^*(X_t, a), \quad \forall t,$$

is optimal in the sense that $V(\{A_t\}, x) = V^*(x)$ and defines a mapping $\pi^* : \mathcal{X} \to \mathcal{A}$ known as the *optimal policy*. The optimal policy determines the optimal decision rule for a given MDP.

More generally, a (Markov) *policy* is any mapping π_t defined over $\mathcal{X} \times \mathcal{A}$ generating a control process $\{A_t\}$ verifying, for all t,

$$\mathbb{P}\left[A_t = a \mid X_t = x\right] = \pi_t(x,a), \quad \forall t.$$

We write $V^{\pi_t}(x)$ instead of $V(\{A_t\}, x)$ if the control process $\{A_t\}$ is generated by policy π_t. A policy π_t is *stationary* if it does not depend on t and *deterministic* if it assigns probability 1 to a single action in each state and is thus represented as a map $\pi_t : \mathcal{X} \to \mathcal{A}$ for every t. Notice that the optimal control process can be obtained from the optimal (stationary, deterministic) policy π^*, which can in turn be obtained from Q^*. Therefore, the optimal control problem is solved once the function Q^* is known for all pairs (x,a).

Now given any real function q defined over $\mathcal{X} \times \mathcal{A}$, we define the Bellman operator

$$(\mathbf{H}q)(x,a) = \int_{\mathcal{X}} \big[r(x,a,y) + \gamma \max_{u\in\mathcal{A}} q(y,u)\big]\mathsf{P}_a(x,dy). \quad (3)$$

The function Q^* in (2) is the fixed-point of $\mathbf{H}$ and, since this operator is a contraction in the sup-norm, a fixed-point iteration can be used to determine Q^* (at least theoretically).

2.1. The Q-Learning Algorithm

We previously suggested that a fixed-point iteration could be used to determine the function Q^*. In practice, this requires two important conditions:

- The kernel P and the reward function r are known;
- The successive estimates for Q^* can be represented compactly and stored in a computer with finite memory.

If P and/or r are not known, a fixed-point iteration using $\mathbf{H}$ is not possible. To solve this problem, Watkins proposed in 1989 the *Q-learning algorithm* (Watkins, 1989). Q-learning proceeds as follows: consider a MDP $\mathcal{M} = (\mathcal{X}, \mathcal{A}, \mathsf{P}, r, \gamma)$ and suppose that $\{x_t\}$ is an infinite sample trajectory of the underlying Markov chain obtained with some policy π_t. The corresponding sample control process is denoted as $\{a_t\}$ and the sequence of obtained rewards as $\{r_t\}$. Given any initial estimate Q_0, Q-learning successively updates this estimate using the rule

$$Q_{t+1}(x,a) = Q_t(x,a) + \alpha_t(x,a)\Delta_t, \quad (4)$$

where $\{\alpha_t\}$ is a step-size sequence and Δ_t is the temporal difference at time t,

$$\Delta_t = r_t + \gamma \max_{b\in\mathcal{A}} Q_t(x_{t+1}, b) - Q_t(x_t, a_t). \quad (5)$$

If both $\mathcal{X}$ and $\mathcal{A}$ are finite sets, each estimate Q_t is simply a $|\mathcal{X}| \times |\mathcal{A}|$ matrix and can be represented explicitly in a computer. In that case, the convergence of Q-learning and several other related algorithms (such as TD(λ) or SARSA) has been thoroughly studied (see, for example, (Bertsekas & Tsitsiklis, 1996) and references therein). However, if either $\mathcal{X}$ or $\mathcal{A}$ are infinite or very large, explicitly representing each Q_t becomes infeasible and some form of compact representation is needed (*e.g.*, using function approximation). In this paper, we address how several RL methods such as Q-learning and SARSA can be combined with function approximation and still retain their main convergence properties.

3. Reinforcement Learning with Linear Function Approximation

In this section, we address the problem of determining the optimal Q-function for MDPs with infinite state-space $\mathcal{X}$. Let $\mathcal{Q} = \{Q_\theta\}$ be a family of real-valued

functions defined in $\mathcal{X} \times \mathcal{A}$. It is assumed that the function class is linearly parameterized, so that $\mathcal{Q}$ can be expressed as the linear span of a *fixed set* of M linearly independent functions $\phi_i : \mathcal{X} \times \mathcal{A} \to \mathbb{R}$. For each M-dimensional parameter vector $\theta \in \mathbb{R}^M$, the function $Q_\theta \in \mathcal{Q}$ is defined as,

$$Q_\theta(x,a) = \sum_{i=1}^{M} \phi_i(x,a)\theta(i) = \phi^\top(x,a)\theta,$$

where $^\top$ represents the transpose operator. We will also denote the above function by $Q(\theta)$ to emphasize the dependence on θ over the dependency on (x,a).

Let π be a fixed stochastic, stationary policy and suppose that $\{x_t\}$, $\{a_t\}$ and $\{r_t\}$ are sampled trajectories of states, actions and rewards obtained from the MDP using policy π. In the original Q-learning algorithm, the Q-values are updated according to (4). The temporal difference Δ_t can be interpreted as a 1-step estimation error with respect to the optimal function Q^*. The update rule in Q-learning "moves" the estimates Q_t closer to the desired function Q^*, minimizing the expected value of Δ_t.

In our approximate setting, we apply the same underlying idea to obtain the update rule for approximate Q-learning:

$$\begin{aligned} \theta_{t+1} &= \theta_t + \alpha_t \nabla_\theta Q_\theta(x_t,a_t)\Delta_t \\ &= \theta_t + \alpha_t \phi(x_t,a_t)\Delta_t, \end{aligned} \tag{6}$$

where, as above, Δ_t is the temporal difference at time t defined in (5). Notice that (6) updates θ_t using the temporal difference Δ_t as the error. The gradient $\nabla_\theta Q_\theta$ provides the "direction" in which this update is performed.

To establish convergence of the algorithm (6) we adopt an ODE argument, establishing the trajectories of the algorithm to closely follow those of an associated ODE with a globally asymptotically stable equilibrium point. This will require several regularity properties on the policy π and on its induced Markov chain that will, in turn, motivate the study of the on-policy version of the algorithm. This on-policy algorithm can be seen as an extension of SARSA to infinite settings.

3.1. Convergence of Q-Learning

We now proceed by identifying conditions that ensure the convergence of Q-learning with linear function approximation as described by (6). Due to space limitations, we overlook some of the technical details in the proofs that can easily be filled in.

We start by introducing some notation that will greatly simplify the presentation. Given an MDP $\mathcal{M} = (\mathcal{X}, \mathcal{A}, \mathsf{P}, r, \gamma)$ with compact state space $\mathcal{X} \subset \mathbb{R}^p$, let $(\mathcal{X}, \mathsf{P}_\pi)$ be the Markov chain induced by a fixed policy π. We assume the chain $(\mathcal{X}, \mathsf{P}_\pi)$ to be uniformly ergodic with invariant probability measure μ_X and the policy π to verify $\pi(x,a) > 0$ for all $a \in \mathcal{A}$ and μ_X-almost all $x \in \mathcal{X}$. We denote by μ_π the probability measure defined for each measurable set $U \subset \mathcal{X}$ and each action $a \in \mathcal{A}$ as

$$\mu_\pi(U \times \{a\}) = \int_U \pi(x,a)\mu_X(dx).$$

Let now $\{\phi_i, i = 1, \ldots, M\}$ be a set of bounded, linearly independent basis functions to be used in our approximate Q-learning algorithm. We denote by Σ_π the matrix defined as

$$\Sigma_\pi = \mathbb{E}_\pi\left[\phi(x,a)\phi^\top(x,a)\right] = \int_{\mathcal{X}\times\mathcal{A}} \phi\,\phi^\top d\mu_\pi$$

Notice that the above expression is well-defined and independent of the initial distribution for the chain, due to our assumption of uniform ergodicity.

For fixed $\theta \in \mathbb{R}^M$ and $x \in \mathcal{X}$, define the set of maximizing actions at x as

$$\mathcal{A}_x^\theta = \{a^* \in \mathcal{A} \mid \phi^\top(x,a^*)\theta = \max_a \phi^\top(x,a)\theta\}$$

and the greedy policy with respect to θ as any policy that, at each state x, assigns positive probability only to actions in $\mathcal{A}_x^\theta$. Finally, let ϕ_x denote the row-vector $\phi^\top(x,a)$, where a is a random action generated according to the policy π at state x; likewise, let ϕ_x^θ denote the row-vector $\phi^\top(x,a_x^\theta)$, where a_x^θ is now any action in $\mathcal{A}_x^\theta$. We now introduce the θ-*dependent* matrix

$$\Sigma_\pi^*(\theta) = \mathbb{E}_\pi\left[\left(\phi_x^\theta\right)^\top \phi_x^\theta\right].$$

By construction, both Σ_π and Σ_π^* are positive definite, since the functions ϕ_i are assumed linearly independent. Notice also the difference between Σ_π and each Σ_π^*: the actions in the definition of the former are taken according to π while in the latter they are taken greedily with respect to a particular θ.

We are now in position to introduce our first result.

Theorem 1 *Let $\mathcal{M}$, π and $\{\phi_i, i = 1, \ldots, M\}$ be as defined above. If, for all θ,*

$$\Sigma_\pi > \gamma^2 \Sigma_\pi^*(\theta) \tag{7}$$

and the step-size sequence verifies

$$\sum_t \alpha_t = \infty \qquad \sum_t \alpha_t^2 < \infty,$$

then the algorithm in (6) *converges w.p.1 and the limit point* θ^* *verifies the recursive relation*

$$Q(\theta^*) = \Pi_{\mathcal{Q}} \mathbf{H} Q(\theta^*),$$

where $\Pi_{\mathcal{Q}}$ *is the orthogonal projection onto* $\mathcal{Q}$.[2]

PROOF We establish the main statement of the theorem using a standard ODE argument.

The assumptions on the chain $(\mathcal{X}, \mathsf{P}_\pi)$ and basis functions $\{\phi_i, i = 1, \ldots, M\}$ and the fact that $\pi(x, a) > 0$ for all $a \in \mathcal{A}$ and μ_X-almost every $x \in \mathcal{X}$ ensure the applicability of Theorem 17 in page 239 of (Benveniste et al., 1990). Therefore, the convergence of the algorithm can be analyzed in terms of the stability of the equilibrium points of the associated ODE

$$\dot{\theta} = \mathbb{E}_\pi \Big[\phi_x^\top \big(r(x, a, y) + \gamma \phi_y^\theta \theta - \phi_x \theta \big) \Big], \qquad (8)$$

where we omitted the explicit dependence of θ on t to avoid excessively cluttering the expression. If the ODE (8) has a globally asymptotically stable equilibrium point, this implies the algorithm (6) to converge w.p.1 (Benveniste et al., 1990). Let then $\theta_1(t)$ and $\theta_2(t)$ be two trajectories of the ODE starting at different initial conditions, and let $\tilde{\theta}(t) = \theta_1(t) - \theta_2(t)$. From (8), we get

$$\frac{d}{dt} \|\tilde{\theta}\|_2^2 = -2 \tilde{\theta}^\top \Sigma_\pi \tilde{\theta} + 2\gamma \mathbb{E}_\pi \Big[\big(\phi_x \tilde{\theta} \big) \big(\phi_y^{\theta_1} \theta_1 - \phi_y^{\theta_2} \theta_2 \big) \Big].$$

Notice now that, from the definition of $\phi_y^{\theta_1}$ and $\phi_y^{\theta_2}$,

$$\phi_y^{\theta_1} \theta_2 \leq \phi_y^{\theta_2} \theta_2 \qquad \phi_y^{\theta_2} \theta_1 \leq \phi_y^{\theta_1} \theta_1.$$

Taking this into account and defining the sets $S_+ = \{(x, a) \mid \phi^\top(x, a) \tilde{\theta} > 0\}$ and $S_- = \mathcal{X} \times \mathcal{A} - S_+$, the previous expression becomes

$$\frac{d}{dt} \|\tilde{\theta}\|_2^2 \leq -2 \tilde{\theta}^\top \Sigma_\pi \tilde{\theta} + 2\gamma \mathbb{E}_\pi \Big[\big(\phi_x \tilde{\theta} \big) \big(\phi_y^{\theta_1} \tilde{\theta} \big) \mathbb{I}_{S_+} \Big] + 2\gamma \mathbb{E}_\pi \Big[\big(\phi_x \tilde{\theta} \big) \big(\phi_y^{\theta_2} \tilde{\theta} \big) \mathbb{I}_{S_-} \Big],$$

where $\mathbb{I}_S$ represents the indicator function for the set S. Applying Hölder's inequality to each of the expectations above, we get

$$\frac{d}{dt} \|\tilde{\theta}\|_2^2 \leq -2 \tilde{\theta}^\top \Sigma_\pi \tilde{\theta} + 2\gamma \sqrt{\mathbb{E}_\pi \Big[(\phi_x \tilde{\theta})^2 \mathbb{I}_{S_+} \Big] \mathbb{E}_\pi \Big[(\phi_x^{\theta_1} \tilde{\theta})^2 \mathbb{I}_{S_+} \Big]} + 2\gamma \sqrt{\mathbb{E}_\pi \Big[(\phi_x \tilde{\theta})^2 \mathbb{I}_{S_-} \Big] \mathbb{E}_\pi \Big[(\phi_x^{\theta_2} \tilde{\theta})^2 \mathbb{I}_{S_-} \Big]}$$

and a few simple computations finally yield

$$\frac{d}{dt} \|\tilde{\theta}\|_2^2 \leq -2 \tilde{\theta}^\top \Sigma_\pi \tilde{\theta} + 2\gamma \sqrt{\tilde{\theta}^\top \Sigma_\pi \tilde{\theta} \max \big(\tilde{\theta}^\top \Sigma_\pi^*(\theta_1) \tilde{\theta}, \tilde{\theta}^\top \Sigma_\pi^*(\theta_2) \tilde{\theta} \big)}.$$

Since, by assumption, $\Sigma_\pi > \gamma^2 \Sigma_\pi^*(\theta)$, we can conclude from the expression above that

$$\frac{d}{dt} \|\tilde{\theta}\|_2^2 < 0.$$

This means, in particular, that $\tilde{\theta}(t)$ converges asymptotically to the origin, *i.e.*, the ODE (8) is globally asymptotically stable. Since the ODE is autonomous (*i.e.*, time-invariant), there exists one globally asymptotically stable equilibrium point for the ODE, that verifies the recursive relation

$$\theta^* = \Sigma_\pi^{-1} \mathbb{E}_\pi \Big[\phi_x \big(r(x, a, y) + \gamma \phi_y^{\theta^*} \theta^* \big) \Big]. \qquad (9)$$

Since Σ_π is, by construction, positive definite, the inverse in (9) is well-defined. Multiplying (9) by $\phi^\top(x, a)$ on both sides yields the desired result. □

It is now important to observe that condition (7) is quite restrictive: since γ is usually taken close to 1, condition (7) essentially requires that, for every θ,

$$\max_{a \in \mathcal{A}} \phi^\top(x, a) \theta \approx \sum_{a \in \mathcal{A}} \pi(x, a) \phi^\top(x, a) \theta.$$

Therefore, such condition will seldom be met in practice, since it implies that the learning policy π is already close to the policy that the algorithm is meant to compute. In other words, the maximization above yields a policy close to the policy used during learning. And, when this is the case, the algorithm essentially behaves like an *on-policy algorithm.*

On the other hand, the above condition can be ensured by considering only a local maximization around the learning policy π. This is the most interesting aspect of the above result: it explicitly relates how much information the learning policy provides about greedy policies, as a function of γ. To better understand this,

[2] The orthogonal projection is naturally defined in the (infinite-dimensional) Hilbert space containing $\mathcal{Q}$ with inner-product given by

$$\langle f, g \rangle = \int_{\mathcal{X} \times \mathcal{A}} f \, g \, d\mu_\pi.$$

notice that each policy π is associated with a particular invariant measure on the induced chain $(\mathcal{X}, \mathsf{P}_\pi)$. In particular, the measure associated with the learning policy may be very different from the one induced by the greedy/optimal policy. Taking into account the fact that γ measures, in a sense, the "importance of the future", Theorem 1 basically states that:

In problems where the performance of the agent greatly depends on future rewards ($\gamma \approx 1$), the information provided by the learning policy can only be "safely generalized" to nearby greedy policies, in the sense of (7). *In problems where the performance of the agent is less dependent on future rewards ($\gamma \ll 1$), the information provided by the learning policy can be safely generalized to more general greedy policies.*

Suppose then that the maximization in the update equation (6) is to be replaced by a local maximization. In other words, instead of maximizing over all actions in $\mathcal{A}$, the algorithm should maximize over a small neighborhood of the learning policy π (in policy space). The difficulty with this approach is that such maximization can be hard to implement. The use of *importance sampling* can readily overcome such difficulty, by making the maximization in policy-space *implicit*. The algorithm thus obtained, which resembles in many aspects the one proposed in (Precup et al., 2001), is described by the update rule

$$\theta_{t+1} = \theta_t + \alpha_t \phi(x_t, a_t) \hat{\Delta}_t, \tag{10}$$

where the modified temporal difference $\hat{\Delta}_t$ is given by

$$\hat{\Delta}_t = r_t + \gamma \sum_b \frac{\pi_\theta(x_{t+1}, b)}{\pi(x_{t+1}, b)} Q_{\theta_t}(x_{t+1}, b) - Q_{\theta_t}(x_t, a_t), \tag{11}$$

where π_θ is, for example, a θ-dependent ε-greedy policy close to the learning policy π.[3] A possible implementation of such algorithm is sketched in Figure 1. We denoted by π_N the behavior policy at iteration N of the algorithm; in the stopping condition for the algorithm, any adequate policy norm can be used.

3.2. SARSA with Linear Function Approximation

The analysis in the previous subsection suggests that on-policy algorithms may potentially yield more reliable convergence properties. Such fact has already been observed in (Tsitsiklis & Van Roy, 1996a; Perkins & Pendrith, 2002). In this subsection we thus focus on on-policy algorithms. We analyze the convergence of SARSA when combined with linear function approximation. In our main result, we recover the essence of the result in (Perkins & Precup, 2003), although in a somewhat different setting. The main differences between our work and that in (Perkins & Precup, 2003) are discussed further ahead.

Once again, we consider a family $\mathcal{Q}$ of real-valued functions, the linear span of a fixed set of M linearly independent functions $\phi_i : \mathcal{X} \times \mathcal{A} \to \mathbb{R}$, and derive an on-policy algorithm to compute a parameter vector θ^* such that $\phi^\top(x, a)\theta^*$ approximates the optimal Q-function. To this purpose, and unlike what has been done so far, we now consider a *θ-dependent* learning policy π_θ verifying $\pi_\theta(x, a) > 0$ for all θ. In particular, we consider at each time step a learning policy π_{θ_t} that is ε-greedy with respect to $\phi^\top(x, a)\theta_t$ and Lipschitz continuous with respect to θ, with Lipschitz constant C (with respect to some preferred metric). We further assume that, for every fixed θ, the Markov chain $(\mathcal{X}, \mathsf{P}_\theta)$ induced by such policy is uniformly ergodic.

Let then $\{x_t\}$, $\{a_t\}$ and $\{r_t\}$ be sampled trajectories of states, actions and rewards obtained from the MDP $\mathcal{M} = (\mathcal{X}, \mathcal{A}, \mathsf{P}, r, \gamma)$ using (at each time-step) the θ-dependent policy π_{θ_t}. The update rule for our approximate SARSA algorithm is:

$$\theta_{t+1} = \theta_t + \alpha_t \phi(x_t, a_t) \Delta_t, \tag{12}$$

where Δ_t is the temporal difference at time t,

$$\Delta_t = r_t + \gamma \phi^\top(x_{t+1}, a_{t+1})\theta_t - \phi^\top(x_t, a_t)\theta_t.$$

In order to use the SARSA algorithm above to approximate the optimal Q-function, it is necessary to slowly decay the exploration rate, ε, to zero, while guaran-

[3] Given $\varepsilon > 0$, a policy π is *ε-greedy* with respect to a function $Q_\theta \in \mathcal{Q}$ if, at each state $x \in \mathcal{X}$, it chooses a random action with probability ε and a greedy action $a \in \mathcal{A}_x^\theta$ with probability $(1 - \varepsilon)$.

teeing the learning policy to verify the necessary regularity conditions (namely, Lipschitz continuous w.r.t. θ). However, as will soon become apparent, decreasing the exploration rate to zero will render our convergent result (and other related results) not applicable.

We are now in position to introduce our main result.

Theorem 2 *Let $\mathcal{M}$, π_{θ_t} and $\{\phi_i, i = 1, \ldots, M\}$ be as defined above. Let C be the Lipschitz constant of the learning policy π_θ with respect to θ. Assume that the step-size sequence verifies*

$$\sum_t \alpha_t = \infty \qquad \sum_t \alpha_t^2 < \infty.$$

Then, there is $C_0 > 0$ such that, if $C < C_0$, the algorithm in (12) *converges w.p.1.*

Proof We again use an ODE argument to establish the statement of the theorem.

As before, the assumptions on $(\mathcal{X}, \mathsf{P}_\theta)$ and basis functions $\{\phi_i, i = 1, \ldots, M\}$ and the fact that the learning policy is Lipschitz continuous with respect to θ and verifies $\pi(x, a) > 0$ ensure the applicability of Theorem 17 in page 239 of (Benveniste et al., 1990). Therefore, the convergence of the algorithm can be analyzed in terms of the stability of the associated ODE:

$$\dot{\theta} = \mathbb{E}_\theta\Big[\phi_x^\top \big(r(x, a, y) + \gamma\phi_y\theta - \phi_x\theta\big)\Big]. \qquad (13)$$

Notice that the expectation is taken with respect to the invariant measure of the chain and learning policy, both θ-dependent. To establish global asymptotic stability, we re-write (13) as

$$\dot{\theta}(t) = \mathbf{A}_\theta\theta(t) + \mathbf{b}_\theta$$

where

$$\mathbf{A}_\theta = \mathbb{E}_\theta\left[\phi_x^\top\big(\gamma\phi_y - \phi_x\big)\right]; \quad \mathbf{b}_\theta = \mathbb{E}_\theta\left[\phi_x^\top r(x, a, y)\right].$$

An equilibrium point of (13) must verify $\theta^* = \mathbf{A}_{\theta^*}^{-1}\mathbf{b}_{\theta^*}$ and the existence of such equilibrium point has been established in (de Farias & Van Roy, 2000) (Theorem 5.1). Let $\tilde{\theta}(t) = \theta(t) - \theta^*$. Then,

$$\frac{d}{dt}\|\tilde{\theta}\|_2^2 = 2\tilde{\theta}^\top\big(\mathbf{A}_\theta\theta + \mathbf{b}_\theta\big) = \\ = 2\tilde{\theta}^\top\big(\mathbf{A}_\theta\theta - \mathbf{A}_{\theta^*}\theta^* + \mathbf{b}_\theta - \mathbf{b}_{\theta^*}\big).$$

Let

$$\lambda_A = \sup_\theta \|\mathbf{A}_\theta - \mathbf{A}_{\theta^*}\|_2 \quad \lambda_b = \sup_{\theta\,\neq\theta^*} \frac{\|\mathbf{b}_\theta - \mathbf{b}_{\theta^*}\|_2}{\|\theta - \theta^*\|_2},$$

where the norm in the definition of λ_A is the induced operator norm and the one in the definition of λ_b is the regular Euclidian norm. The previous expression thus becomes

$$\frac{d}{dt}\|\tilde{\theta}\|_2^2 = \\ = 2\tilde{\theta}^\top\mathbf{A}_{\theta^*}\tilde{\theta} + 2\tilde{\theta}^\top(\mathbf{A}_{\theta^*} - \mathbf{A}_\theta)\theta + 2\tilde{\theta}^\top(\mathbf{b}_\theta - \mathbf{b}_{\theta^*}) \\ \leq 2\tilde{\theta}^\top\mathbf{A}_{\theta^*}\tilde{\theta} + 2(\lambda_A + \lambda_b)\|\tilde{\theta}\|_2^2.$$

Letting $\lambda = \lambda_A + \lambda_b$, the above expression can be written as

$$\frac{d}{dt}\|\tilde{\theta}\|_2^2 \leq \tilde{\theta}^\top\big(\mathbf{A}_{\theta^*} + \lambda\mathbf{I}\big)\tilde{\theta}.$$

The fact that the learning policy is assumed Lipschitz w.r.t. θ and the uniform ergodicity of the corresponding induced chain implies that $\mathbf{A}_\theta$ and $\mathbf{b}_\theta$ are also Lipschitz w.r.t. θ (with a different constant). This means that λ goes to zero with C and, therefore, for C sufficiently small, $(A + \lambda\mathbf{I})$ is a negative definite matrix.[4] Therefore, the ODE (13) is globally asymptotically stable and the conclusion of the theorem follows. □

Several remarks are now in order. First of all, Theorem 2 basically states that, for fixed ε if the dependence of the learning policy π_θ can be made sufficiently "smooth", then SARSA converges w.p.1. This result is similar to the result in (Perkins & Precup, 2003), although the algorithms are not exactly similar: we consider a continuing task, while the algorithm featured in (Perkins & Precup, 2003) is implemented in an episodic fashion. Furthermore, in our case, convergence was established using an ODE argument, instead of the contraction argument in (Perkins & Precup, 2003). Nevertheless, both methods of proof are, in its essence, equivalent and the results in both papers concordant.

A second remark is related with the implementation of SARSA with a decaying exploration policy. The analysis of one such algorithm could be conducted using, once again, an ODE argument. In particular, SARSA could be described as a two-time-scale algorithm: the iterations of the main algorithm (corresponding to (12)) would develop on a faster time-scale and the decaying exploration rate would develop at a slower time-scale. The analysis in (Borkar, 1997) could then be replicated. However, it is well-known that, as ε approaches zero, the learning policy will approach the greedy policy w.r.t. θ which is, in general, discontinuous. Therefore, there is little hope that the smoothness

[4] The fact that $\mathbf{A}_\theta$ is negative definite has been established in several works. See, for example, Lemma 3 in (Perkins & Precup, 2003) or, in a slightly different setting (easily extendable to our setting) the proof of Theorem 1 in (Tsitsiklis & Van Roy, 1996a).

condition in Theorem 2 (or its equivalent in (Perkins & Precup, 2003)) can be met as ε approaches to zero.

4. Discussion

We now briefly discuss some of the assumptions in the above theorems.

We start by emphasizing that all stated conditions are only *sufficient*, meaning that it is possible that convergence may occur even if some (or all) fail to hold. We also discuss the relation between our results and other related works from the literature.

Seconsly, uniform ergodicity of a Markov chain essentially means that the chain quickly converges to a stationary behavior uniformly over the state-space and we can study any properties of the stationary chain by direct sampling.[5] This property and the requirement that $\pi(x,a) > 0$ for all $a \in \mathcal{A}$ and μ_X-almost all $x \in \mathcal{X}$ can be interpreted as a continuous counterpart to the usual condition that all state-action pairs are visited infinitely often. In fact, uniform ergodicity implies that all the regions of the state-space with positive μ_X measure are "sufficiently" visited (Meyn & Tweedie, 1993), and the condition $\pi(x,a) > 0$ ensures that, at each state, every action is "sufficiently" tried. It appears to be a standard requirement in this continuous scenario, as it has also been used in other works (Tsitsiklis & Van Roy, 1996a; Singh et al., 1994; Perkins & Precup, 2003).[6] The requirement that $\pi(x,a) > 0$ for all $a \in \mathcal{A}$ and μ_X-almost all $x \in \mathcal{X}$ also corresponds to the concept of *fair control* as introduced in (Borkar, 2000).

We also remark that the divergence example in (Gordon, 1996) is due to the fact that the learning policy fails to verify the Lipschitz continuity condition stated in Theorem 2 (as discussed in (Perkins & Pendrith, 2002)).

4.1. Related Work

In this paper, we analyzed how RL algorithms can be combined with linear function approximation to approximate the optimal Q-function in MDPs with infinite state-spaces. In the last decade or so, several authors have addressed this same problem from different perspectives. We now briefly discuss several such approaches and their relation to the results in this paper.

One possible approach is to rely on *soft-state aggregation* (Singh et al., 1994; Gordon, 1995; Tsitsiklis & Van Roy, 1996b), partitioning the state-space into "soft" regions. Treating the soft-regions as "hyper-states", these methods then use standard learning methods (such as Q-learning or SARSA) to approximate the optimal Q-function. The main differences between such methods and those using linear function approximation (such as the ones portrayed here) are that, in the former, only one component of the parameter vector is updated at each iteration and the basis functions are, by construction, restrained to be positive and to add to one at each point of the state-space.

Sample-based methods (Ormoneit & Sen, 2002; Szepesvári & Smart, 2004) further generalize the applicability of soft-state aggregation methods by using *spreading functions/kernels* (Ribeiro & Szepesvári, 1996). Sample-based methods thus exhibit superior convergence rate when compared with simple soft-state aggregation methods, although under somewhat more restrictive conditions.

Finally, RL with general linear function approximation was thorougly studied in (Tsitsiklis & Van Roy, 1996a; Tadić, 2001). Posterior works extended the applicability of such results. In Precup01icml, an off-policy convergent algorithm was proposed that uses an importance-sampling principle similar to the one described in Section 3. In (Perkins & Precup, 2003), the authors establish the convergence of SARSA with linear function approximation.

4.2. Concluding Remarks

We conclude by observing that all methods analyzed here as well as those surveyed above experience a degradation in performance as the distance between the target function and the chosen linear space increases. If the functions in the chosen linear space provide only a poor approximation of the desired function, there are no practical guarantees on the usefulness of such approximation. The error bounds derived in (Tsitsiklis & Van Roy, 1996a) are reassuring in that they state that the performance of approximate TD "gracefully" degrades as the distance between the target function and the chosen linear space increases. Although we have not addressed such topic in our analysis, we expect the error bounds in (Tsitsiklis & Van Roy, 1996a) to carry with little changes to our setting. Finally, we make no use of eligibility traces in our algorithms. However, it is just expectable that the methods described herein can easily be adapted to ac-

[5] Explicit bounds on the rate of convergence to stationarity are available in the literature (Meyn & Tweedie, 1994; Diaconis & Saloff-Coste, 1996; Rosenthal, 2002). However, for general chains, such bounds tend to be loose.

[6] Most of these works make use of geometric ergodicity which, since we admit a compact state-space, is a consequence of uniform ergodicity.

commodate for eligibility traces, this eventually yielding better approximations (with tighter error bounds) (Tsitsiklis & Van Roy, 1996a)

Abstract

Sampling is a popular way of scaling up machine learning algorithms to large datasets. The question often is how many samples are needed. Adaptive stopping algorithms monitor the performance in an online fashion and they can stop early, saving valuable resources. We consider problems where probabilistic guarantees are desired and demonstrate how recently-introduced empirical Bernstein bounds can be used to design stopping rules that are efficient. We provide upper bounds on the sample complexity of the new rules, as well as empirical results on model selection and boosting in the filtering setting.

1. Introduction

Being able to handle large datasets and streaming data is crucial to scaling up machine learning algorithms to many-real world settings. When making even a single pass through the data is prohibitive, sampling may offer a good solution. In order for the resulting algorithms to be theoretically sound, sampling techniques that come with probabilistic guarantees are desirable. For example, when estimating the error of a classifier on a large dataset one may want to sample until the estimated error is within some small number ϵ of the true error with probability at least $1 - \delta$. The key problem is one of *stopping* or determining the required number of samples. Taking too many samples will result in inefficient algorithms, while taking too few may not be enough to achieve the desired guarantees.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Finite sample bounds, such as Hoeffding's inequality (Hoeffding, 1963), are the key technique used by recent, non-parametric stopping algorithms with probabilistic guarantees. While these stopping algorithms have proved to be effective for scaling up machine learning algorithms (Bradley & Schapire, 2008), (Domingos & Hulten, 2001), they can be significantly improved by incorporating variance information in a principled manner. We show how to employ the recently introduced empirical Bernstein bounds (Audibert et al., 2007a) to improve stopping algorithms and provide sample complexity bounds and empirical results to demonstrate the effect of incorporating variance information.

Before proceeding, we identify two classes of stopping problems that will be examined. The first class concerns problems where some unknown quantities have to be measured either up to some prespecified level of accuracy or to support making a binary decision. Examples in this class include stopping with a fixed relative or absolute accuracy, with applications in hypothesis testing such as deciding on the sign of the mean, independence tests, and change detection. In problems belonging to the second group, the task is to pick the best option from a finite pool while measuring their performance using samples. Some notable examples include various versions of bandit problems, Hoeffding Races (Maron & Moore, 1993), and the general framework for scaling up learning algorithms proposed by Domingos (2001).

The paper is organized as follows. In Section 2 we examine Hoeffding's inequality and introduce the empirical Bernstein bound. In Section 3, we introduce a new stopping algorithm for stopping with a predefined relative accuracy and show that it is more efficient than previous algorithms. Section 4 demonstrates how a simple application of the empirical Bernstein bound can result in substantial improvements for problems

from the second class. Conclusions and future work directions are presented in Section 5.

2. Hoeffding Bounds vs. Empirical Bernstein Bounds

Let $X_1, \ldots, X_t$ real-valued *i.i.d.* random variables with range R and, mean μ, and let $\overline{X}_t = 1/t \sum_{i=1}^{t} X_i$. Hoeffding's inequality (Hoeffding, 1963) states that with probability at least $1 - \delta$

$$|\overline{X}_t - \mu| \leq R\sqrt{\frac{\log(2/\delta)}{2t}}.$$

Due to its generality, Hoeffding's inequality has been widely used in online learning scenarios. A drawback of the bound is that it scales linearly with the range R and does not scale with the variance of X_i. If a bound on the variance is known, Bernstein's inequality can be used instead, which can yield significant improvements when the variance bound is small relative to the range. Since useful a priori bounds on the variance are rarely available, this approach is not practical.

An approach that is more suitable to online scenarios is to apply Bernstein's inequality to the sum of $X_1, \ldots, X_t$, as well as the sum of the squares to obtain a single bound on the mean of $X_1, \ldots, X_t$. The resulting bound, which we will refer to as the *empirical Bernstein bound* (Audibert et al., 2007a) states that with probability at least $1 - \delta$

$$|\overline{X}_t - \mu| \leq \overline{\sigma}_t\sqrt{\frac{2\log(3/\delta)}{t}} + \frac{3R\log(3/\delta)}{t},$$

where $\overline{\sigma}_t$ is the empirical standard deviation of $X_1, \ldots, X_t$: $\overline{\sigma}_t^2 = \frac{1}{t}\sum_{i=1}^{t}(X_i - \overline{X}_t)^2$. The term involving the range R decreases at the rate of t^{-1} and quickly becomes negligible when the variance is large, while the square root term depends on $\overline{\sigma}_t$ instead of R. Hence, when $\overline{\sigma}_t \ll R$ the empirical Bernstein bound quickly becomes much tighter than Hoeffding's inequality.

3. Stopping Rules

Let $X_1, X_2, \ldots$ be i.i.d. random variables with mean μ and variance σ^2. We will refer to an algorithm as a stopping rule if at time t it observes X_t and based on past observations decides whether to stop or continue sampling. If a stopping rule $\mathcal{S}$ returns $\hat{\mu}$ that satisfies

$$\mathbb{P}\left[|\hat{\mu} - \mu| \leq \epsilon|\mu|\right] \geq 1 - \delta, \tag{1}$$

then $\mathcal{S}$ is a (ϵ, δ)-stopping rule and $\hat{\mu}$ is an (ϵ, δ)-approximation of μ. In this section, we develop an (ϵ, δ)-stopping rule for bounded X_i.

Algorithms proposed for this problem include the Nonmonotonic Adaptive Sampling (NAS) algorithm, shown as Algorithm 1, due to Domingo et al. (2000a). The general idea is to first use Hoeffding's inequality to construct a sequence $\{\alpha_t\}$ such that the event $\mathcal{E} = \left\{|\overline{X}_t - \mu| \leq \alpha_t,\, t \in \mathbb{N}^+\right\}$ occurs with probability at least $1 - \delta$, and then use this sequence to design a stopping criterion that stops only if $\left|\overline{X}_t - \mu\right| \leq \epsilon|\mu|$ given that $\mathcal{E}$ holds.

Algorithm 1 Algorithm NAS

```
t ← 0
repeat
  t ← t + 1
  Obtain X_t
  α ← sqrt((1/2t) log(t(t+1)/δ))
until |X̄_t| < α(1 + 1/ε)
return X̄_t
```

Domingo et al. (2000a) argue that if T is the number of samples after which NAS stops, and $|\mu| > 0$, then there exists a constant C such that with probability at least $1 - \delta$

$$T < C \cdot \frac{R^2}{\epsilon^2\mu^2}\Big(\log\frac{2}{\delta} + \log\frac{R}{\epsilon\mu}\Big). \tag{2}$$

The assumption that $|\mu| > 0$ is necessary for guaranteeing that the algorithm will indeed stop, and will be assumed for the rest of the section.

Dagum et al. (2000) introduced the $\mathcal{AA}$ algorithm for the case of bounded and nonnegative X_i. The $\mathcal{AA}$ algorithm is a three step procedure. In the first step, an $(\max(\sqrt{\epsilon}, 1/2), \delta/3)$-approximation of μ, $\tilde{\mu}$, is obtained. In the second step $\tilde{\mu}$ is used to determine the number of samples necessary to produce an estimate $\tilde{\sigma}^2$ of σ^2 such that $\max(\tilde{\sigma}^2, \epsilon\tilde{\mu})$ is a high probability upper bound on $\max(\sigma^2, \epsilon\mu)/2$. In the last step, $c\max(\tilde{\sigma}^2, \epsilon\tilde{\mu})\frac{\log(1/\delta)}{\epsilon^2\tilde{\mu}^2}$ samples are drawn and their average is returned as $\hat{\mu}$, where c is a universal constant.

Dagum et al. (2000) prove that $\hat{\mu}$ is indeed an (ϵ, δ)-approximation of μ and that that if T is the number of samples taken by $\mathcal{AA}$, then there exists a constant C such that with probability at least $1 - \delta$

$$T \leq C \cdot \max(\sigma^2, \epsilon\mu) \cdot \frac{1}{\epsilon^2\mu^2}\log\frac{2}{\delta}. \tag{3}$$

In addition, Dagum et al. prove that if T is the number of samples taken by any (ϵ, δ)-stopping rule, then there exists a constant C' such that with probability at least $1 - \delta$

$$T \geq C' \cdot \max(\sigma^2, \epsilon\mu) \cdot \frac{1}{\epsilon^2\mu^2}\log\frac{2}{\delta}.$$

Hence, for bounded X_i, the $\mathcal{AA}$ algorithm requires a number of samples that is at most a multiplicative constant larger than that required by any other (ϵ, δ)-stopping rule. In this sense the algorithm achieves "optimal" efficiency, up to a multiplicative constant.

While the $\mathcal{AA}$ algorithm is able to take advantage of variance, it requires the random variables to be nonnegative. Any trivial extension of the $\mathcal{AA}$ algorithm to the case of signed random variables seems unlikely since the rule heavily relies on the monotonicity of partial sums that is present in the nonnegative case. On the other hand, Equation (2) suggests that the NAS algorithm is not able to take advantage of variance.

As the first demonstration of how the empirical Bernstein bound can be used to design improved stopping algorithms, we propose a new algorithm, EBStop, which uses empirical Bernstein Bounds to achieve nearly the same scaling properties as the $\mathcal{AA}$ algorithm and, like the NAS algorithm, only requires the random variables to be bounded.

3.1. EBStop

Similarly to the NAS algorithm, EBStop relies on a sequence $\{c_t\}$ with the property that the event $\mathcal{E} = \{|\overline{X}_t - \mu| \leq c_t, t \in \mathbb{N}^+\}$ occurs with probability at least $1-\delta$. Let d_t be a positive sequence satisfying $\sum_{t=1}^{\infty} d_t \leq \delta$ and let

$$c_t = \overline{\sigma}_t \sqrt{\frac{2\log(3/d_t)}{t}} + \frac{3R\log(3/d_t)}{t}.$$

Since $\{d_t\}$ sums to at most δ and $(\overline{X}_t - c_t, \overline{X}_t + c_t)$ is a $1-d_t$ confidence interval for μ obtained from the empirical Bernstein bound, by a union bound argument, the event $\mathcal{E}$ indeed occurs with probability at least $1-\delta$. In our work, we use $d_t = c/t^p$ and $c = \delta(p-1)/p$.

The pseudocode for EBStop is shown as Algorithm 2, but the general idea is as follows. After drawing t samples, we set LB to $\max(0, \max_{1\leq s\leq t} |\overline{X}_s| - c_s)$ and UB to $\min_{1\leq s\leq t}(|\overline{X}_s| + c_s)$. EBStop terminates as soon as $(1+\epsilon)\text{LB} \geq (1-\epsilon)\text{UB}$ and returns $\hat{\mu} = \text{sgn}(\overline{X}_t)\cdot 1/2\cdot [(1+\epsilon)\text{LB} + (1-\epsilon)\text{ UB}]$.

To see why $\hat{\mu}$ is an (ϵ, δ)-approximation, suppose the stopping condition has been satisfied and event $\mathcal{E}$ holds. Then

$$|\hat{\mu}| \leq 1/2 \cdot [(1+\epsilon)\text{LB} + (1+\epsilon)\text{LB}] \leq (1+\epsilon)|\mu|,$$

and similarly $(1-\epsilon)|\mu| \leq |\hat{\mu}|$. From the definition of LB, it also follows that $|\overline{X}_t| > c_t \geq |\overline{X}_t - \mu|$ which implies that $\text{sgn}(\hat{\mu}) = \text{sgn}(\mu)$. Since event $\mathcal{E}$ holds with probability at least $1-\delta$, $\hat{\mu}$ is indeed an (ϵ, δ)-approximation of μ.

Algorithm 2 Algorithm EBStop

```
LB ← 0
UB ← ∞
t ← 1
Obtain X_1
while (1 + ε)LB < (1 − ε)UB do
  t ← t + 1
  Obtain X_t
  LB ← max(LB, |X̄_t| − c_t)
  UB ← min(UB, |X̄_t| + c_t)
end while
return sgn(X̄_t) · 1/2· [(1 + ε)LB +(1 − ε) UB]
```

While we omit the proof due to space constraints[1], we note that if X is a random variable distributed with range R, and if T is the number of samples taken by EBStop on X, then there exists a constant C such that with probability at least $1-\delta$

$$T < C \cdot \max\left(\frac{\sigma^2}{\epsilon^2\mu^2}, \frac{R}{\epsilon|\mu|}\right)\left(\log\frac{1}{\delta} + \log\frac{R}{\epsilon|\mu|}\right). \quad (4)$$

This bound is very similar to the upper bound for the stopping time of the $\mathcal{AA}$ algorithm, with the only difference being the extra $\log\frac{R}{\epsilon|\mu|}$ term. This term comes from constructing a confidence interval at each t and is not an artifact of our proof techniques. However, this extra term can be reduced to $\log\log\frac{1}{\epsilon|\mu|}$ by applying a geometric grid as we will see in the next section. Since EBStop does not require the variables to be non-negative, we can say that EBStop combines the best properties of NAS and $\mathcal{AA}$ algorithms for signed random variables.

3.2. Improving EBStop

While EBStop has the desired scaling properties, we make two simple improvements in order to make it more efficient in practice.

The first improvement is based on the idea that if the algorithm is not close to stopping, there is no point in checking the stopping condition at every point. We incorporate this idea into EBStop by adopting a *geometric* sampling schedule, also used by Domingo and Watanabe (2000a). Instead of testing the stopping criterion after each sample, we perform the kth test after $\lceil\beta^k\rceil$ samples have been taken for some $\beta > 1$. Under this sampling strategy, when EBStop constructs a $1-d$ confidence interval after t samples, d is of the order $1/(\log_\beta t)^p$, which is much larger than $1/t^p$. Since

[1] A version of the paper containing the proofs will be made available as a technical report.

this results in tighter confidence intervals, LB and UB will approach each other faster and the stopping condition will be satisfied after fewer samples.

While geometric sampling can often reduce the number of required samples, it can also lead to taking roughly β times too many samples, because testing is only done at the ends of intervals. Nevertheless, the following result due to Audibert et al. (2007b) can be used to test the stopping condition after each sample without sacrificing the advantages of geometric sampling. Let $t_1 \leq t_2$ for $t_1, t_2 \in \mathbb{N}$ and let $\alpha \geq t_2/t_1$. Then with probability at least $1-d$, for all $t \in \{t_1, \ldots, t_2\}$

$$|\overline{X}_t - \mu| \leq \overline{\sigma}_t \sqrt{2\alpha \log(3/d)/t} + 3\alpha \log(3/d)/t. \quad (5)$$

We use Equation (5) with $t_1 = \lfloor \beta^k \rfloor + 1$, $t_2 = \lfloor \beta^{k+1} \rfloor$, and $d = c/k^p$ to construct c_t for each $t \in \{t_1, \ldots, t_2\}$. This allows us to test the stopping condition after each sample, and use d that is on the order of $1/(\log_\beta t)^{p\alpha}$ after t samples. A variant of EBStop that incorporates these two improvements is shown as Algorithm 3.

Algorithm 3 Algorithm EBGStop

```
LB ← 0
UB ← ∞
t ← 1
k ← 0
Obtain X_1
while (1 + ε)LB < (1 − ε)UB do
  t ← t + 1
  Obtain X_t
  if t > floor(β^k) then
    k ← k + 1
    α ← floor(β^k)/floor(β^{k−1})
    x ← −α log d_k/3
  end if
  c_t ← σ̄_t sqrt(2x/t) + 3Rx/t
  LB ← max(LB, |X̄_t| − c_t)
  UB ← min(UB, |X̄_t| + c_t)
end while
return sgn(X̄_t) · 1/2· [(1 + ε)LB +(1 − ε) UB]
```

One can show that as the result of adding geometric sampling to EBStop reduces the $\log \frac{1}{\epsilon|\mu|}$ term in inequality (4) to $\log\log \frac{1}{\epsilon|\mu|}$. It should be noted that from the arguments of Dagum et al. (2000), no stopping rule can achieve a better bound than (3) for the case of bounded non-negative random variables. Hence, EBGStop is very close to being "optimal" in this sense. Where it would loose (for non-negative random variables) to $\mathcal{AA}$ is when ϵ, μ and δ are such that $\log(R/(\epsilon\mu))$ becomes significantly larger than $1/\delta$. We do not expect to see this happening in practice for not too large values of δ. For example, for $\delta = 0.05$, $R = 1$, the condition is $\epsilon\mu < e^{-20}$.

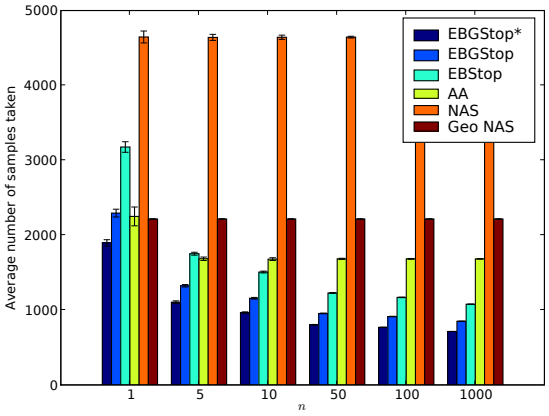

Figure 1. Comparison of stopping rules on averages of uniform random variables with varying variances. Error bars are at one standard deviation.

3.3. Results: Synthetic Data

In this section we evaluate the stopping rules $\mathcal{AA}$, NAS, geometric NAS, EBStop, and EBGStop on the problem of estimating means of various random variables. To make the comparison fair, the geometric version of the NAS algorithm and EBGStop both grew intervals by a factor of 1.5, as this value worked best in previous experiments (Domingo & Watanabe, 2000b). We also used $d_t = (t(t+1))^{-1}$ in EBStop and EBGStop since this is the sequence implicitly used in NAS for constructing confidence intervals at time t. Since this put EBGStop at a slight disadvantage, we also include results for EBGStop, denoted by EBGStop*, with our default choice of $d_t = c/(\log_\beta t)^p$, $p = 1.1$, and $\beta = 1.1$. In all the experiments we used $\epsilon = \delta = 0.1$. We use only non-negative valued random variables as they allow comparison to $\mathcal{AA}$. Finally, we only compare the number of samples taken because none of the algorithms produced any estimates with relative error greater than ϵ in any of our experiments.

The first set of experiments was meant to test how well the various stopping rules are able to exploit the variance when it is small. Let the average of n uniform $[a, b]$ random variables be denoted by $U(a, b, n)$. Note that the expected value and variance of $U(a, b, n)$ are $(a + b)/2$ and $(b - a)^2/(12n)$, respectively. For this comparison we fixed a to 0, b to 1, and varied n to control the variance for a fixed mean. Figure 1 shows the results of running each stopping rule 100 times on $U(0, 1, n)$ random variables for $n = 1, 5, 10, 50, 100, 1000$. Not surprisingly, NAS and geometric NAS fail to make use of the variance

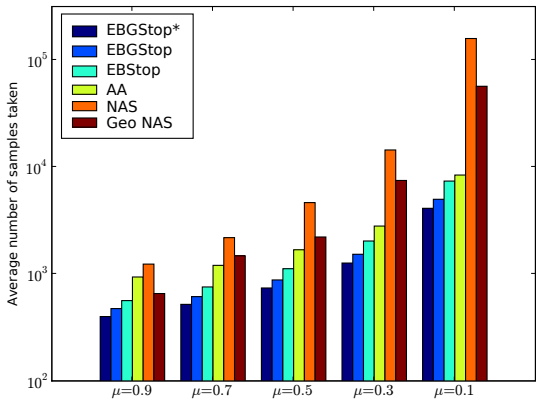

Figure 2. Comparison of stopping rules on averages of uniform random variables with varying means. The number of samples is shown in log scale.

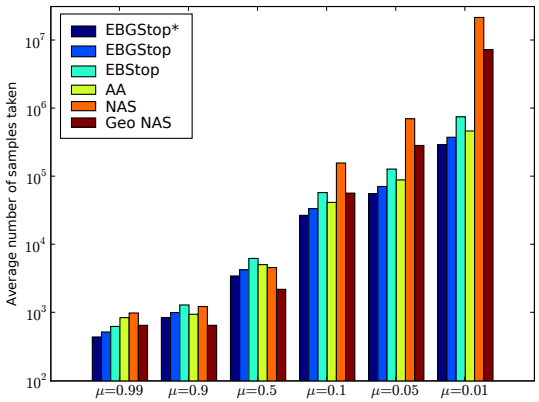

Figure 3. Comparison of stopping rules on Bernoulli random variables. The number of samples is shown in log scale.

and take roughly the same numbers of samples for all values of n. Variants of EBStop improve when the variance decreases, with EBGStop* performing especially well, beating all the other algorithms for all the scenarios tested. $\mathcal{AA}$ initially improves with the decreasing variance, but the effect is not as large as with EBGStop* because of the multi-phase structure of $\mathcal{AA}$.

In the second set of experiments we fix n at 10 and $b - a$ at 0.2, keeping the variance fixed, and vary the mean. The variance is small enough that EBStop, its variants, and $\mathcal{AA}$ should take a number of samples in the order of $R/(\epsilon\mu)$. The results are presented in Figure 2 and suggest that both variants of NAS require $1/\mu$ times more samples than the variance-adaptive methods. Note that Figure 2 shows the number of samples taken by each method in log scale.

It may be surprising that in both experiments the $\mathcal{AA}$ algorithm did not outperform EBStop and EBGStop even though $\mathcal{AA}$ offers better guarantees on sample complexity. We believe that EBStop is able make better use of the data because it uses all samples in its stopping criterion, while $\mathcal{AA}$ wastes some samples on intermediate quantities. However, this difference should be reflected in the hidden constants. As discussed earlier, for really small values of μ and ϵ the $\mathcal{AA}$ algorithm should stop earlier than EBStop.

Finally, we include a comparison of the stopping rules on Bernoulli random variables. Since Bernoulli random variables have maximal variance of all bounded random variables, the advantage of variance estimation should be diminished. However, inequality (4) suggests that in the case of Bernoulli random variables EBStop requires $O(1/(\epsilon^2\mu))$ samples since $\sigma^2 = \mu(1-\mu)$. Similarly, inequality (2) suggests that NAS requires $O(1/(\epsilon^2\mu^2))$ samples.

Figure 3 shows the results of running each stopping rule on Bernoulli random variables with means 0.99, 0.9, 0.5, 0.1, 0.05, and 0.01, averaged over 100 runs. As in the previous set of experiments, the variance-adaptive methods seem to require $1/\mu$ times fewer samples to stop. It should also be noted that the geometric version of the NAS algorithm does outperform EBStop for some intermediate values of μ, where the variance is the largest. However the performance difference is not large, and so we think the price paid for the unboundedly better performance of EBStop for small or large values of μ is not large.

3.4. Results: FilterBoost

Boosting by filtering (Bradley & Schapire, 2008) is a framework for scaling up boosting algorithms to large or streaming datasets. Instead of working with the entire training set, all steps, such as finding a weak learner that has classification accuracy of at least 0.5, are done through sampling that employs stopping algorithms. Bradley and Schapire showed that such an approach can lead to a drastic speedup over a batch boosting algorithm.

We evaluated the suitability of EBGStop and both variants of the NAS algorithm for the boosting by filtering setting by plugging them into the FilterBoost algorithm (Bradley & Schapire, 2008). The $\mathcal{AA}$ algorithm was not included because it cannot deal with signed random variables.

Following Bradley and Schapire, the Adult and Covertype datasets from the UCI machine learning repository (Asuncion & Newman, 2007) were used. The covertype dataset was converted into a binary classi-

fication problem by taking "Lodgepole Pine" as one class and merging the other classes. In setting up boosting we followed the procedure of Domingo and Watanabe (2000b) who also considered the use of stopping rules in the same context. Accordingly, we used decisions stumps as weak learners and we discretized all continuous attributes by binning their values into five equal bins. The results for the Adult dataset were averaged over 10 runs on the training set, while 10-fold cross-validation was used for the Covertype dataset.

As shown in Figure 4, EBGStop required fewer samples and offered lower variance in stopping times than either variant of the NAS algorithm on both datasets. At the same time, the resulting classification accuracies were within 0.2% of each other on the Adult dataset and within 0.04% of each other on the Covertype dataset.

4. Racing Algorithms

In this section we demonstrate how a general stopping algorithm that makes use of finite sample deviation bounds can be improved with the use of empirical Bernstein bounds. We consider the Hoeffding races algorithm (Maron & Moore, 1993) since it is representative of the class of general stopping algorithms.

Racing algorithms aim to reduce the computational burden of performing tasks such model selection using a hold-out set by discarding poor models quickly (Maron & Moore, 1993; Ortiz & Kaelbling, 2000). The context of racing algorithms is the one of multi-armed bandit problems. Formally, consider M options. When option m is chosen the t^{th} time, it gives a random value $X_{m,t}$ from an unknown distribution ν_m. The samples $\{X_{m,t}\}_{t\geq 1}$ are independent of each other. Let $\mu_m = \int x\nu_m(dx)$ be the mean reward obtained of option m. The goal is to find the options with the highest mean reward.

Let $\delta > 0$ be the confidence level parameter and N be the maximal amount of time allowed for deciding which option leads to the best expected reward. A racing algorithm either terminates when it runs out of time (i.e. at the end of the N-th round) or when it can say that with probability at least $1-\delta$, it has found the best option, i.e. an option m^* with $\mu_{m^*} = \max_{m\in\{1,\ldots,M\}} \mu_m$.

The Hoeffding race is an algorithm based on discarding options which are likely to have smaller mean than the optimal one until only one option remains. Precisely, for each time step and each distribution, $\delta/(MN)$ confidence intervals are constructed for the mean. Options with upper confidence smaller than the lower confidence bound of another option are discarded. The algorithm samples one by one all the options that have not been discarded yet.

We assume that the rewards have a bounded range R. If $\overline{X}_{m,t}$ denotes the sample mean for option m after seeing t samples of this option then according to Hoeffding's inequality, a $\delta/(MN)$ confidence interval for the mean of option m is

$$\left[\overline{X}_{m,t} - R\sqrt{\frac{\log(2MN/\delta)}{2t}}, \overline{X}_{m,t} + R\sqrt{\frac{\log(2MN/\delta)}{2t}}\right]$$

The Hoeffding race has been introduced and studied in (Maron & Moore, 1993; Maron & Moore, 1997) in a slightly different viewpoint since there the target was to find an option with mean at most ϵ below the optimal mean $\max_{m\in\{1,\ldots,M\}} \mu_m$, where ϵ is a given positive parameter. The same problem was also studied by (Even-Dar et al., 2002, Theorem 3) in the infinite horizon setting.

By substituting Hoeffding's inequality with the empirical Bernstein bound we obtain a new algorithm, which we will refer to as the empirical Bernstein race.

4.1. Analysis of Racing Algorithms

For the analysis we are interested in the expected number of samples taken by the Hoeffding race and the empirical Bernstein race. Due to space limitations, we omit the proofs of the following theorems.

Let $\Delta_m = \mu_{m^*} - \mu_m$, where option m^* still denotes an optimal option: $\mu_{m^*} = \max_{m\in\{1,\ldots,M\}} \mu_m$. Let $\lceil u \rceil$ denote the smallest integer larger or equal to u, and let $\lfloor u \rfloor$ denote the largest integer smaller or equal to u.

Theorem 1 (Hoeffding Race)**.** *Let* $n_H(m) = \left\lceil \frac{8R^2\log(2MN/\delta)}{\Delta_m^2} \right\rceil$. *Without loss of generality, assume that* $n_H(1) \leq n_H(2) \leq \ldots \leq n_H(m)$. *The number of samples, T, taken by the Hoeffding race is bounded by*

$$2\sum_{\mu_m<\mu_{m*}} n_H(m).$$

The probability that no optimal option is returned is bounded by δ. *If the algorithm runs out of time, then with probability at least* $1-\delta$, *(i) the number of discarded options is at least d, where d is the largest integer such that* $2\sum_{m=1}^{d} n_H(m) \leq N$, *and (ii) the non-discarded options satisfy*

$$\mu_m \geq \mu_{m^*} - 4R\sqrt{\frac{\log(2MN/\delta)}{2\lfloor N/M \rfloor}}.$$

We recall that the principle of the empirical Bernstein race algorithm is the same as the Hoeffding's one. We

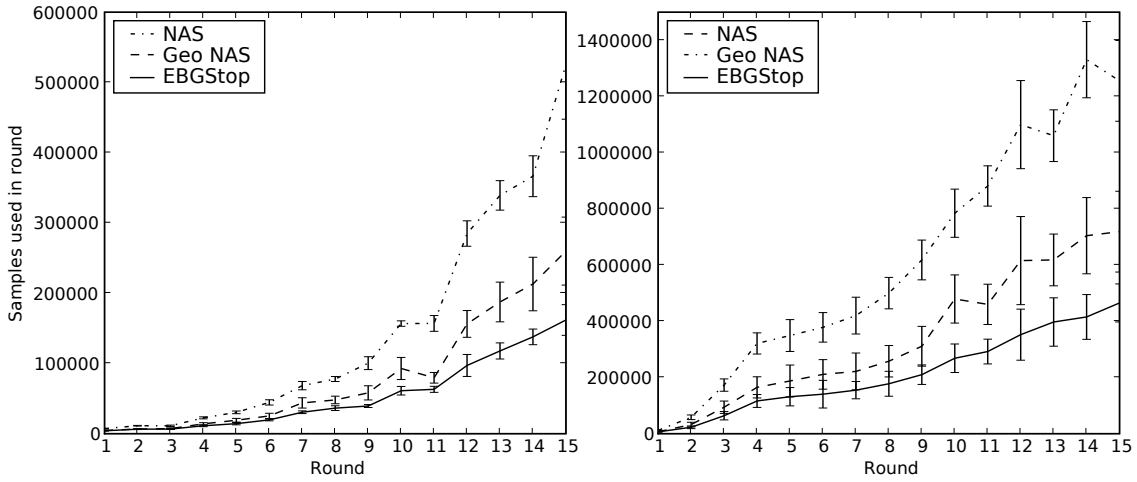

Figure 4. Comparison of the number of samples required by different stopping rules in FilterBoost. Parameters ϵ, δ were set to 0.1 for both methods while τ was set to 0.25. Error bars are at 1 standard deviation. a) Results on the Adult dataset b) Results on the covertype dataset.

sample one by one all the distributions that has not been discarded yet. The algorithm discards an option as soon as the upper bound on its mean reward is smaller than at least one of the lower bound on the mean of any other option.

Theorem 2 (Empirical Bernstein Race)**.** *Let σ_m denote the standard deviation of ν_m. Introduce $\Sigma_m = \sigma_{m^*} + \sigma_m$ and*

$$n(m) = \left\lceil \frac{8\Sigma_m^2 + 18R\Delta_m}{\Delta_m^2} \log(4MN/\delta) \right\rceil.$$

Without loss of generality, assume that $n(1) \leq n(2) \leq \ldots \leq n(m)$. The number of samples taken by the empirical Bernstein race is bounded by

$$2 \sum_{\mu_m < \mu_{m^*}} n(m).$$

The probability that no optimal option is returned is bounded by δ. If the algorithm runs out of time, then with probability at least $1 - \delta$, (i) the number of discarded options is at least d, where d is the largest integer such that $2\sum_{m=1}^{d} n_H(m) \leq N$, and (ii) the non-discarded options satisfy

$$\mu_m \geq \mu_{m^*} - \Sigma_m \sqrt{\frac{8\log(4MN/\delta)}{\lfloor N/M \rfloor}} - \frac{9R\log(4MN/\delta)}{\lfloor N/M \rfloor}.$$

As can be seen from the bounds, the result of incorporating the variance estimates is similar to what was observed in Section 3: The dependence of the number of required samples on R^2 is reduced to a dependence on R and the variance. Similar results can be expected when applying the empirical Bernstein bound to other situations.

4.2. Results

Following the procedure of Maron and Moore (1997), we evaluated the Hoeffding and empirical Bernstein races on the task of selecting the best k for k-nearest neighbor regression and classification through leave-one-out cross-validation.[2] Three datasets of different types were used for the comparison. The SARCOS data presents a regression problem which involves predicting the torques at 7 joints of a robot arm based on the positions, velocities and accelerations at those joints. We only considered predicting the torque at the first joint. The Covertype2 dataset consists of 50,000 points sampled from the Covertype dataset from Section 3.4 and is a binary classification task. The Local dataset presents a regression problem that was created by sampling 10,000 points from a noisy piecewise-linear function defined on the unit interval and having a range of 1.

The value of the range parameter R was set to 1 for the Covertype2 and Local datasets. For the SARCOS dataset, R was set to the range of the target values in the dataset. This differs from the approach of setting R separately for each option to several times the standard deviation in the samples observed, suggested by Maron and Moore (1997). We do not follow this approach because it invalidates the use of Hoeffding's inequality.

[2]Since leave-one-out cross-validation creates dependencies between the samples, the analysis does not apply to this case. However, our experiments gave similar results when we used a separate hold-out set. We decided to present results for leave-one-out cross-validation to facilitate comparison with the original papers.

Table 1. Percentage of work saved / number of options left after termination.

Data set	Hoeffding	EB
SARCOS	0.0% / 11	44.9% / 4
Covertype2	14.9% / 8	29.3% / 5
Local	6.0% / 9	33.1% / 6

All methods were given the options $k = 2^0, 2^1, 2^2, 2^3, \ldots, 2^{10}$ to begin with. The results are presented in Table 1. The table shows the percentage of work saved by each method ($1-$ number of samples taken by method / MN), as well as the number of options remaining after termination.

The empirical Bernstein racing algorithm, which is denoted by EB, significantly outperforms the Hoeffding racing algorithm on all three datasets. The advantage of incorporating variance estimates is the smallest on the Covertype2 classification dataset. This is expected because the samples come from Bernoulli distributions which have the largest possible variance for a bounded random variable. The advantage of variance estimation is the largest on the SARCOS dataset, where R is much larger than the variance. While one may argue that the Hoeffding racing algorithm would do much better if R was set to a smaller value based on the standard deviation, the empirical Bernstein algorithm would also benefit. However, tweaking R this way is merely an unprincipled way of incorporating variance estimates into a racing algorithm.

5. Conclusions and Future Work

We showed how variance information can be exploited in stopping problems in a principled manner. Most notably, we presented a near-optimal stopping rule for relative error estimation on bounded random variables, significantly extending the results of Domingo and Watanabe, and Dagum et al.. We also provided empirical and theoretical results on the effect that can be expected from incorporating variance estimates into existing stopping algorithms.

One interesting question that should be addressed is if the bound achieved by the $\mathcal{AA}$ algorithm in the non-negative case, which is known to be optimal, can be achieved without the non-negativity condition.

Efficiently Solving Convex Relaxations for MAP Estimation

M. Pawan Kumar PAWAN@ROBOTS.OX.AC.UK
Department of Engineering Science, University of Oxford

P.H.S. Torr PHILIPTORR@BROOKES.AC.UK
Department of Computing, Oxford Brookes University

Abstract

The problem of obtaining the maximum *a posteriori* (MAP) estimate of a discrete random field is of fundamental importance in many areas of Computer Science. In this work, we build on the tree reweighted message passing (TRW) framework of (Kolmogorov, 2006; Wainwright et al., 2005). TRW iteratively optimizes the Lagrangian dual of a linear programming relaxation for MAP estimation. We show how the dual formulation of TRW can be extended to include cycle inequalities (Barahona & Mahjoub, 1986) and some recently proposed second order cone (SOC) constraints (Kumar et al., 2007). We propose efficient iterative algorithms for solving the resulting duals. Similar to the method described in (Kolmogorov, 2006), these algorithms are guaranteed to converge. We test our approach on a large set of synthetic data, as well as real data. Our experiments show that the additional constraints (i.e. cycle inequalities and SOC constraints) provide better results in cases where the TRW framework fails (namely MAP estimation for non-submodular energy functions).

1. Introduction

The problem of obtaining the maximum *a posteriori* (MAP) estimate of a discrete random field plays a central role in various applications, e.g. stereo reconstruction (Szeliski et al., 2006) and protein side-chain prediction (Sontag & Jaakkola, 2007). Furthermore, it is closely related to many important combinatorial optimization problems such as MAXCUT (Goemans & Williamson, 1995) and 0-extension (Karzanov, 1998). It is therefore not surprising that a number of approximate MAP estimation approaches exist in the literature. One such class of approaches which provides a good approximation, both in theory and in practice, is based on convex relaxations (e.g. see (Kumar et al., 2007) for an overview). In this work, we focus on the issue of solving these relaxations efficiently with the goal of handling a large number of random variables, e.g. variables corresponding to pixels in an image.

A discrete random field is defined over random variables $\mathbf{v} = \{v_0, \cdots, v_{n-1}\}$, each of which can take a label from the set $\mathbf{l} = \{l_0, \cdots, l_{h-1}\}$. Throughout this paper, we will assume a conditional random field (CRF) while noting that all our results are applicable to the Markov random field framework. A CRF describes a neighbourhood relationship $\mathcal{E}$ between the variables such that $(a, b) \in \mathcal{E}$ if, and only if, v_a and v_b are neighbours. A labelling of the CRF is specified by a function $f : \{0, \cdots, n-1\} \longrightarrow \{0, \cdots, h-1\}$ (i.e. variable v_a takes label $l_{f(a)}$). Given data $\mathbf{D}$, the energy of the labelling is given by

$$Q(f; \mathbf{D}, \boldsymbol{\theta}) = \sum_{v_a \in \mathbf{v}} \theta^1_{a;f(a)} + \sum_{(a,b) \in \mathcal{E}} \theta^2_{ab;f(a)f(b)}, \quad (1)$$

where $\theta^1_{a;f(a)}$ and $\theta^2_{ab;f(a)f(b)}$ are the data-dependent unary and pairwise potentials respectively, and $\boldsymbol{\theta}$ denotes the parameter of the CRF. The problem of MAP estimation is to obtain the labelling f^* with the minimum energy (or equivalently the maximum posterior probability), i.e. $f^* = \arg\min_f Q(f; \mathbf{D}, \boldsymbol{\theta})$.

Related Work: We build upon the linear programming (LP) relaxation of (Wainwright et al., 2005), which we call LP-S (since it was first proposed by (Schlesinger, 1976) for the special case of hard constraint pairwise potentials). Although the LP-S relaxation can be solved in polynomial time using Interior Point algorithms, the state of the art softwares can only handle up to a few hundred variables due to their large memory requirements. To overcome this prob-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

lem, two iterative algorithms were proposed by (Wainwright et al., 2005) for solving the dual of the LP-S relaxation. Similar to min-sum belief propagation (BP), these algorithms are not guaranteed to converge. The work of (Kolmogorov, 2006) addressed this problem by proposing a convergent sequential tree-reweighted message passing (TRW-S) algorithm for solving the dual.

Despite its strong theoretical foundation, it was observed that TRW-S yields labellings with very high energies when the energy function contains non-submodular terms (Kolmogorov, 2006). This is not surprising since the LP-S relaxation provides an inaccurate approximation in such cases (e.g. see (Kumar et al., 2007)). In this work, we address this deficiency of TRW-S by appending the LP-S relaxation with some useful constraints.

Our Results: We show how the dual formulation of the LP-S relaxation can be extended to include linear cycle inequalities (Barahona & Mahjoub, 1986) (section 3). Furthermore, we incorporate the recently proposed second order cone (SOC) constraints of (Kumar et al., 2007) within this framework (section 4). Note that although the importance of cycle inequalities and SOC constraints is well-recognized, their use has been limited to a small number of random variables due to the lack of efficient algorithms (Sontag & Jaakkola, 2007). Our results on including these constraints within the TRW formulation allow us to develop efficient convergent algorithms for solving the resulting duals. We successfully apply these algorithms to several synthetic and real problems containing a large number of variables which could not be handled by previous approaches (section 5). Our experiments indicate that incorporating these constraints provides a much better approximation for the MAP estimation problem within reasonable computational times compared to several state of the art algorithms. Additional experimental results and proofs are provided in (Kumar & Torr, 2008).

2. Preliminaries

We begin by introducing some notation which would allow us to describe our results concisely.

Optimal Energy and Min-Marginals: The energy of the optimal labelling and the min-marginals of random variables and neighbouring random variables is given by the following equations respectively:

$$q(\boldsymbol{\theta}) = \min_{f} Q(f : \mathbf{D}), \tag{2}$$

$$q_{a;i}(\boldsymbol{\theta}) = \min_{f, f(a)=i} Q(f; \mathbf{D}, \boldsymbol{\theta}), \tag{3}$$

$$q_{ab;ij}(\boldsymbol{\theta}) = \min_{f, f(a)=i, f(b)=j} Q(f; \mathbf{D}, \boldsymbol{\theta}), \tag{4}$$

where the term $\mathbf{D}$ is dropped from the LHS to make the notation less cluttered.

Reparameterization: A parameter $\overline{\boldsymbol{\theta}}$ is called a reparameterization of the parameter $\boldsymbol{\theta}$ (denoted by $\overline{\boldsymbol{\theta}} \equiv \boldsymbol{\theta}$) if, and only if,

$$Q(f; \mathbf{D}, \overline{\boldsymbol{\theta}}) = Q(f; \mathbf{D}, \boldsymbol{\theta}), \forall f. \tag{5}$$

Over-complete Representations: A labelling f can be represented using an over-complete set of boolean variables $\mathbf{y}$ defined as

$$y_{a;i} = \begin{cases} 1 & \text{if } f(a) = i, \\ 0 & \text{otherwise.} \end{cases}, \quad y_{ab;ij} = y_{a;i} y_{b;j}. \tag{6}$$

We also define variables $(\mathbf{x}, \mathbf{X})$ such that

$$x_{a;i} = 2y_{a;i} - 1, \;\; X_{ab;ij} = 4y_{ab;ij} - 2y_{a;i} - 2y_{b;j} + 1. \tag{7}$$

We will sometimes specify the additional constraints (i.e. cycle inequalities and SOC constraints) using variables $(\mathbf{x}, \mathbf{X})$, since they will allow us to write these constraints concisely.

The LP-S Relaxation: The LP-S relaxation of the MAP estimation problem is given by

$$\mathbf{y}^* = \arg\min_{\mathbf{y} \in LOCAL(\mathbf{v}, \mathcal{E})} \mathbf{y}^\top \boldsymbol{\theta},$$

$$LOCAL(\mathbf{v}, \mathcal{E}) = \begin{cases} y_{a;i} \in [0,1], y_{ab;ij} \in [0,1], \\ \sum_{l_i \in \mathbf{l}} y_{a;i} = 1, \\ \sum_{l_j \in \mathbf{l}} y_{ab;ij} = y_{a;i}. \end{cases} \tag{8}$$

The term $LOCAL(\mathbf{v}, \mathcal{E})$ stands for *local consistency polytope* (Wainwright et al., 2005) and denotes the feasibility region of the LP-S relaxation (specified by the above constraints for all $v_a \in \mathbf{v}, (a,b) \in \mathcal{E}, l_i, l_j \in \mathbf{l}$).

Dual of the LP-S Relaxation: Let $\mathcal{T}$ denote a set of tree-structured CRFs defined over subsets of the given random variables. For a CRF $T \in \mathcal{T}$, we denote its random variables by $\mathbf{v}_T$, its neighbourhood relationship by $\mathcal{E}_T$ and its parameter as $\boldsymbol{\theta}^T$. The parameter $\boldsymbol{\theta}^T$ consists of unary potentials $\theta^{T1}_{a;i}$ and pairwise potentials $\theta^{T2}_{ab;ij}$. Let $\boldsymbol{\rho} = \{\rho(T), T \in \mathcal{T}\}$ be a set of non-negative real numbers which sum to one. Using the above notation, the dual of the LP-S relaxation can be written as follows (Kolmogorov, 2006; Wainwright et al., 2005):

$$\max_{\sum_{T \in \mathcal{T}} \rho(T) \boldsymbol{\theta}^T \equiv \boldsymbol{\theta}} \sum_T \rho(T) q(\boldsymbol{\theta}^T). \tag{9}$$

The TRW-S Algorithm: Table 1 describes the TRW-S algorithm (Kolmogorov, 2006) which attempts to solve the dual of the LP-S relaxation. In other words, it solves for the set of parameters $\boldsymbol{\theta}^T$, $T \in \mathcal{T}$, which maximize the dual (9). There are two main steps: (i)

reparameterization, which involves running one pass of BP on the tree structured CRFs T; and (ii) averaging operation. TRW-S is guaranteed not to decrease the value of the dual (9) at each iteration. Further, it can be shown that it converges to a solution which satisfies the *weak tree agreement* (WTA) (Kolmogorov, 2006).

Initialization

1. For every $\omega \in \mathbf{v} \bigcup \mathcal{E}$, find all trees $\mathcal{T}_\omega \subseteq \mathcal{T}$ which contains ω.
2. Initialize $\boldsymbol{\theta}^T$ such that $\sum_T \rho(T)\boldsymbol{\theta}^T \equiv \boldsymbol{\theta}$.
   Typically, we set $\rho(T) = \frac{1}{|\mathcal{T}|}$ for all $T \in \mathcal{T}$.
   Then we can initialize $\theta^{T1}_{a;i} = \theta^1_{a;i} \frac{|\mathcal{T}|}{|\mathcal{T}_{v_a}|}$ for all $T \in \mathcal{T}_{v_a}$.
   Similarly, $\theta^{T2}_{ab;ij} = \theta^2_{ab;ij} \frac{|\mathcal{T}|}{|\mathcal{T}_{(a,b)}|}$ for all $T \in \mathcal{T}_{(a,b)}$.

Iterative Steps

3. Pick an element $\omega \in \mathbf{v} \bigcup \mathcal{E}$.
4. For all $T \in \mathcal{T}_\omega$, reparameterize $\boldsymbol{\theta}^T$ to $\overline{\boldsymbol{\theta}}^T$ such that
   (i) $\overline{\theta}^{T1}_{a;i} = q_{a;i}(\boldsymbol{\theta}^T)$, if $\omega = v_a \in \mathbf{v}$,
   (ii) $\overline{\theta}^{T1}_{a;i} + \overline{\theta}^{T1}_{b;j} + \overline{\theta}^{T2}_{ab;ij} = q_{ab;ij}(\boldsymbol{\theta}^T)$, if $\omega = (a,b) \in \mathcal{E}$.
   This step involves running one iteration of BP for T.
5. Averaging operation:
   (i) If $\omega = v_a \in \mathbf{v}$,
   (a) Compute $\nu_{a;i} = \frac{1}{\rho_a} \sum_{T \in \mathcal{T}_a} \rho(T) \overline{\theta}^{T1}_{a;i}$.
   (b) Set $\overline{\theta}^{T1}_{a;i} = \nu_{a;i}$, for all $T \in \mathcal{T}_{v_a}$.
   (ii) If $\omega = (a,b) \in \mathcal{T}$,
   (a) Compute $\nu_{ab;ij} = \frac{1}{\rho_{ab}} \sum_{T \in \mathcal{T}_{(a,b)}} \rho(T)(\overline{\theta}^{T1}_{a;i} + \overline{\theta}^{T1}_{b;j} + \overline{\theta}^{T2}_{ab;ij})$.
   (b) Set $\overline{\theta}^{T1}_{a;i} + \overline{\theta}^{T1}_{b;j} + \overline{\theta}^{T2}_{ab;ij} = \nu_{ab;ij}$, for all $T \in \mathcal{T}_{(a,b)}$.
6. Repeat steps 3, 4 and 5 till convergence.

Table 1. The TRW-S algorithm. Recall that $\theta^{T1}_{a;i}$ and $\theta^{T2}_{ab;ij}$ are the unary and pairwise potentials for the parameter $\boldsymbol{\theta}^T$. Similarly, $\overline{\theta}^{T1}_{a;i}$ and $\overline{\theta}^{T2}_{ab;ij}$ are the unary and pairwise potentials defined by the parameter $\overline{\boldsymbol{\theta}}$. The terms $\rho_a = \sum_{T, v_a \in \mathbf{v}_T} \rho(T)$ and $\rho_{ab} = \sum_{T,(a,b) \in \mathcal{E}_T} \rho(T)$ are the variable and edge appearance terms for $v_a \in \mathbf{v}$ and $(a,b) \in \mathcal{E}$ respectively. In step 3, the value of the dual (9) remains unchanged. Step 4, i.e. the averaging operation, ensures that the value of the dual does not decrease. TRW-S converges to a solution which satisfies the WTA condition.

3. Adding Linear Constraints

We now show how the results of (Kolmogorov, 2006; Wainwright et al., 2005) can be extended to include an arbitrary number of linear cycle inequalities (Barahona & Mahjoub, 1986; Kumar et al., 2007). This requires us to incorporate cycle inequalities into the dual (11).

We begin by briefly describing cycle inequalities. Consider a cycle of length c in the graphical model of the given CRF, which is specified over a set of random variables $\mathbf{v}_C = \{v_b, b = a_1, a_2, \cdots, a_c\}$ such that $\mathcal{E}_C = \{(a_1,a_2),(a_2,a_3),\cdots,(a_n,a_1)\} \subseteq \mathcal{E}$. Further, let $\mathcal{E}_F \subseteq \mathcal{E}_C$ such that $|\mathcal{E}_F|$ (i.e. the cardinality of $\mathcal{E}_F$) is odd. Using these sets of edges, a cycle inequality can be specified as

$$\sum_{(a_k,a_m) \in \mathcal{E}_F} X_{a_k a_m; i_k i_m} - \sum_{(a_k,a_m) \in \mathcal{E}_C - \mathcal{E}_F} X_{a_k a_m; i_k i_m} \geq 2 - c, \tag{10}$$

where $l_{i_k}, l_{i_m} \in \mathbf{l}$[1]. The variables $X_{a_k a_m; i_k i_m}$ are defined in equation (7). It can be shown that adding cycle inequalities to LP-S, i.e. problem (8), provides a better relaxation than LP-S alone. Their importance is reflected in their wide use in recent literature such as (Sontag & Jaakkola, 2007; Zwick, 1999).

In general, a set of N_C cycle inequalities defined on a cycle $C = (\mathbf{v}_C, \mathcal{E}_C)$ (using different labels l_{i_k} for variables $v_{a_k} \in \mathbf{v}_C$) can be written as $\mathbf{A}^C \mathbf{y} \geq \mathbf{b}^C$. In other words, for every cycle we can define up to h^c cycle inequalities (where $h = |\mathbf{l}|$), i.e. $N_C \in \{0, 1, \cdots, h^c\}$. Let $\mathcal{C}$ be a set of cycles in the given CRF. Theorem 1 (given below) provides us with the dual of the LP relaxation obtained by appending problem (8) with cycle inequalities (defined over cycles in the set $\mathcal{C}$). We refer to the resulting relaxation as LP-C (where C denotes cycles).

Theorem 1: The following problem is the dual of problem (8) appended with a set of cycle inequalities $\mathbf{A}^C \mathbf{y} \geq \mathbf{b}^C$, for all $C \in \mathcal{C}$ (hereby referred to as the LP-C relaxation):

$$\begin{aligned} \max \quad & \textstyle\sum_T \rho(T) q(\boldsymbol{\theta}^T) + \sum_C \rho'(C) (\mathbf{b}^C)^\top \mathbf{u}^C, \\ \text{s.t.} \quad & \textstyle\sum_T \rho(T) \boldsymbol{\theta}^T + \sum_C \rho'(C) (\mathbf{A}^C)^\top \mathbf{u}^C \equiv \boldsymbol{\theta}, \\ & u^C_k \geq 0, \forall k \in \{1, 2, \cdots, N_C\}, C \in \mathcal{C}. \end{aligned} \tag{11}$$

Here $\boldsymbol{\rho}' = \{\rho'(C), C \in \mathcal{C}\}$ is some (fixed) set of non-negative real numbers which sum to one, and $\mathbf{u}^C = \{u^C_k, k = 1, \cdots, N_C\}$ are some non-negative slack variables.

Similar to the dual (9), the above problem cannot be solved using standard software for a large number of variables $\mathbf{v}$. In order to overcome this deficiency we propose a convergent algorithm (similar to TRW-S) to approximately solve problem (11). We call our approach the TRW-S(LP-C) algorithm. In order to describe TRW-S(LP-C), we need the following definitions.

We say that a tree structured random field $T = (\mathbf{v}_T, \mathcal{E}_T) \in \mathcal{T}$ *belongs to* a cycle $C = (\mathbf{v}_C, \mathcal{E}_C) \in \mathcal{C}$ (denoted by $T \in C$) if, and only if, there exists an edge $(a,b) \in \mathcal{E}_T$ such that $(a,b) \in \mathcal{E}_C$. In other words, $T \in C$ if they share a common pair of neighbouring random variables $(a,b) \in \mathcal{E}$. We also define the following problem:

$$\max \quad \textstyle\sum_{T \in C} \rho(T) q(\boldsymbol{\theta}^T) + \rho'(C) (\mathbf{b}^C)^\top \mathbf{u}^C,$$

[1]Note that using the variable $\mathbf{y}$ would result in a less compact representation of cycle inequalities.

$$\text{s.t.} \quad \sum_{T \in C} \rho(T)\boldsymbol{\theta}^T + \rho'(C)(\mathbf{A}^C)^\top \mathbf{u}^C = \boldsymbol{\theta}^C, \quad u_k^C \geq 0, \forall k \in \{1, 2, \cdots, N_C\}, \tag{12}$$

for some parameter $\boldsymbol{\theta}^C$. The variables of the above problem are restricted to u_k^C, $\theta_{a;i}^{T1}$ and $\theta_{ab;ij}^{T2}$ where $(a, b) \in \mathcal{E}_T \bigcap \mathcal{E}_C$ for some $T \in C$. In other words, problem (12) has fewer variables and constraints than dual (11) and can be solved easily using standard Interior Point algorithms for small cycles C. As will be seen, even using cycles of size 3 or 4 results in much better approximations of the MAP estimation problem for non-submodular energy functions.

Table 2 describes the convergent TRW-S(LP-C) algorithm for approximately solving the dual (11). The algorithm consists of two main steps : (i) solving problem (12) for a cycle; and (ii) running steps 4 and 5 of the TRW-S algorithm. Note that our approach is different from other generalizations of TRW, e.g. (Wiegernick, 2005) which computes marginals. Specifically, we do not cluster random variables but include additional constraints to reduce the feasibility region of the relaxation. Our experiments in section 5 show that, unlike (Wiegernick, 2005), we always outperform BP. The properties of the TRW-S(LP-C) algorithm are summarized below.

Initialization
1. Choose a set of tree structured random fields $\mathcal{T}$. Choose a set of cycles $\mathcal{C}$. For example, if the 4-neighbourhood is employed, $\mathcal{C}$ can be the set of all cycles of size 4.
2. Initialize $\boldsymbol{\theta}^T$ such that $\sum_T \rho(T)\boldsymbol{\theta}^T \equiv \boldsymbol{\theta}$. Initialize $u_k^C = 0$ for all C and k.
Iterative Steps
3. Pick an element $\omega \in \mathbf{v} \bigcup \mathcal{C}$. Find all cycles $\mathcal{C}_\omega \subseteq \mathcal{C}$ which contains ω.
4. For a cycle $C \in \mathcal{C}_\omega$, compute $\boldsymbol{\theta}^C = \sum_{T \in C} \rho(T)\boldsymbol{\theta}^T + \rho'(C)(\mathbf{A}^C)^\top \mathbf{u}^C$ using the values of $\boldsymbol{\theta}^T$ and $\mathbf{u}^C$ obtained in the previous iteration. Solve problem (12) using an Interior Point method. Update the values of $\boldsymbol{\theta}^T$ and $\mathbf{u}^C$.
5. For all trees $T \in \mathcal{T}$ which contain ω, run steps 4 and 5 of the TRW-S algorithm.
6. Repeat steps 3 and 4 for all cycles $C \in \mathcal{C}_\omega$.
7. Repeat steps 3 to 5 for all elements ω till convergence.

Table 2. The TRW-S(LP-C) algorithm.

3.1. Properties of the TRW-S(LP-C) Algorithm.

Property 1: *At each step of the algorithm, the reparameterization constraint is satisfied, i.e.*

$$\sum_T \rho(T)\boldsymbol{\theta}^T + \sum_C \rho'(C)(\mathbf{A}^C)^\top \mathbf{u}^C \equiv \boldsymbol{\theta}. \tag{13}$$

The constraint in problem (12) ensures that parameter vector $\boldsymbol{\theta}^C$ of cycle C remains unchanged. Hence, after step 4 of the TRW-S(LP-C) algorithm, the reparameterization constraint is satisfied. It was also shown that step 5 (i.e. running TRW-S) provides a reparameterization of $\boldsymbol{\theta}$ (see Lemma 3.3 of (Kolmogorov, 2006) for details). This proves Property 1.

Property 2: *At each step of the algorithm, the value of the dual (11) never decreases.* Clearly, step 4 of the TRW-S(LP-C) algorithm does not decrease the value of the dual (11) (since the objective function of problem (12) is part of the objective function of dual (11)). The work of (Kolmogorov, 2006) showed that step 5 (i.e. TRW-S) also does not decrease this value. Note that the LP-C relaxation is guaranteed to be bounded since it dominates the LP-S relaxation (Kumar et al., 2007), which itself is bounded (Kolmogorov, 2006). Therefore, by the Bolzano-Weierstrass theorem (Fitzpatrick, 2006), it follows that TRW-S(LP-C) will converge.

Property 3: *Like* TRW-S*, the necessary condition for convergence of* TRW-S(LP-C) *is that the parameter vectors $\boldsymbol{\theta}^T$ of the trees $T \in \mathcal{T}$ satisfy* WTA. This follows from the fact that TRW-S increases the value of the dual in a finite number of steps as long as the set of parameters $\boldsymbol{\theta}^T$, $T \in \mathcal{T}$, do not satisfy WTA (see (Kolmogorov, 2006) for details).

Property 4: *Unlike* TRW-S, WTA *is not the sufficient condition for convergence.* One of the main drawbacks of the TRW-S algorithm is that it converges as soon as the WTA condition is satisfied. Experiments in (Kolmogorov, 2006) indicate that this results in high energy solutions for the MAP estimation problem when the energy function is non-submodular. Using a counter-example, it can be shown that WTA is not the sufficient condition for the convergence of TRW-S(LP-C) (Kumar & Torr, 2008).

Obtaining the Labelling: Similar to the TRW-S algorithm, TRW-S(LP-C) solves the dual (11) and not the primal problem. In other words, it does not directly provide a labelling of the random variables. In order to obtain a labelling, we use the same scheme as the one suggested in (Kolmogorov, 2006) for the TRW-S algorithm. Briefly, we assign labels to the variables $\mathbf{v} = \{v_0, v_1, \cdots, v_{n-1}\}$ in increasing order (i.e. we label variable v_0, followed by variable v_1 and so on). Let $\boldsymbol{\theta}^{\mathcal{T}} = \sum_T \rho(T)\boldsymbol{\theta}^T$. At each stage, a variable v_a is assigned the label $l_{f(a)}$ such that

$$f(a) = \arg\min_{i, l_i \in \mathbf{l}} \left(\theta_{a;i}^{\mathcal{T}1} + \sum_{b<a, (a,b) \in \mathcal{E}} \theta_{ab;i,f(b))}^{\mathcal{T}2} \right), \tag{14}$$

where $\theta_{a;i}^{\mathcal{T}1}$ and $\theta_{ab;i,f(b)}^{\mathcal{T}2}$ are the unary and pairwise potentials corresponding to the parameter $\boldsymbol{\theta}^{\mathcal{T}}$ respec-

tively. It can be shown that under certain conditions the above procedure provides the optimal labelling (Meltzer et al., 2005).

4. Adding SOC Constraints

We now show how second order cone (SOC) constraints can be added to the dual (9). Specifically, we consider the two SOC constraints proposed in (Kumar et al., 2007) which result in the SOCP-C and SOCP-Q relaxations described below.

The SOCP-C Relaxation: Consider a set of random variables $\mathbf{v}_C = \{v_b, b = a_1, \cdots, a_c\} \subseteq \mathbf{v}$ such that $\mathcal{E}_C = \{(a_1, a_2), (a_2, a_3), (a_c, a_1)\} \subseteq \mathcal{E}$ (i.e. $\mathbf{v}_C$ forms a cycle of length c). We define a vector $\mathbf{x}_C$ whose k^{th} element is given by $x_{a_k;i_k}$ and a matrix $\mathbf{X}_C$ whose $(k,m)^{th}$ element is given by $X_{a_k a_m;i_k i_m}$ (where $l_{i_k}, l_{i_m} \in \mathbf{l}$). SOCP-C specifies constraints $||\mathbf{U}^\top \mathbf{x}_C||^2 \leq \mathbf{C} \bullet \mathbf{X}_C$ where $\mathbf{C} = \mathbf{D}_c + \lambda_c I = \mathbf{U}\mathbf{U}^\top$ and $(\bullet)$ represents the Frobenius inner product. The $c \times c$ matrix $\mathbf{D}_c$ is given by

$$D_c(i,j) = \begin{cases} (-1)^{c-1} & \text{if} \quad |i-j| = c-1, \\ 1 & \text{if} \quad |i-j| = 1, \\ 0 & \text{otherwise}, \end{cases} \tag{15}$$

and λ_c is the absolute value of the smallest eigenvalue of $\mathbf{D}_c$.

The SOCP-Q Relaxation: Consider a set of random variables $\mathbf{v}_C = \{v_b, b = a_1, \cdots, a_c\} \subseteq \mathbf{v}$ such that $\mathcal{E}_C = \{(a_i, a_j), i, j = 1, \cdots, c\} \subseteq \mathcal{E}$ (i.e. $\mathbf{v}_C$ form a clique of size c). SOCP-Q specifies constraints of the form $||\mathbf{U}^\top \mathbf{x}_C||^2 \leq \mathbf{C} \bullet \mathbf{X}_C$ where $\mathbf{C}$ is a matrix whose elements are all 1.

In general, a set of N_C SOC constraints on a cycle/clique can be defined as

$$||\mathbf{A}_k^C \mathbf{y} + \mathbf{b}_k^C|| \leq \mathbf{y}^\top \mathbf{c}_k^C + d_k^C, k \in \{1, 2, \cdots, N_C\}. \tag{16}$$

Let $\mathcal{C}$ be a set of cycles/cliques in the graphical model of the given random field. The following theorem provides us with the dual of the SOCP relaxation obtained by appending problem (8) with SOC constraints defined over the set $\mathcal{C}$.

Theorem 2: The following problem is the dual of problem (8) appended with a set of SOC constraints $||\mathbf{A}_k^C \mathbf{y} + \mathbf{b}_k^C|| \leq \mathbf{y}^\top \mathbf{c}_k^C + d_k^C$ for $k \in \{1, 2, \cdots, N_C\}$ and $C \in \mathcal{C}$.

$$\begin{aligned} \max \quad & \textstyle\sum_T \rho(T) q(\boldsymbol{\theta}^T) - \sum_C \rho'(C) \sum_k p_k^C, \\ \text{s.t.} \quad & \textstyle\sum_T \rho(T) \boldsymbol{\theta}^T + \sum_C \rho'(C) \sum_k q_k^C \equiv \boldsymbol{\theta}, \\ & ||\mathbf{u}_k^C|| \leq v_k^C, \forall k \in \{1, 2, \cdots, N_C\}, C \in \mathcal{C}. \end{aligned} \tag{17}$$

where

$$p_k^C = (\mathbf{b}_k^C)^\top \mathbf{u}_k^C + d_k^C v_k^C, \tag{18}$$

$$q_k^C = (\mathbf{A}_k^C)^\top \mathbf{u}_k^C + \mathbf{c}_k^C v_k^C. \tag{19}$$

Here $\mathbf{u}_k^C$ and v_k^C are some slack variables.

We can define up to h^c SOC constraints for a cycle/clique, where c is the size of the cycle/clique (i.e. $N_C \in \{0, 1, \cdots, h^c\}$). Before proceeding further, we also define the following problem:

$$\begin{aligned} \max \quad & \textstyle\sum_{T \in C} \rho(T) q(\boldsymbol{\theta}^T) - \rho'(C) \sum_k p_k^C, \\ \text{s.t.} \quad & \textstyle\sum_{T \in C} \rho(T) \boldsymbol{\theta}^T + \rho'(C) \sum_k q_k^C = \boldsymbol{\theta}^C, \\ & ||\mathbf{u}_k^C|| \leq v_k^C, \forall k \in \{1, 2, \cdots, N_C\}, \end{aligned} \tag{20}$$

where $\boldsymbol{\theta}^C$ is some parameter vector. The variables of the above problem are restricted to $\mathbf{u}_k^C$, v_k^C, $\theta_{a;i}^{T1}$ and $\theta_{ab;ij}^{T2}$ where $(a,b) \in \mathcal{E}_T \bigcap \mathcal{E}_C$. Like problem (12), we can solve problem (20) using standard Interior Point algorithms for small cycles/cliques C.

Similar to TRW-S(LP-C), a convergent algorithm can now be described for solving the dual (17). This algorithm differs from TRW-S(LP-C) in only step 4, where it solves problem (20) for a cycle/clique C instead of problem (12). We refer to this algorithm as either TRW-S(SOCP-C) or TRW-S(SOCP-Q) depending upon the SOCP relaxation that we are solving. When using the TRW-S(SOCP-Q) algorithm, we include all slack variables corresponding to the cycle inequalities defined over the cycles in clique C. It can easily be shown that both TRW-S(SOCP-C) and TRW-S(SOCP-Q) satisfy all the properties given in § 3.1. Note that, like TRW-S and TRW-S(LP-C), these algorithms do not directly provide a labelling for the random variables of the CRF. Instead we use the procedure described in § 3.1 to obtain the final solution.

5. Experiments

We tested the approaches described in this paper using both synthetic and real data. For synthetic data experiments, we closely follow the setup of (Kolmogorov, 2006). We show that our algorithms overcome a well-known deficiency of TRW-S, namely that it does not provide good MAP estimates for non-submodular energy functions. Next, we consider the problem of segmentation using real data and show favourable comparison between our methods and several other standard MAP estimation techniques.

5.1. Synthetic Data

Datasets: We conducted two sets of experiments using binary grid CRFs (i.e. $h = |\mathbf{l}| = 2$) of size 30×30. In the first experiment the edges of the graphical model, i.e. $\mathcal{E}$, were defined using a 4-neighbourhood system while the second experiment used an 8-neighbourhood system. Similar to (Kolmogorov, 2006), the unary potentials $\theta_{a;0}^1$ and $\theta_{a;1}^1$ were generated using the normal distribution $\mathcal{N}(0,1)$. The pairwise potentials $\theta_{ab;00}^2$ and

$\theta^2_{ab;11}$ were set to 0 while $\theta^2_{ab;01}$ and $\theta^2_{ab;10}$ were generated using $\mathcal{N}(0, \sigma^2)$. For both experiments, 50 CRFs were generated using the method described above. All the CRFs defined non-submodular energy functions (i.e. there exists an $(a, b) \in \mathcal{E}$ such that $\theta_{ab;01} + \theta_{ab;10} < 0$) which are in general NP-hard to minimize. As noted in (Kolmogorov, 2006), TRW-S performs considerably worse than BP on such examples.

Implementation Details: We tested the LP-C and the SOCP-C relaxations in the first experiment. Constraints were defined on all cycles of size 4. The LP-C and SOCP-Q relaxation were tested in the second experiment. Cycles inequalities were defined on all cycles of size 3. In addition, for SOCP-Q, SOC constraints were defined on all cliques of size 4. In both the experiments, our algorithms were tested using trees defined by individual edges of the graphical model for ease of implementation. In other words, a tree $T = (\mathbf{v}_T, \mathcal{E}_T) \in \mathcal{T}$ such that $\mathbf{v}_T = \{v_a, v_b\}$ and $\mathcal{E}_T = \{(a, b)\} \subseteq \mathcal{E}$. However, we note here that our algorithms are general and can be applied for any choice of trees. Although our current set of trees are quite restrictive, the results show that they outperform several state of the art algorithms. The TRW-S algorithm, as well as other standard approaches, was tested using the publically available code which uses monotonic chains as trees.

The terms $\rho(T)$ and $\rho'(C)$ were set to $1/|\mathcal{T}|$ and $1/|\mathcal{C}|$ respectively for all $T \in \mathcal{T}$ and $C \in \mathcal{C}$. We found it sufficient to define one cycle inequality per cycle C using a set of labels $\{l_{i_1}, l_{i_2}, \cdots, l_{i_c}\}$ which satisfies

$$\sum_{(a_k,a_m)\in\mathcal{E}_F} \theta_{a_k a_m; i_k i_m} - \sum_{(a_k,a_m)\in\mathcal{E}_C-\mathcal{E}_F} \theta^2_{a_k a_m; i_k i_m} \geq \sum_{(a_k,a_m)\in\mathcal{E}_F} \theta_{a_k a_m; j_k j_m} - \sum_{(a_k,a_m)\in\mathcal{E}_C-\mathcal{E}_F} \theta^2_{a_k a_m; j_k j_m},$$

for all sets of labels $\{l_{j_1}, \cdots, l_{j_c}\}$. Here $\mathcal{E}_C = \{(a_1, a_2), \cdots, (a_n, a_1)\}$ and $\mathcal{E}_F \subseteq \mathcal{E}_C$ such that $|\mathcal{E}_F| = 3$. As proposed in (Kumar et al., 2007), we also define only one SOC constraint per cycle/clique when considering the SOCP-C and the SOCP-Q relaxations. At each iteration, problems (12) and (20) were solved using the MOSEK software (available at http://www.mosek.com).

Results: Figure 1 (a) shows the results obtained for the first experiment using $\sigma = \frac{10}{\sqrt{d}}$ (where d is the degree of the variables in the graphical model). Note that since the energy functions are non-submodular, TRW-S provides labellings with higher energies than BP as observed in (Kolmogorov, 2006). However, the additional constraints in the LP-C and SOCP-C algorithm enable us to obtain labelling with lower energies than BP. Further, unlike BP, they also provide us with the value of the dual at each iteration. This value allows us to find out how close we are to the global optimum (since the energy of the optimal labelling cannot be less than the value of the dual). Also note that the value of the LP-C dual is greater than the value of the SOCP-C dual. This provides empirical evidence that LP-C dominates SOCP-C as conjectured in (Kumar et al., 2007).

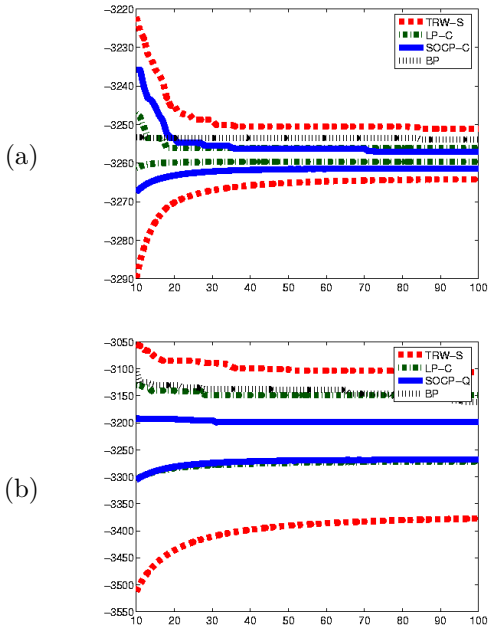

Figure 1. Results of the synthetic data experiment. **(a)** First experiment. The x-axis shows the iteration number. The lower curves show the average value of the dual at each iteration over 50 random CRFs while the upper curves show the average energy of the best labelling found till that iteration. The additional constraints in the LP-C and SOCP-C relaxations enable us to obtain labellings with lower energy compared to TRW-S and BP. Cycle inequalities provide a better approximation than the SOC constraint of the SOCP-C relaxation. **(b)** Second experiment. Note that the value of the dual obtained using SOCP-Q is greater than the value of the dual of the LP-C relaxation.

The results of the second experiment are shown in Figure 1 (b) using $\sigma = \frac{10}{\sqrt{d}}$. Again, BP outperforms TRW-S, while LP-C and SOCP-Q provide better approximations. The SOC constraints defined over cliques in SOCP-Q provide a greater value of the dual compared to the LP-C relaxation. The complexity and timings for all the algorithms are given in tables 3 and 4.

5.2. Real Data - Segmentation

We now present the results of our method on interactive segmentation (Boykov & Jolly, 2001) where, given some seed pixels for all the segments present in an image, we wish to obtain the segmentation of the image.

Problem Formulation: The problem of obtaining the segmentation of an image can be cast within the CRF framework. Specifically, we define a CRF over random variables $\mathbf{v} = \{v_0, \cdots, v_{n-1}\}$, where each variable

Algorithm	No. of Var.	No. of Cons.	Time(sec)
BP	-	-	0.0018
TRW-S	$nh + \|\mathcal{E}\|h^2$	$n + 2\|\mathcal{E}\|h$	0.0018
LP-C	$nh + \|\mathcal{E}\|h^2$	$2n + 2\|\mathcal{E}\|h$	7.5222
SOCP-C	$nh + \|\mathcal{E}\|h^2$	$2n + 2\|\mathcal{E}\|h$	8.9091

Table 3. Complexity and timings of the algorithms for the first synthetic data experiment with a 4-neighbourhood relationship. Recall that $n = |\mathbf{v}|$ is the number of random variables, $h = |\mathbf{l}|$ is the size of the label set and $\mathcal{E}$ is the neighbourhood relationship defined by the CRF. The second and third columns show the number of variables and constraints in the primal problem respectively. The fourth column shows the average time of the each algorithm for one iteration (in seconds). All timings are reported for a Pentium IV 3.3 GHz processor with 2GB RAM.

Algorithm	No. of Var.	No. of Cons.	Time(sec)
BP	-	-	0.0027
TRW-S	$nh + \|\mathcal{E}\|h^2$	$n + 2\|\mathcal{E}\|h$	0.0027
LP-C	$nh + \|\mathcal{E}\|h^2$	$5n + 2\|\mathcal{E}\|h$	7.7778
SOCP-Q	$nh + \|\mathcal{E}\|h^2$	$6n + 2\|\mathcal{E}\|h$	9.1170

Table 4. Complexity and timings for the second synthetic data experiment with an 8-neighbourhood relationship. Note that SOCP-Q includes all the constraints of LP-C.

corresponds to a pixel of the frame. Each label in the set $\mathbf{l} = \{l_0, \cdots, l_{h-1}\}$ corresponds to a segment (where h is the total number of segments). The unary potential of assigning a variable v_a to segment l_i is specified by the negative log-likelihood of the RGB value of pixel a given the seed pixels of the segment l_i. The pairwise potentials encourage continuous segments whose boundaries lie on image edges. For more details, we refer the reader to (Boykov & Jolly, 2001). The problem of obtaining the segmentation of a frame then boils down to that of finding the MAP estimate of the CRF.

Datasets and Implementation Details: We used the well-known 'Garden' sequence to conduct our experiments (with frame size 120×175). The seed pixels were provided using the ground truth segmentation of a keyframe as shown in Fig. 2.

Similar to the synthetic data experiment, we defined the trees as individual edges of the graphical model of the CRF for our algorithms. Other algorithms were tested using publically available code (including TRW-S which uses monotonic chains as trees). We specified one cycle inequality and one SOC constraint for each cycle/clique (as described in the previous section). The terms $\rho(T)$ and $\rho'(C)$ were set to $1/|\mathcal{T}|$ and $1/|\mathcal{C}|$ respectively for all $T \in \mathcal{T}$ and $C \in \mathcal{C}$. Once again, problems (12) and (20) were solved using MOSEK.

Results: For the first set of experiments, we used a 4-neighbourhood system and tested the following algorithms: TRW-S, LP-C, SOCP-C, $\alpha\beta$-swap, α-expansion and BP. Fig. 3 shows the segmentations (of frames

Figure 2. Segmented keyframe of the 'Garden' sequence. The left image shows the keyframe while the right image shows the corresponding segmentation provided by the user. The four different colours indicate pixels belonging to the four segments namely sky, house, garden and tree.

Algorithm	Avg. Time-1 (s)	Avg. Time-2 (s)
BP	0.1400	0.1740
TRW-S	0.1400	0.1740
$\alpha\beta$-swap	0.1052	0.1201
α-expansion	0.1100	0.1240
LP-C	140.3320	142.2226
SOCP-C/SOCP-Q	143.6365	144.9890

Table 5. Average timings of the algorithms (per iteration) for the first experiment on video segmentation with a 4-neighbourhood relationship (column 2) and the second experiment with an 8-neighbourhood relationship (column 3). Again, all timings are reported for a Pentium IV 3.3 GHz processor with 2GB RAM.

other than the keyframe) and the values of the energy function obtained for all algorithms. Note that, by incorporating additional constraints using all cycles of length 4, LP-C and SOCP-C outperform other methods. Further, the cycle inequalities in LP-C provide better results than the SOC constraints of SOCP-C. Table 5 provides the average time for all algorithms.

The second set of experiments used an 8-neighbourhood system and tested the following algorithms: TRW-S, LP-C, SOCP-Q, $\alpha\beta$-swap, α-expansion and BP. For the LP-C algorithm, cycle inequalities were specified for all cycles of size 3. In addition, the SOCP-Q algorithm specifies SOC constraints on all cliques of size 4. Fig. 4 shows the segmentations and energies obtained for all the algorithms. The average timings per iteration are shown in table 5. Note that, similar to the synthetic data examples, SOCP-Q outperforms LP-C by incorporating additional SOC constraints.

6. Discussion

We extended the LP-S relaxation based approach of (Kolmogorov, 2006; Wainwright et al., 2005) for the MAP estimation problem. Specifically, we showed how cycle inequalities and SOC constraints can be incorporated within the TRW framework. We also proposed convergent algorithms for solving the resulting duals. Our experiments indicate that these additional constraints provide a more accurate approximation for MAP estimation when the energy function is non-submodular. Although our algorithm is much faster than Interior Point methods, it is slower than TRW-S and BP. An interesting direction for future re-

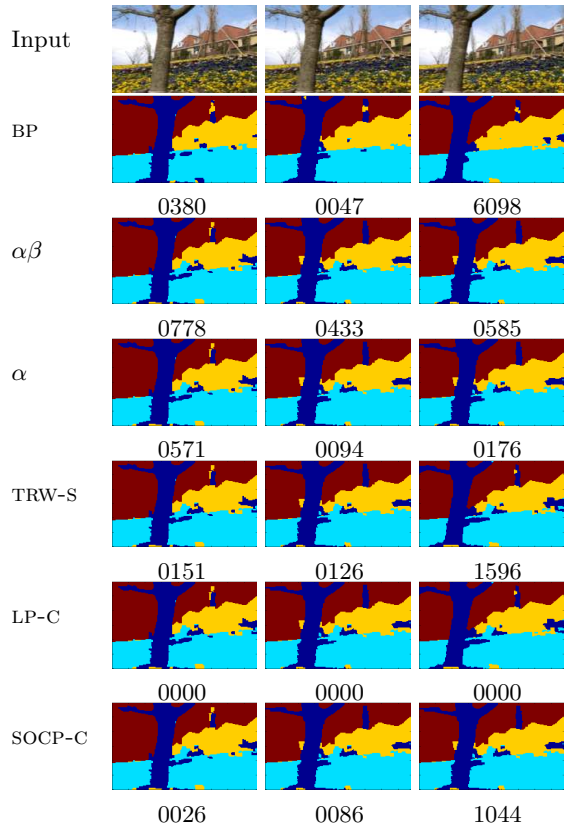

Figure 3. Segmentations obtained for the 'Garden' video sequence using 4-neighbourhood. The corresponding energy values (scaled up to integers for using $\alpha\beta$-swap and α-expansion) of all the algorithms are shown below the segmentation. The following constant terms are subtracted from the energy values of all algorithms for the three frames respectively (to make minimum energy among all algorithms 0): 5139499, 5145234 and 5126941.

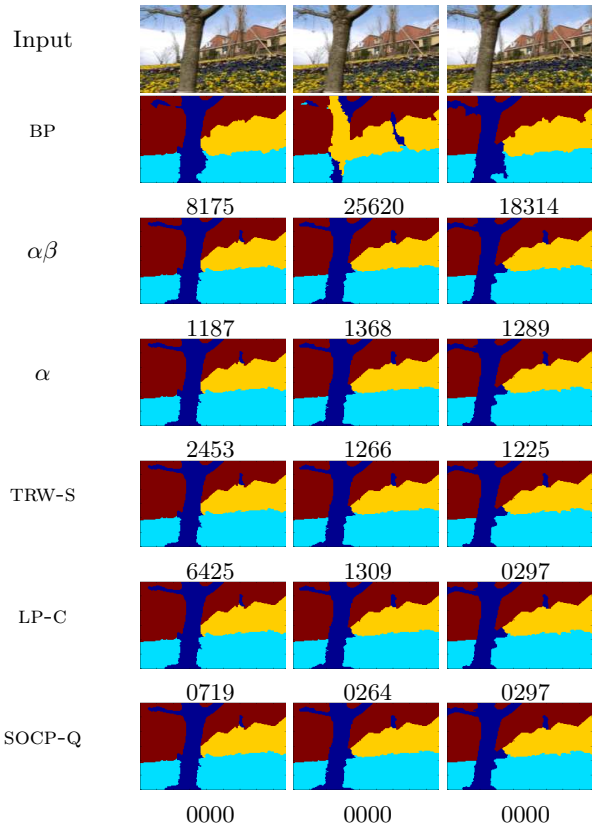

Figure 4. Segmentations obtained for the 'Garden' video sequence using 8-neighbourhood. The corresponding energy values (reduced by 5304466, 5299756 and 5292224 for the three frames respectively) are also shown.

search would be to develop specialized algorithms for solving problems (12) and (20) (which are used in our approach).

Abstract

In this work we address the question of finding symmetries of a given MDP. We show that the problem is *Isomorphism Complete*, that is, the problem is polynomially equivalent to verifying whether two graphs are isomorphic. Apart from the theoretical importance of this result it has an important practical application. The reduction presented can be used together with any off-the-shelf Graph Isomorphism solver, which performs well in the average case, to find symmetries of an MDP. In fact, we present results of using NAutY (the best Graph Isomorphism solver currently available), to find symmetries of MDPs.

1. Introduction

Markov Decision Processes (MDPs) are widely employed to model sequential decision problems. But current solution techniques for MDPs do not scale well with the size of the MDPs, and hence are proving inadequate in solving large real-world problems. While building abstract models of real-world problems, it can be seen that a high degree of redundancy is present which can be exploited to reduce size of the model. This reduction in size could possibly lead to more efficient solution methods.

One such notion of redundancy is a degree of symmetry that is present in any real-world problem. (Amarel, 1968) first looked at exploiting such symmetries in solving a missionaries and cannibals problem. In this work we use the notion of symmetries in MDPs introduced in (Ravindran, 2004). While it is widely believed that finding symmetries in MDPs is a hard problem, no one has investigated before exactly how hard this problem is.

Intuitively this seems harder than finding symmetries in graphs, due to the additional structure introduced by MDPs. In this work we show that finding symmetries in MDPs is no harder than the problem of graph isomorphism. We also show that existing graph isomorphism solvers can be used to find symmetries in MDPs.

We present some notation in the next section, and some related work in Section 3. In Section 4 we formally define the problem, and present a constructive algorithm in Section 5 for showing the equivalence to graph isomorphism. We discuss some results Section 6 and conclude in Section 7.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

2. Homomorphisms and Symmetry Groups

Let B be a partition of a set X. For any $x \in X, [x]_B$ denotes the block of B to which x belongs. Any function f from a set X to a set Y induces a partition (or equivalence relation) on X, with $[x]_f = [x']_f$ if and only if $f(x) = f(x')$ and x, x' are f-equivalent written $x \equiv_f x'$. Let B be a partition of $Z \subseteq X \times Y$, where X and Y are arbitrary sets. The projection of B onto X is the partition $B|X$ of X such that for any $x, x' \in X, [x]_{B|X} = [x']_{B|X}$ if and only if every block containing a pair in which x is a component also contains a pair in which x' is a component or every block containing a pair in which x' is a component also contains a pair in which x is a component.

Definition 1. An *MDP homomorphism* h from an MDP $\mathcal{M} = \langle S, A, \Psi, P, R \rangle$ to an MDP $\mathcal{M}' = \langle S', A', \Psi', P', R' \rangle$ is a surjection from Ψ to Ψ', defined by a tuple of surjections $< f, \{g_s | s \in S\} >$, with $h((s,a)) = (f(s), g_s(a))$, where $f : S \rightarrow S'$ and $g_s : A_s \rightarrow A'_{f(s)}$ for $s \in S$, such that: $\forall s, s' \in S, a \in A_s$

$$P'(f(s), g_s(a), f(s')) = \sum_{s'' \in [s']_f} P(s, a, s'') \quad (1)$$

$$R'(f(s), g_s(a)) = R(s, a) \quad (2)$$

We use the shorthand $h(s,a)$ for $h((s,a))$. Often for convenience, we use $< f, \{g_s\} >$ to denote $< f, \{g_s | s \in S\} >$.

Definition 2. Let $\mathcal{M}$' be an image of the MDP $\mathcal{M}$ under homomorphism $h =< f, \{g_s\} >$. For any $s \in S, g_s^{-1}(a')$ denotes the set of actions that have the same image $a' \in A'_{f(s)}$ under g_s. Let π' be a stochastic policy in $\mathcal{M}'$. Then π' lifted to $\mathcal{M}$ is the policy $\pi_{\mathcal{M}'}$ such that for any $a \in g_s^{-1}(a'), \pi'_{\mathcal{M}}(s,a) = \pi'(f(s),a')/|g_s^{-1}(a')|$

Definition 3. An MDP homomorphism $h =< f, \{g_s\} >$ from MDP $\mathcal{M} = \langle S, A, \Psi, P, R\rangle$ to MDP $\mathcal{M}' = \langle S', A', \Psi', P', R'\rangle$ is an MDP *isomorphism* from $\mathcal{M}$ to $\mathcal{M}'$ if and only if f and g_s, are bijective. $\mathcal{M}$ is said to be *isomorphic* to $\mathcal{M}'$ and vice versa. An MDP isomorphism from MDP $\mathcal{M}$ to itself is called an *automorphism* of $\mathcal{M}$.

Definition 4. The set of all automorphisms of an MDP $\mathcal{M}$, denoted by $Aut\mathcal{M}$, forms a group under composition of homomorphisms. This group is the *symmetry group* of $\mathcal{M}$.

Let $\mathcal{G}$ be a subgroup of $Aut\mathcal{M}$. The image of $\mathcal{M}$ under $\mathcal{G}$ is called the *$\mathcal{G}$-reduced image* of $\mathcal{M}$.

Definition 5. An MDP $\mathcal{M}'$ is said to be a *reduced model* of an MDP $\mathcal{M}$, iff there exists an MDP homomorphism $h : \mathcal{M} \to \mathcal{M}'$.

3. Related Work

MDP Minimization is a well studied problem. As stated earlier, in the model minimization approach, a reduced MDP that that preserves some key properties as the original MDP is found by combining "equivalent" states. The reduced MDP found depends on the notion of equivalence between states used in the aggregation. The notion of equivalence chosen will be fundamental in designing and analyzing algorithms for reducing MDPs. In (Dean & Givan, 1997) a minimization algorithm is proposed based on the notion of *stochastic bi-simulation homogeneity*. Informally, a partition of the state space for an MDP is said to be homogeneous if for each action, states in the same block have the same probability of transitioning to each other block. They also provide an algorithm for finding the coarsest homogeneous refinement of any partition of the state space of an MDP. The algorithm starts with an initial partition P_0 and iteratively refines it by splitting the blocks until the coarsest homogeneous refinement of P_0 is obtained. A notion of stability of a block with respect to another is defined and unstable blocks are split till all blocks of the partition are stable. The complexity of the algorithm is expressed in terms of the partition manipulation operations. Hence, the actual complexity depends on the underlying partition representation and manipulation algorithms. (Givan et al., 2003) discuss the application of the algorithm to solving factored MDP problems. Enumerating the state space is avoided by describing large blocks of equivalent states in factored form with the block descriptions being inferred directly from the original factored representation.

(Ravindran, 2004) proposes a more generic framework based on the notion of MDP homomorphisms with *state-dependent action recoding* as introduced in Section 2. This allows a greater reduction in problem size and aids in modeling many other notions of equivalence like symmetries. A polynomial time algorithm to find the reduced model under the notion of MDP homomorphisms is also proposed by extending the algorithm proposed by (Givan et al., 2003) and (Lee & Yannakakis, 1992). Again, the algorithm is polynomial in the number of block operations, the stability criterion is modified to suit the equivalence notion and the same process of iterative splitting is used. The notion of stability used is called the *stochastic substitution property*, which is an extension of the *substitution property* for finite state machines (Hartmanis, 1966).

However, literature on MDP minimization using symmetries is sparse. (Zinkevich & Balch, 2001) define symmetries based on state-action equivalence but do not make any connections to group-theoretic concepts or minimization algorithms.

Another dimension to analyze the literature is the approach to symmetry finding. Two main approaches exist:

1. To derive a set of necessary conditions for elements to be symmetric
2. Prove Isomorphism Completeness and use a graph isomorphism finding system

Intuitively symmetries seem easier to identify than homomorphisms and we tried the first approach to find a polynomial time algorithm for symmetry finding, along the lines of the MDP homomorphism finding, with the motivation of finding better algorithms for MDP minimization. The MDP homomorphism definition allows for deriving this easily because, two state action pairs $(s_1, a_1), (s_2, a_2)$ are homomorphically equivalent if

$$\begin{aligned} h(s_1,a_1) &= h(s_2,a_2) \\ P'(f(s_1), g_{s_1}(a_1), f(s')) &= P'(f(s_2), g_{s_2}(a_2), f(s')) \\ T(s_1,a_1,[s']_{B_h|S}) &= T(s_2,a_2,[s']_{B_h|S}) \end{aligned}$$

for all $s' \in S$. This is the stochastic substitution property and it allows us to deal just with blocks without worrying about the actual functions. However, a similar attempt for symmetries still needs the symmetry f in the necessary condition as below:

$$\begin{aligned} h(s_1,a_1) &= (s_2,a_2) \\ P(f(s_1), g_{s_1}(a_1), f(s')) &= P(s_2,a_2,f(s')) \\ P(s_1,a_1,s') &= P(s_2,a_2,f(s')) \end{aligned}$$

(Flener et al., 2002) and (Crawford, 1992) point that symmetry finding for CSPs in general is Isomorphism Com-

plete. However, there also exist results showing that symmetry finding is NP-complete (in case of geometric automorphism of graphs (Manning, 1990)). So we were still unclear whether symmetry finding for MDPs is Isomorphism Complete or NP-complete due to the presence of factorially many action recoding functions. A better understanding of the use of symmetries for abstraction in MDPs is the motivation for this work.

4. Problem Definition

To exploit the power of abstraction using symmetries, we identify them and construct a reduced model by abstracting away the symmetric portions. As the reduced model can be significantly smaller, it can be easier to solve. We use the notion of automorphisms to model symmetries. So formally, given an MDP $\mathcal{M}$,

1. Find the automorphism group, $Aut\mathcal{M}$ and
2. Given the automorphism group, $Aut\mathcal{M}$ find the corresponding reduced model, the $Aut\mathcal{M}$-Reduced Image

5. Finding Symmetries

5.1. Problem Simplification

Let us consider the first part of our problem, i.e., given an MDP $\mathcal{M}$, find the automorphism group of $\mathcal{M}$, $Aut\mathcal{M}$. We know that a group can be specified using its generators. So we simplify the problem to finding the generators of $Aut\mathcal{M}$. Let $AMGEN(\mathcal{M})$ denote the problem of finding the generators of $Aut\mathcal{M}$. We write $A \propto B$ if a problem A is polynomially reducible to B. We say that problems A and B are polynomially equivalent iff $A \propto B$ and $B \propto A$. We denote polynomial equivalence by $\equiv_\propto$.

Definition 6. A problem A is *Isomorphism Complete* iff A is polynomially equivalent to finding whether two graphs are isomorphic.

Let G_1, G_2 be two simple graphs unless otherwise mentioned. The following is a list of relevant *Isomorphism Complete* problems (Booth & Colbourn, 1977) on graphs:

- $ISO(G_1, G_2)$: Isomorphism recognition for G_1 and G_2
- $IMAP(G_1, G_2)$: Isomorphism Map from G_1 to G_2(if it exists),
- $AGEN(G_1)$: Generators of the automorphism group, $AutG_1$
- $DGEN(G)$: Generators of the automorphism group, $AutG$, where G is a weighted digraph

From (Mathon, 1979), (Read & Corneil, 1977), (Miller, 1977) we have,
$DGEN(G) \equiv_\propto AGEN(G) \equiv_\propto IMAP(G_1, G_2) \equiv_\propto ISO(G_1, G_2)$.

We intend to prove that $AMGEN(\mathcal{M})$ is *Isomorphism Complete*. We are done if we prove that $AMGEN(\mathcal{M}) \equiv_\propto DGEN(G_\mathcal{M})$, where $G_\mathcal{M}$ is a weighted graph constructed in polynomial time from $\mathcal{M}$, that is, $AMGEN(\mathcal{M}) \propto DGEN(G_\mathcal{M})$ and $DGEN(G_\mathcal{M}) \propto AMGEN(\mathcal{M})$. It is easy to see that $DGEN(G_\mathcal{M}) \propto AMGEN(\mathcal{M})$ is true because we can always construct a degenerate MDP from a digraph. So we need to prove that $AMGEN(\mathcal{M}) \propto DGEN(G_\mathcal{M})$.

5.2. *Isomorphism Completeness* of the problem

An MDP $\mathcal{M}$ can be considered as a pseudograph with states acting as vertices and actions acting as edges. Since there can be more than one action affecting the transition between 2 states, we need to represent this as a pseudograph. The transition probabilities and rewards can be thought of as weight functions. Next, we formally pose $AMGEN(\mathcal{M})$ as a problem on a weighted pseudograph.

Let $G_\mathcal{M} =< \Sigma_a, V, E, W_P, W_R >$ be the pseudograph corresponding to $\mathcal{M}$, where

Σ_a : Alphabet for labelling corresponding to actions
V : Set of vertices corresponding to states
E : Set of edges, where each edge is a triple (u, a, v) where, $u, v \in V$ and $a \in \Sigma_a$ corresponding to state transitions

W_P : $E \to \mathbb{R}$ corresponding to transition probabilities
W_R : $E \to \mathbb{R}$ corresponding to rewards with $W_R(u, a, v) = W_R(u, a, v')$ $\forall\ (u, a, v), (u, a, v') \in E$

Note, $E = \bigcup_{u,v \in V} E_{uv}$ where, $E_{uv} = \{\ (u', a, v') \in E \mid u' = u \text{ and } v' = v\ \}$

$AMGEN(\mathcal{M})$ can be formulated as finding the generators of the group of bijections $h : V \times \Sigma_a \to V \times \Sigma_a$. h is defined by $h(u, a) = (f(u), g_u(a))$, where

f : $V \to V$ and
g_u : $\Sigma_a \to \Sigma_a$ defined for each $u \in V$ are bijections s. t.

$W_P(f(u), g_u(a), f(v)) = W_P(u, a, v)$ and
$W_R(f(u), g_u(a), f(v)) = W_R(u, a, v)\ \forall\ (u, a, v) \in E$

These two components of each generator can be interpreted as follows:

1. f is a function that permutes the states/vertices
2. The set of functions $\{g_u\}$ defined for each state/vertex permutes the actions/edge labels. These are called the State-Dependent Action Recoding (SDAR) functions.

5.2.1. Set Bijections

Let us assume, for a moment, that we have a procedure that constructs a weighted digraph $WD_{\mathcal{M}}$ from $G_{\mathcal{M}}$. Now, solving $DGEN(WD_{\mathcal{M}})$ gives the generators of $WD_{\mathcal{M}}$. Even if these were somehow same as the fs we are looking for, we still need a way to find the SDAR functions. To achieve this, we define the notion of a *set bijection* which represents a set of bijections very compactly. In the worst case, for each f, there can be factorially many SDAR functions. So a normal explicit representation cannot be used. We also define the operations of intersection between two *set bijections* to find the bijections that are common to both *set bijections*, composition between two *set bijections* and an inverse of a *set bijection*. All these operations can be done in time polynomial of the number of elements in the domain of a bijection belonging to the *set bijection*.

Definition 7. Consider two finite sets A and B. Let $U_A = \{U_{A_1}, U_{A_2}, \ldots, U_{A_k}\}$ and $U_B = \{U_{B_1}, U_{B_2}, \ldots, U_{B_k}\}$ be partitions of A and B respectively. U_A and U_B are said to be *similar* iff $|U_A| = |U_B|$ and for each $U_{A_i} \in U_A$ there exists a unique $U_{B_j} \in U_B$ such that $|U_{A_i}| = |U_{B_j}|$. We denote it by $U_A \sim U_B$.

Note that, by definition the sets A and B will be of the same size.

Definition 8. Let A and B be two finite sets and $U_A = \{U_{A_1}, U_{A_2}, \ldots, U_{A_k}\}$ and $U_B = \{U_{B_1}, U_{B_2}, \ldots, U_{B_k}\}$ be partitions of A and B respectively such that $U_A \sim U_B$. A bijective map $X : U_A \to U_B$ where $X(U_{A_i}) = U_{B_j}$ implies $|U_{A_i}| = |U_{B_j}|$ for all $U_{A_i} \in U_A$ is called a *set bijection*.

Informally, a *set bijection* can be interpreted as representing a set of bijections from A to B. $X(U_{A_i}) = U_{B_j}$ represents all possible bijective mappings from elements in U_{A_i} to elements in U_{B_j}. A bijection from A to B in the set of bijections that represent the *set bijection*, can be formed by collating mappings from each $X(U_{A_i}) = U_{B_j}$. The *set bijection* represents all mappings that can be formed by such collations. To formalize this notion, we define the *interpretation function* next.

Let $X_{AB} \triangleq \{$ all bijections $X : U_A \to U_B$ such that U_A and U_B are similar partitions of A and B respectively $\}$ be the set of all *set bijections*. Let $2^{S_{|V|}}$ be the powerset set of all permutations from $A \to B$. Define, $\hat{I} : X_{AB} \to 2^{S_{|V|}}$ such that $\hat{I}(X : U_A \to U_B) = \{$ all bijections $l : A \to B \mid l(x \in U_{A_i}) \in X(U_{A_i})\ \forall U_{A_i} \in U_A\}$. Evidently, $\hat{I}$ is only injective and not surjective as there exist sets of $2^{S_{|V|}}$ that cannot be represented by a *set bijection*. For example, consider the set of bijections, between $\{a, b, c\}$ and $\{1, 2, 3\}$, $L = \{(a \to 1, b \to 2, c \to 3), (a \to 2, b \to 1, c \to 3), (a \to 2, b \to 3, c \to 1)\}$. Clearly there does not exist an $X : U_A \to U_B$ such that $\hat{I}(X) = L$. All we can say is that there exists an X such that $L \subset \hat{I}(X)$. To get a bijective interpretation function, we define, $I : X_{AB} \to image(\hat{I})$ such that $I(X : U_A \to U_B) = \hat{I}(X : U_A \to U_B)$. Clearly I is a bijection and we call this the interpretation function.

Definition 9. Let A be a finite set and let $U^1_A = \{U^1_{A_1}, U^1_{A_2}, \ldots, U^1_{A_k}\}$, $U^2_A = \{U^2_{A_1}, U^2_{A_2}, \ldots, U^2_{A_k}\}$ be two partitions of A such that, $U^1_A \sim U^2_A$. We define the intersection of two similar partitions of a finite set as $U^1_A \cap U^2_A = \{U^1_{A_i} \cap U^2_{A_j} \mid U^1_{A_i} \in U^1_A, U^2_{A_j} \in U^2_A \text{ and } U^1_{A_i} \cap U^2_{A_j} \neq \emptyset\}$.

Definition 10. Let A and B be two finite sets and $U^1_A = \{U^1_{A_1}, U^1_{A_2}, \ldots, U^1_{A_k}\}$, $U^2_A = \{U^2_{A_1}, U^2_{A_2}, \ldots, U^2_{A_k}\}$ be two partitions of A and $U^1_B = \{U^1_{B_1}, U^1_{B_2}, \ldots, U^1_{B_k}\}$, $U^2_B = \{U^2_{B_1}, U^2_{B_2}, \ldots, U^2_{B_k}\}$ be two partitions of B. Also let $U^1_A \sim U^1_B$ and $U^2_A \sim U^2_B$. Let two *set bijections* X_1 and X_2 be defined from U^1_A to U^1_B and from U^2_A to U^2_B respectively. If $(U^1_A \cap U^2_A) \sim (U^1_B \cap U^2_B)$, we define the intersection between the two set bijections $X = X_1 \cap X_2$ as follows: $\forall U^1_{A_i} \in U^1_A, U^2_{A_j} \in U^2_A$ such that $U^1_{A_i} \cap U^2_{A_j} \neq \emptyset$, $X(U^1_{A_i} \cap U^2_{A_j}) = X_1(U^1_{A_i}) \cap X_2(U^2_{A_j})$. Note that, $X : U^1_A \cap U^2_A \to U^1_B \cap U^2_B$ and it can be shown that $I(X) = I(X_1) \cap I(X_2)$.

Definition 11. Let A be a finite set. Let $U^1_A = \{U^1_{A_1}, U^1_{A_2}, \ldots, U^1_{A_k}\}$, $U^2_A = \{U^2_{A_1}, U^2_{A_2}, \ldots, U^2_{A_k}\}$ be two *similar* partitions of A. Let X be a *set bijection* defined from U^1_A to U^2_A. We define the *inverse* of X as $X^{-1} : U^2_A \to U^1_A$ such that $X^{-1}(U^2_{A_i}) = U^1_{A_j}$ iff $X(U^1_{A_j}) = U^2_{A_i}$.

Definition 12. Let A, B and C be three finite sets and $U_A = \{U_{A_1}, U_{A_2}, \ldots, U_{A_k}\}$, $U_B = \{U_{B_1}, U_{B_2}, \ldots, U_{B_k}\}$ and $U_C = \{U_{C_1}, U_{C_2}, \ldots, U_{C_k}\}$ be partitions of A, B and C respectively . Also let U_A, U_B and U_C be pairwise similar to each other. Let two *set bijections* X_1 and X_2 be defined from U_B to U_C and U_A to U_B respectively. We define the composition of X_1 and X_2, $X = X_1 \odot X_2$ as the *set bijection* from U_A to U_C defined by $X(U_{A_i}) = X_1(X_2(U_{A_i}))$, for each $U_{A_i} \in U_A$. It can be shown that for each $l \in I(X)$ there exist, $l_1 \in I(X_1)$ and $l_2 \in I(X_2)$ such that $l = l_1 \circ l_2$ where $\circ$ denotes normal function composition.

5.2.2. Vector-Weighted Digraph

We assume that Σ_a can be ordered and let O be such an ordering.

Without loss of generality, we can assume that $|E_{uv}| =$

$k, \forall u, v \in V$ because, we can always take $max_{u,v \in V}|E_{uv}| = k$ and if $\exists u, v \in V$ such that $(u, a, v) \in E$ for some $a \in \Sigma_a$ and $|E_{uv}| < k$, then add dummy labels (chosen from the remaining labels in Σ_a) and zero weights to make $|E_{uv}| = k$. This corresponds to the general assumption in MDPs that $|A_s| = k, \forall s \in S$.

Let $< a_1, a_2, \ldots, a_k >$ ordered as per O be the k-tuple representing the label of each edge in E_{uv}. This being the same for all edges, we leave out labeling from the graph definition.

Now we define the vector-weighted digraph corresponding to $\mathcal{M}$, $VWG_{\mathcal{M}} =< V, E', \mathbf{W_P}, \mathbf{W_R} >$, as follows:

$$
\begin{aligned}
E' &= \{(u,v) \mid \exists a \in \Sigma_a \text{ and } (u,a,v) \in E\} \\
\mathbf{W_P} &: E' \to \mathbb{R}^k \text{ defined by} \\
&\quad \mathbf{W_P}(\mathbf{u},\mathbf{v}) =< W_P(u,a_1,v), \ldots, W_P(u,a_k,v) > \\
\mathbf{W_R} &: E' \to \mathbb{R}^k \text{ defined by} \\
&\quad \mathbf{W_R}(\mathbf{u},\mathbf{v}) =< W_R(u,a_1,v), \ldots, W_R(u,a_k,v) >
\end{aligned}
$$

where $a_1, a_2, \ldots, a_k$ are ordered as per O.

5.2.3. Sorted Vector-Weighted Digraph

We define the sorted vector-weighted digraph, $SVWG_{\mathcal{M}} =< V, E', \mathbf{W_{P_s}}, \mathbf{W_{R_s}} >$, as follows:

$$
\begin{gathered}
\mathbf{W_{P_s}} : E' \to \mathbb{R}^k \text{ defined by} \\
\mathbf{W_{P_s}}(\mathbf{u},\mathbf{v}) =< W_P(u, p_{uv}(1), v), \ldots, W_P(u, p_{uv}(k), v) > \\
\text{where, } p_{uv} : \mathbb{N}_k \to \Sigma_a \text{ such that} \\
W_P(u, p_{uv}(1), v) \leq \ldots \leq W_P(u, p_{uv}(k), v) \\
\mathbf{W_{R_s}} : E' \to \mathbb{R}^k \text{ defined by} \\
\mathbf{W_{R_s}}(\mathbf{u},\mathbf{v}) =< W_R(u, r_{uv}(1), v), \ldots, W_R(u, r_{uv}(k), v) > \\
\text{where, } r_{uv} : \mathbb{N}_k \to \Sigma_a \text{ such that} \\
W_R(u, r_{uv}(1), v) \leq \ldots \leq W_R(u, r_{uv}(k), v)
\end{gathered}
$$

Note that, p_{uv} and r_{uv} are not unique. So we choose them such that the order O is preserved.

5.2.4. *Set Bijections* that sort the vector-weights

Here we show that there exists a *set bijection* whose interpretation is the set of permutations that sort the vector-weights. Let $\mathbb{N}_k$ be the set of first k natural numbers. Let $D^P_{uv} \triangleq \{$ all permutations $l : \mathbb{N}_k \to \Sigma_a \mid l$ sorts $\mathbf{W_P}(\mathbf{u},\mathbf{v})\}$ be defined for each $(u,v) \in E'$. So, $\mathbf{W_{P_s}}(\mathbf{u},\mathbf{v}) =< W_P(u,l(1),v), \ldots, W_P(u,l(k),v) >$ and $W_P(u,l(1),v) \leq W_P(u,l(2),v) \leq \ldots \leq W_P(u,l(k),v)$. Clearly, $\mathbb{N}_k$ can be partitioned into $U^{uv}_{\mathbb{N}_k} = \{\mathbb{N}^1_k, \mathbb{N}^2_k, \ldots, \mathbb{N}^j_k\}$ such that, $\forall t \in \mathbb{N}^y_k$, $W_P(u,l(t),v)$ has the same value for each $y = 1, 2, \ldots, j$ and if $t \in \mathbb{N}^y_k$ and $t' \in \mathbb{N}^{y+1}_k$ then $W_P(u,l(t),v) < W_P(u,l(t'),v)$. This partition induces a corresponding partition $U^{uv}_{\Sigma_a} = \{\Sigma^1_a, \Sigma^2_a, \ldots, \Sigma^j_a\}$ where $\Sigma^i_a = \{l(t) \mid t \in \mathbb{N}^i_k\}$. Since, each l sorts $\mathbf{W_P}(\mathbf{u},\mathbf{v})$, they satisfy the property that $l(x \in \mathbb{N}^i_k) \in \Sigma^i_a$. Therefore, there exists a set bijection $Q^P_{uv} : U^{uv}_{\mathbb{N}_k} \to U^{uv}_{\Sigma_a}$ such that, $I(Q^P_{uv}) = D^P_{uv}$.

Using a similar procedure, we can show that there exists set bijection $Q^R_{uv} : U^{uv}_{\mathbb{N}_k} \to U^{uv}_{\Sigma_a}$ whose interpretation is the set of permutations that sort $\mathbf{W_R}(\mathbf{u},\mathbf{v})$.

Let $Q_{uv} = Q^P_{uv} \cap Q^R_{uv}$. If $Q_{uv} = \emptyset$, then there doesn't exist an automorphism for the MDP $\mathcal{M}$.

5.2.5. Weighted Digraph

Now we define the weighted digraph $WG_{\mathcal{M}} =< V, E', W' >$ as follows:

$$
\begin{aligned}
W' &: E' \to \mathbb{R} \text{ such that } W'(u,v) = m(\mathbf{W_{P_s}}(u,v). \\
&\quad \mathbf{W_{R_s}}(u,v)) \text{ where m is a bijection from } \mathbb{R}^{2k} \to \mathbb{R} \\
&\quad \text{and . denotes concatenation}
\end{aligned}
$$

Algorithm 1 Construction

1: Given $\mathcal{M} = \langle S, A, \Psi, P, R \rangle$
2: Let *SOLN* be an empty set
3: Construct the pseudograph $G_{\mathcal{M}} =< \Sigma_a, V, E, W_P, W_R >$ as defined in Section 5.2
4: Construct the vector-weighted digraph $VWG_{\mathcal{M}} =< V, E', \mathbf{W_P}, \mathbf{W_R} >$ as defined in Section 5.2.2
5: Construct the sorted vector-weighted digraph $SVWG_{\mathcal{M}} =< V, E', \mathbf{W_{P_s}}, \mathbf{W_{R_s}} >$ as defined in Section 5.2.3
6: **for** each $(u,v) \in E'$ **do**
7: Compute Q^P_{uv} and Q^R_{uv} by finding the partition of $\mathbb{N}_k$ as described in Section 5.2.4
8: $Q_{uv} \leftarrow Q^P_{uv} \cap Q^R_{uv}$
9: **if** $Q^P_{uv} \cap Q^R_{uv}$ does not exist **then**
10: **exit**
11: **end if**
12: **end for**
13: Construct the weighted digraph $WG_{\mathcal{M}} =< V, E', W' >$ using m as described in Section 5.2.5
14: $F \leftarrow DGEN(WG_{\mathcal{M}})$ where F is the set of generators of $AutWG_{\mathcal{M}}$
15: **for** each $f \in F$ **do**
16: **for** each $(u,v) \in E'$ **do**
17: $G_{uv} \leftarrow Q_{f(u)f(v)} \odot Q^{-1}_{uv}$
18: **end for**
19: Let $\hat{H^f}$ be an empty set
20: **for** each $u \in V$ **do**
21: $G_u \leftarrow G_{uv}$ from some $v \in V$
22: **for** each $v \in V$ **do**
23: $G_u \leftarrow G_u \cap G_{uv}$
24: **end for**
25: Add G_u to $\hat{H^f}$
26: **end for**
27: Add $< f, \hat{H^f} >$ to *SOLN*
28: **end for**

5.2.6. CONSTRUCTION

The procedure for finding symmetries of an MDP $\mathcal{M}$ is given in Algorithm 1.

The complexity of the algorithm is as follows. The construction steps in lines 3 to 5, are at most polynomial in $|E|$. Using a constant access time data structure like a hashtable, Q^P_{uv} and Q^R_{uv} can be constructed in $O(|E_{uv}|)$ time.The intersection takes $O(|E_{uv}|^2)$ time. Since this runs for $|E'|$ iterations, computation of Q_{uv} is at most polynomial in $|E|$. Since m is known, the construction of weighted digraph in line 13, is polynomial in $|E|$. With the use of procedures that return at most $|V|$ automorphisms of $AutWG_{\mathcal{M}}$ (Mathon, 1979), the construction of G_u for each f, from lines 15 to 26, runs for at most $|V|$ iterations.

The most expensive part of the loop from lines 20 to 26 is the computation of $|V|^2$ intersections. But this is still polynomial in $|V||E|$ time. Hence the algorithm takes polynomially more time than the solution time of *DGEN*. Also to extract a solution from *SOLN*, we need to extract $|V|$ SDAR functions from $\hat{H^f}$ for each f, which takes $|E_{uv}|$ time if we use a constant access time data structure. So extraction of a solution takes $O(|V|^2|E|)$ which is still polynomial in $|V||E|$. While one can intuitively see that the reduction is indeed polynomial time, the proof is presented in an associated technical report (Narayanamurthy & Ravindran, 2008), due to lack of space.

5.3. Significance

The above result is significant both theoretically and practically. Practically speaking, the reduction to Graph Isomorphism allows us to use any of the numerous off-the-shelf Graph Isomorphism solvers to find symmetries on MDPs. In fact, we use NAutY - No Automorphisms, Yes?, the best Graph Isomorphism solver currently available (Skiena, 1997) to find out symmetries in MDPs. NAutY solves *AGEN*(*G*). It uses backtracking and a refinement procedure to find the canonical labeling. If two different labelings lead to the same graph, then an automorphism can be found using these labelings (McKay, 1981). In the worst case it can take exponential time. So it allows the use of a variety of vertex invariants, which act like heuristics, to solve harder problems. However, for random graphs with n vertices and edge probability 0.5, average execution times for large n are about n^2 nanosecs.We use NAutY in the fourteenth line in the construction, where we need to solve *DGEN*(*G*). We first convert the weighted digraph into an unweighted digraph using standard procedure. We then use NAutY to find the generators of the automorphism group of the so found digraph. From these we extract generators of *AutWG* as per the above procedure. We present some results in Section 6.

6. Results

The experiments were run on the following two domains. We describe results per domain.

6.1. Probabilistic GridWorld

The domain is an $N \times N$ GridWorld with four probabilistic actions of going UP, DOWN, RIGHT and LEFT having a 90% success probability. The initial state was (0,0) and the goal states were $\{(0, N-1), (N-1, 0)\}$. We used Algorithm 1 to find the symmetries with NAutY being used as the *DGEN* solver. We then used the symmetries to find the partition of Ψ. We were able to find the partition corresponding to the symmetry group, that is, for a grid of size $M \times N$, states (x,y), (y,x), (M-1-x,N-1-y) and (N-1,M-1-x) are equivalent. We present the time taken by the algorithm for GridWorlds of different sizes.

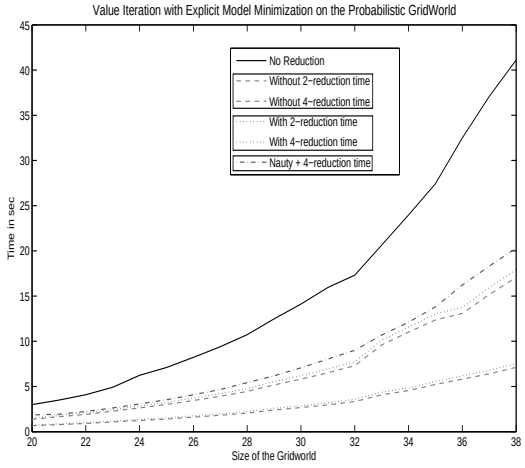

Figure 1. Average running times of the value iteration algorithm with explicit model minimization on Probabilistic GridWorld vs size of the GridWorld. Each of the 3 sets should be compared with the graph for no reduction. Curves in a set represent different degrees of symmetry. Each set shows the time reduction with reduced model usage. First one discounts the time taken to find symmetries and for reduction. The next set includes the time for reduction but discounts time taken to find symmetries. The last one includes both the time taken to find symmetries using NAutY and time for reduction.

To complete the end-to-end approach, we ran the $\mathcal{G}$-reduced image algorithm, presented in (Ravindran, 2004), to find the reduced image and ran the Value Iteration algorithm on the reduced image. To show the efficiency of reduction, we show the time taken for reduction and solution separately. We also present the case of a handcrafted 2-folded symmetry which is used with the $\mathcal{G}$-reduced image algorithm and reduced model is used with Value Iteration.

From Figure 1 it is evident that the reduced model con-

struction is efficient and adds little overhead. However, the results of the end-to-end approach show a significant overhead due to symmetry finding. It cuts the saving by almost half. Still the results are significant because they double the size of the largest GridWorld that can be solved in some given time.

6.2. GridWorld Soccer

The domain is a soccer-inspired grid domain. It is a slightly modified version of that described in (Bowling, 2003). We first describe the original version of the domain and then state the modification.

It is an $M \times N$ grid with two agents. One is denoted the attacker (**A**) who holds the ball and the other as the defender (**B**) who tries to snatch the ball from the attacker. The center lines/grids(depending on whether M and N are even or odd) for both x-axis and y-axis are chosen naturally. The state is defined by the non-identical positions of the attacker and the defender. This defines the state space with $(MN)^2 - (MN)$ states. The actions are movements in the four compass directions: **N**, **E**, **W**, **S** and the hold action **H**. It is a single player game, in that, only the attacker chooses actions deliberately while the defender executes random actions. The action chosen by the attacker and the random action of the defender are executed in random order, which determines the next state. However if the defender tries to move into the attacker's location then the state is unchanged and if the attacker tries to move into the defender's location, the game is reset to the initial state which is shown in Figure 2. The right hand section of the grid is the attacker's half and the left hand section that of the defender. The goal is chosen to be situated beyond the first column of grids occupying one grid on each side of the y-axis central line/grid. A **W** action from the squares in front of the goal state leads to a goal with a reward of 1 and to the end of an episode. Everywhere else the reward is 0. A 5×4 domain is shown in Figure 2.

Intuitively, the domain seems symmetric around the y-axis center line. However, the results of using Algorithm 1 on this domain showed us that the domain is not symmetric due to the existence of the reset action when the attacker tries to move into the defender's position. So we modified the domain to have symmetric reset, that is, reset happens to the initial state and its symmetric state around the y-axis center line with equal probability. This makes the domain symmetric as per intuition, which the algorithm confirms.

Interestingly, the algorithm also finds that the existence of the hold action adds further symmetry. The grids along the border of the domain act as walls. For example, the northern wall stops the **N** action leaving the state unchanged which is the same result if the agent were to execute a **H** action. These additional symmetries which we did not think

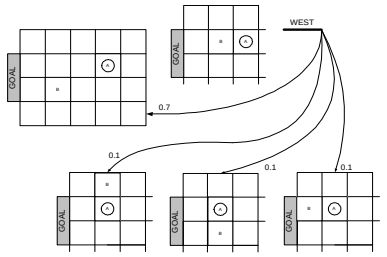

Figure 2. Single Player grid soccer where agent **B** selects it actions randomly. The initial state is shown on the left and an example of transitions and associated probabilities are given for a particular state and action on the right. Notice that fifty percent of the time **A**'s actions are executed first causing it to lose the ball and the game reset to the initial state. In addition, if **B** selects **H** or **E** it does not move and so **A** still loses the ball and returns to the initial state. The other outcomes are equiprobable.

of before running algorithm were found by the algorithm. This suggests that there might exist complicated symmetries that will be discovered by the algorithm, which are hard to find, even upon a close examination. Also in many cases, symmetries are size invariant. So we can use the algorithm on a relatively smaller version of the domain and find symmetries which might still hold on the larger version.

We present the time taken by the algorithm for different sizes. An increment of one here means an increase of one along both axes. The presence of two agents, blows up the state space very rapidly and we hit the limit on the order of the graph imposed by NAutY very soon (for a 11×10 grid).To present similar graphs as in the probabilistic GridWorld case, we use the explicit model minimization approach with Value Iteration. The results are presented in Figure 3.

In this case, we find that the overheads due to the construction and the $\mathcal{G}$-reduced image algorithm is negligible. Though efficiency of the $\mathcal{G}$-reduced image algorithm is expected, the efficiency of the construction can be possibly because of the structure of the domain yielding an easy graph to find automorphisms on.

7. Conclusion

In this work, we have provided a constructive proof for the *Isomorphism Completeness* of the problem of finding symmetries. We have also proposed the use of this constructive proof along with an efficient minimization algorithm to solve an MDP using symmetries and demonstrated it empirically. As part of future work, we are looking at adapting approximation algorithms for finding graph isomorphisms to finding approximate symmetries in MDPs.

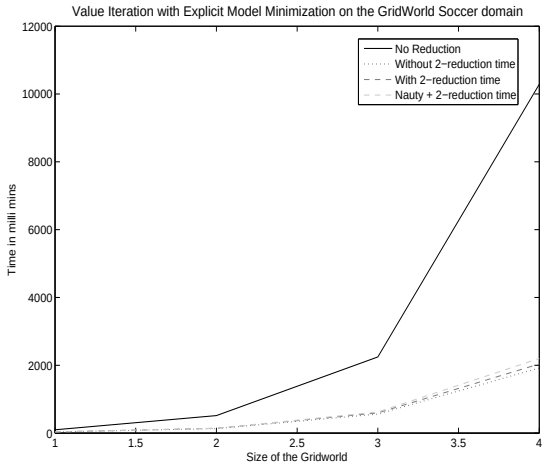

Figure 3. Average running times of the value iteration algorithm with explicit model minimization on GridWorld Soccer domain vs size of the domain. Size of one represents the 5×4 grid. Thereafter an increment of one means an increment of one along both axes. Each graph should be compared with the graph for no reduction. The other graphs show the time reduction with reduced model usage. First one discounts the time taken to find symmetries and for reduction. The next one includes the time for reduction but discounts time taken to find symmetries. The last one includes both the time taken to find symmetries using NAutY and time for reduction.

Bayes Optimal Classification for Decision Trees

Siegfried Nijssen SIEGFRIED.NIJSSEN@CS.KULEUVEN.BE
K.U. Leuven, Celestijnenlaan 200A, 3001 Leuven, Belgium

Abstract

We present an algorithm for exact Bayes optimal classification from a hypothesis space of decision trees satisfying leaf constraints. Our contribution is that we reduce this classification problem to the problem of finding a rule-based classifier with appropriate weights. We show that these rules and weights can be computed in linear time from the output of a modified frequent itemset mining algorithm, which means that we can compute the classifier in practice, despite the exponential worst-case complexity. In experiments we compare the Bayes optimal predictions with those of the maximum a posteriori hypothesis.

1. Introduction

We study the problem of Bayes optimal classification for density estimation trees. A density estimation tree in this context is a decision tree which has a probability density for a class attribute in each of its leaves. One can distinguish two Bayesian approaches to density estimation using a space of such trees.

In the first approach a single *maximum a posteriori* (MAP) density estimation tree is identified first:

$$T = \arg\max_T P(T|\mathbf{X}, \vec{y}),$$

where $\mathbf{X}$ and $\vec{y}$ together constitute the training data. The posterior probability $P(T|\mathbf{X}, \vec{y})$ of a hypothesis T is usually the product of a prior and a likelihood. The MAP hypothesis can then be used to classify a test example x' using the densities in the leaves.

The second approach is to marginalize over all possible trees, instead of preferring a single one:

$$\arg\max_c P(c|x', \mathbf{X}, \vec{y}) = \arg\max_c \sum_T P(c|x', T)P(T|\mathbf{X}, \vec{y}).$$

Predictions that are performed using this second approach are called *Bayes optimal predictions*. It has been claimed that "no single tree classifier using the same prior knowledge as an optimal Bayesian classifier can obtain better performance on average" (Mitchell, 1997). The Bayesian point of view is that Bayesian averaging cancels out the effects of overfitted models (Buntine, 1990), and "solves" overfitting problems.

This claim was challenged by Domingos (2000). Domingos demonstrated experimentally that an ensemble of decision trees that are weighted according to posterior probabilities performs worse than uniformly weighted hypotheses. It was found that one overfitting tree usually dominates an ensemble.

However, these results were obtained by sampling from the hypothesis space. Even though Domingos argued that similar issues should also occur in the truly optimal approach, this claim could not be checked in practice as the exact computation of Bayes optimal predictions was considered to be impractical. Indeed, in (Chipman et al., 1998) it was already claimed that "exhaustive evaluation ... over all trees will not be feasible, except in trivially small problems, because of the sheer number of trees". Similar claims were made in other papers studying Bayesian tree induction (Buntine, 1992; Chipman et al., 1998; Angelopoulos & Cussens, 2005; Oliver & Hand, 1995), and have led to the use of sampling techniques such as Markov Chain Monte Carlo sampling.

In this paper we present an algorithm that can be used to evaluate Domingos' claim in a reasonable number of non-trivial settings. Our algorithm allows us to exactly compute the Bayes optimal predictions given priors that assign non-zero probability to trees that satisfy certain constraints. An example of a constraint is that every leaf covers a significant number of examples; this constraint has been used very often in the literature (Buntine, 1992; Quinlan, 1993; Chipman et al., 1998; Angelopoulos & Cussens, 2005; Oliver & Hand, 1995).

Our algorithm is an extension of our earlier work, in

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

which we developed the DL8 algorithm for determining one tree that maximizes accuracy (Nijssen & Fromont, 2007). DL8 is based on dynamic programming on a pre-computed lattice of itemsets, and scans these itemsets decreasing in size. Its time complexity is linear in the size of the lattice. In this paper we extend this algorithm to a Bayesian setting. From a technical point of view, the main contribution is that we prove that a different pass over the lattice allows us to perform Bayes optimal predictions without increasing the asymptotic complexity of building the lattice.

The task that our algorithm addresses is similar to the task addressed in (Cleary & Trigg, 1998). Compared to this earlier work, we study the more common Dirichlet priors also considered in (Chipman et al., 1998; Angelopoulos & Cussens, 2005); furthermore, by exploiting the link to itemset mining, our algorithm is more efficient, and its results are more interpretable.

The paper is organized as follows. Notation and concepts are introduced in Section 2. Bayes optimal classification is formalized in Section 3. We show how to map this problem to the problem of finding itemsets and building a classifier with weighted rules in Section 4. Experiments are performed in Section 5.

2. Preliminaries

Before we are ready to formalize our problem and our proposed solution, we require some notation. We restrict ourselves to binary data; we assume that data is converted in this form in a preprocessing step. The data is stored in binary matrix $\mathbf{X}$, of which each row $\vec{x}_k$ corresponds to one example. Every example $\vec{x}_k$ has a class label y_k out of a total number of C class labels. Class labels are collected in a vector $\vec{y}$.

We assume that the reader is familiar with the concept of decision trees (see (Breiman et al., 1984; Quinlan, 1993) for details). Essential in our work is a link between decision trees and *itemsets*. Itemsets are a concept that was introduced in the data mining literature (Agrawal et al., 1996). If $\mathcal{I}$ is a domain of items, $I \subseteq \mathcal{I}$ is an itemset. In our case, we assume that we have *two* types of items: for every attribute there is a positive item i that represents a positive value, and a negative item $\neg i$ that represents a negative value. An example $\vec{x}$ can be represented as an itemset

$$\{i | x_i = 1\} \cup \{\neg i | x_i = 0\}.$$

Thus, for a data matrix with n columns, we have that $\mathcal{I} = \mathcal{I}_{pos} \cup \mathcal{I}_{neg}$, where $\mathcal{I}_{pos} = \{1, 2, \ldots n\}$ and $\mathcal{I}_{neg} = \{\neg 1, \neg 2, \ldots \neg n\}$. We overload the use of the $\subseteq$ operator: when I is an itemset, and $\vec{x}$ is an example, we use $I \subseteq \vec{x}$ to denote that I is a subset of $\vec{x}$ after translating $\vec{x}$ into an itemset.

Every sequence of test outcomes in a decision tree, starting from the root of the tree to an arbitrary node deeper down the tree, can be represented as an itemset. For instance, a decision tree with B in the root, and A in its right-hand branch can be represented by:

$$T = \{\emptyset, \{B\}, \{\neg B\}, \{\neg B, A\}, \{\neg B, \neg A\}\}.$$

Every itemset in T corresponds to one node in the tree. By $\mathcal{T}$ we denote all subsets of $2^{\mathcal{I}}$ that represent decision trees. A decision tree structure is an element $T \in \mathcal{T}$. Consequently, when T is a decision tree we can write $I \in T$ to determine if the itemset I corresponds to a path occurring in the tree.

An itemset is an unordered set: given an itemset in a tree, we cannot derive from this itemset in which order its tests appear in the tree. This order can only be determined by considering all itemsets in a tree T.

We are not always interested in all nodes of a tree. The subset of itemsets that correspond to the leaves of a tree T will be denoted by $leaves(T)$; in our example,

$$leaves(T) = \{\{B\}, \{\neg B, A\}, \{\neg B, \neg A\}\}.$$

The most common example of a decision tree is the *classification tree*, in which every leaf is labeled with a single class. In a *density estimation tree*, on the other hand, we attach a class *distribution* to each leaf, represented by a vector $\vec{\theta}_I$; for each class c this vector contains the probability θ_{Ic} that examples $\vec{x} \supseteq I$ belong to class c. All the parameters of the leaves of a tree are denoted by $\mathbf{\Theta}$. The vectors in $\mathbf{\Theta}$ are thus indexed by the itemsets representing leaves of the tree.

For the evaluation of a tree T on a binary matrix $\mathbf{X}$, it is useful to have a shorthand notation for the number of examples covered by a leaf:

$$f(I, \mathbf{X}) = |\{\vec{x}_k | \vec{x}_k \supseteq I\}|;$$

usually we omit the matrix $\mathbf{X}$ in our notation, as we assume the training data to be fixed. We call $f(I, \mathbf{X})$ the *frequency* of I. Class-based frequency is given by:

$$f_c(I, \mathbf{X}, \vec{y}) = |\{\vec{x}_k | \vec{x}_k \supseteq I, y_k = c\}|.$$

The *frequent itemset mining* problem is the problem of finding all $I \subseteq \mathcal{I}$ such that $f(I) \geq \gamma$, for a given threshold γ. Many algorithms for computing this set exist (Agrawal et al., 1996; Goethals & Zaki, 2003). They are based on the property that the frequency constraint is *anti-monotonic*. A binary constraint p on itemsets is called anti-monotonic iff $\forall I' \subseteq I : p(I) =$

$true \implies p(I') = true$. Consequently, these algorithms do not need to search through all supersets $I' \supseteq I$ of an itemset I that is found to be infrequent.

One application of itemsets is in the construction of rule-based classifiers (CMAR (Li et al., 2001) is an example). Many rule-based classifiers traverse rules sequentially when predicting examples. Here, we study a rule-based classifier that derives a prediction from all rules through voting. Such a classifier can be seen as a subset $\mathcal{P} \subseteq 2^{\mathcal{I}}$ of itemsets, each of which has a weight vector $\vec{w}(I)$. We predict an example $\vec{x}$ by computing

$$\arg\max_c \sum_{\{I \in \mathcal{P} | I \subseteq \vec{x}\}} w_c(I),$$

where we thus pick the class that gets most votes of all rules in the ruleset; each rule votes with a certain weight on each class. The aim of this paper is to show that we can derive a set of itemsets $\mathcal{P}$ and weights $\vec{w}(I)$ for all $I \in \mathcal{P}$ such that the predictions of the rule-based classifier equal those of a Bayes optimal classifier. The rules in $\mathcal{P}$ represent all paths that can occur in trees in the hypothesis space.

3. Problem Specification

In this section we formalize the problem of Bayes optimal classification for a hypotheses space of decision trees. Central in the Bayesian approach is that we first define the probability of the data given a tree structure T and parameters $\mathbf{\Theta}$:

$$P(\vec{y}|\mathbf{X}, T, \mathbf{\Theta}) = \prod_{I \in leaves(T)} \prod_{c=1}^{C} (\theta_{Ic})^{f_c(I)}$$

In Bayes optimal classification we are interested in finding for a particular example $\vec{x}'$ the class y' which maximizes the probability

$$\begin{aligned} y' &= \arg\max_c P(c|\vec{x}', \mathbf{X}, \vec{y}) \qquad (1) \\ &= \arg\max_c \sum_{T \in \mathcal{T}} \int_{\mathbf{\Theta}} P(c|\vec{x}', T, \mathbf{\Theta}) P(T, \mathbf{\Theta}|\mathbf{X}, \vec{y}) d\mathbf{\Theta}, \end{aligned}$$

where we sum over the space of all decision trees and integrate over all possible distributions in the leaves of each tree. Applying Bayes' rule on the second term, and observing that $\mathbf{\Theta}$ is dependent on the tree T, we can rewrite this into

$$\sum_{T \in \mathcal{T}} \int_{\mathbf{\Theta}} P(c|\vec{x}', T, \mathbf{\Theta}) P(\vec{y}|T, \mathbf{\Theta}, \mathbf{X}) P(\mathbf{\Theta}|T, \mathbf{X}) P(T|\mathbf{X}) d\mathbf{\Theta}; \qquad (2)$$

in this formula $P(T|\mathbf{X})$ is the probability of a tree given that we have seen all data except the class labels. Our method is based on the idea that we can constrain the space of decision trees by manipulating this term.

A first possibility is that we set $P(T|\mathbf{X}) = 0$ if there is a leaf $I \in leaves(T)$ such that $f(I) < \gamma$, for a frequency threshold γ. We call such leaves *small leaves*. The class estimates of a small leaf are often unreliable, and it is therefore common in many algorithms to consider only large leaves.

Additionally, we can set $P(T|\mathbf{X}) = 0$ if the depth of the decision tree exceeds a predefined threshold.

Both limitations impose *hard constraints* on the trees that are considered to be feasible estimators. We denote trees in $\mathcal{T}$ that satisfy all hard constraints by $\mathcal{L}$.

In the simplest case we can assume a uniform distribution on the trees that satisfy the hard constraints. Effectively, this would mean that we set $P(\mathbf{\Theta}|T, \mathbf{X}) = 1$ in Equation 2 for all $T \in \mathcal{L}$. However, we will study a more sophisticated prior in this paper to show the power of our method. The aim of this prior, which was proposed in (Chipman et al., 1998), is to give more weight to smaller trees; it can be seen as a *soft constraint*. This prior is defined as follows.

$$P(T|\mathbf{X}) = \prod_{I \in T} P_{node}(I, T, \mathbf{X})$$

Here, the term $P_{node}(I, T, \mathbf{X})$ is defined as follows.

$$P_{node}(I, T, \mathbf{X}) = \begin{cases} P_{leaf}(I, \mathbf{X}), & \text{if } I \text{ is a leaf in } T; \\ P_{intern}(I, \mathbf{X}), & \text{if } I \text{ is internal in } T; \end{cases}$$

where

$$P_{leaf}(I, \mathbf{X}) = \begin{cases} 0, & \text{if } f(I) < \gamma \text{ or } |I| > \delta; \\ 1, & \text{else if } |I| = \delta \text{ or } e(I) = 0; \\ 1 - \alpha(1 + |I|)^{-\beta}, & \text{otherwise;} \end{cases}$$

and

$$P_{intern}(I, \mathbf{X}) = \begin{cases} 0, & \text{if } f(I) < \gamma \text{ or } |I| \geq \delta \\ & \text{or } e(I) = 0; \\ \alpha(1 + |I|)^{-\beta}/e(I), & \text{otherwise;} \end{cases}$$

Here $e(I)$ is the size of the set $\{i \in \mathcal{I}_{pos} | f(I \cup i) \geq \gamma \wedge f(I \cup \neg i) \geq \gamma\}$, which consists of all possible tests that can still be performed to split the examples covered by itemset I.

The term $\alpha(1 + |I|)^{-\beta}$ makes it less likely that nodes at a higher depth are split. The term $e(I)$ determines how many tests are still available if a test is to be performed. We assume that tests are apriori equally likely, independent of the order in which the previous tests on the path have been performed. An alternative could be to give more likelihood to tests that are well-balanced.

Note that P_{leaf} and P_{intern} are computed for an itemset I almost independently from the tree T: we only need to know if I is a leaf or not.

As common in Bayesian approaches, we assume that the parameters in every leaf of the tree are Dirichlet distributed with the same parameter vector $\vec{\alpha}$, i.e.

$$P(\mathbf{\Theta}|T,\mathbf{X}) = P(\mathbf{\Theta}|T) = \prod_{I \in leaves(T)} Dir(\vec{\theta}_I|\vec{\alpha}),$$

where

$$Dir(\vec{\theta}_I|\vec{\alpha}) = \frac{\Gamma(\sum_c \alpha_c)}{\prod_c \Gamma(\alpha_c)} \prod_c {\theta_{Ic}}^{\alpha_c - 1},$$

and Γ is the gamma function.

Finally, it can be seen that

$$P(c|\vec{x}', T, \mathbf{\Theta}) = \theta_{I(T,\vec{x}')c},$$

where $I(T,\vec{x}')$ is the leaf of T for which $I \subseteq \vec{x}'$.

We now have formalized all terms of Equation 2.

4. Solution Strategy

An essential step in our solution strategy is the construction of the set

$$\mathcal{P} = \{I | T \in \mathcal{L}, I \in T\},$$

which consists of all itemsets in trees that satisfy the hard constraints. Only these paths are needed when we wish to compute the posterior distribution over class labels, and are used as rules in our rule-based classifier. The weights of these rules are obtained by rewriting the Bayesian optimization criterion for a test example $\vec{x}'$ (Equation 1) as

$$\arg\max_c \sum_{\{I \in \mathcal{P} | I \subseteq \vec{x}'\}} w_c(I)$$

where

$$w_c(I) = \sum_{T \in \mathcal{L},\ \text{has leaf } I} \left(\prod_{I \in T} P_{node}(I,T,\mathbf{X}) \right) \left(\int_{\mathbf{\Theta}} \theta_{Ic} \prod_{I' \in leaves(T)} Dir(\vec{\theta}'_I|\vec{\alpha}) \prod_c \theta_{I'_c}^{f_c(I')} d\mathbf{\Theta} \right). \quad (3)$$

The idea behind this rewrite is that the set of all trees in $\mathcal{L}$ can be partitioned by considering in which leaf a test example ends up. An example ends in exactly one leaf in every tree, and thus every tree belongs to one partition as determined by that leaf. We sum first over all possible leaves that can contain the example, and then over all trees having that leaf. The weights of the rules in our classifier consist of the terms $w_c(I)$, and will be computed from the training data in the training phase; the sum of the weights $w_c(I)$ is computed for a test example in the classification phase.

This rewrite shows that in the training phase we need to compute weights for all itemsets that are in $\mathcal{P}$. We will discuss now how to compute these.

In the formulation above we multiply over all leaves, including the leaf that we assumed the example ended up in. Taking this special leaf apart we obtain:

$$w_c(I) = W_c(I) \sum_{T \in \mathcal{L},\ \text{has leaf } I} \prod_{I' \in T, I' \neq I} V(I',T); \quad (4)$$

where

$$W_c(I) = P_{leaf}(I,\mathbf{X}) \int_{\vec{\theta}_I} \theta_{Ic} Dir(\vec{\theta}_I|\vec{\alpha}) \prod_c \theta_{Ic}^{f_c(I)} d\vec{\theta}_I$$

and

$$V(I,T) = \begin{cases} P_{intern}(I,\mathbf{X}) & \text{if } I \text{ is internal in } T; \\ P_{leaf}(I,\mathbf{X}) \int_{\vec{\theta}_I} Dir(\vec{\theta}_I|\vec{\alpha}) \prod_c \theta_{Ic}^{f_c(I)} d\vec{\theta}_I, & \text{otherwise.} \end{cases}$$

This rewrite is correct due to the fact that we can move the integral of Equation 3 within the product over the leaves: the parameters of the leaves are independent from each other.

Let us write the integrals in closed form. First consider $W_c(I)$. As the Dirichlet distribution is the conjugate prior of the binomial distribution, we have

$$W_c(I) = P_{leaf}(I,\mathbf{X}) \frac{\Gamma(\sum_c \alpha_c)}{\prod_c \Gamma(\alpha_c)} \int_{\vec{\theta}_I} \theta_{Ic} \prod_c \theta_{Ic}^{\alpha_c - 1 + f_c(I)} d\vec{\theta}_I = P_{leaf}(I,\mathbf{X}) \frac{\Gamma(\sum_c \alpha_c)}{\prod_c \Gamma(\alpha_c)} \frac{\prod_c \Gamma(\alpha_c + f'_c(I))}{\Gamma(\sum_c \alpha_c + f'_c(I))}$$

Here $f'_{c'}(I) = f_{c'}(I)$ if $c \neq c'$, else $f'_{c'}(I) = f_{c'}(I) + 1$.

Similarly, we can compute $V(I,T)$ as follows.

$$V(I,T) = \begin{cases} V_{intern}(I) = P_{intern}(I,\mathbf{X}), \\ \qquad \text{if } I \text{ is internal in } T; \\ V_{leaf}(I) = \\ \quad P_{leaf}(I,\mathbf{X}) \frac{\Gamma(\sum_c \alpha_c) \prod_c \Gamma(\alpha_c + f_c(I))}{\prod_c \Gamma(\alpha_c) \Gamma(\sum_c \alpha_c + f_c(I))}, \\ \qquad \text{otherwise.} \end{cases}$$

The remaining question is now how to avoid summing all trees of Equation 4 explicitly. In the following, we will derive a dynamic programming algorithm to

implicitly compute this sum. We use a variable that is defined as follows.

$$u(I) = \sum_{T \in \mathcal{L}(I)} \prod_{I' \in T} V(I', T); \tag{5}$$

Here we define $\mathcal{L}(I)$ as follows:

$$\mathcal{L}(I) = \{\{I' \in T | I' \supseteq I\} | \text{ all } T \in \mathcal{L} \text{ for which } I \in T\};$$

thus, $\mathcal{L}(I)$ consists of all subtrees that can be put below an itemset I while satisfying the hard constraints. As usual, we represent a subtree by listing all its paths.

For this variable we will first prove the following.

Theorem 1. *The following recursive relation holds for $u(I)$:*

$$u(I) = V_{leaf}(I) + \sum_{i \in \mathcal{I}_{pos} \text{ s.t. } I \cup i, I \cup \neg i \in \mathcal{P}} V_{intern}(I) u(I \cup i) u(I \cup \neg i).$$

Proof. We prove this by induction. Assume that for all itemsets $|I| > k$ our definition holds. Let us fill in our definition in the recursive formula, then we get:

$$u(I) = V_{leaf}(I) + \sum_{i \in \mathcal{I}_{pos}, \text{ s.t. } I \cup i, I \cup \neg i \in \mathcal{P}} \sum_{T \in \mathcal{L}(I \cup i)} \sum_{T' \in \mathcal{L}(I \cup \neg i)} V_{intern}(I) \prod_{I' \in T} V(I', T) \prod_{I' \in T'} V(I', T');$$

This can be written as Equation 5 to prove our claim: the term for V_{leaf} corresponds to the possibility that I is a leaf, the first sum passes over all possible tests if the node is internal, the second and third sum traverse all possible left-hand and right-hand subtrees; the product within the three sums is over all nodes in each resulting tree. □

We can use this formula to write $w_c(I)$ as follows.

Theorem 2. *The formula $w_c(I)$ can be written as:*

$$w_c(I) = W_c(I) \sum_{\pi \in \Pi(I)} \prod_{i=1}^{|I|} V_{intern}(\{\pi_1, \ldots, \pi_{i-1}\}) u(\{\pi_1, \ldots, \pi_{i-1}, \neg \pi_i\}).$$

Here, $\Pi(I)$ contains all permutations $(\pi_1, \ldots, \pi_n)$ of the items in I for which it holds that $\forall 1 \leq i \leq n : \{\pi_1, \ldots, \pi_i\}, \{\pi_1, \ldots, \pi_{i-1}, \neg \pi_i\} \in \mathcal{P}$.

Proof. The set of permutations $\Pi(I)$ consists of all (ordered) paths that can be constructed from the items in I and that fulfill the constraints on size and frequency. Each tree $T \in \mathcal{L}$ with $I \in T$ must have exactly one of these paths. Given one such path, Equation 4 requires us to sum over all trees that contain this path. Each tree in this sum consists of a particular choice of subtrees for each sidebranch of the path. Every node in a tree $T \in \mathcal{L}$ with $I \in T$ is either (1) part of the path to node I or (2) part of a sidebranch; this means that we can decompose the product $\prod_{I' \in T, I' \neq I} V(I', T)$, which is part of Equation 4, into a product for nodes in sidebranches, and a product for nodes on the path to I. The term for nodes on the path is computed by

$$W_c(I) \prod_{i=1}^{|I|} V_{intern}(\{\pi_1, \ldots, \pi_{i-1}\});$$

considering the side branches, $u(I)$ sums over all possible subtrees below sidebranches of the path $\{\pi_1, \ldots, \pi_n\}$; using the product-of-sums rule that $\prod_{i=1}^{n} \sum_{j=1}^{m_i} \alpha_{ij} = \sum_{i_1=1}^{m_1} \cdots \sum_{i_n=1}^{m_n} x_{1\alpha_1} \cdots \alpha_{ni_n}$, where $\sum_{j=1}^{m_i} \alpha_{ij}$ corresponds to a u-value of a sidebranch, we can deduce that the product $\prod_{i=1}^{|I_k|} u(\{\pi_1, \ldots, \pi_{i-1}, \neg \pi_i\})$ sums over all possible combinations of side branches. □

Given their potentially exponential number it is undesirable to enumerate all permutations of item orders for every itemset. To avoid this let us define

$$v(I) = \sum_{\pi \in \Pi(I)} \prod_{k=1}^{|I|} V_{intern}(\{\pi_1, \ldots, \pi_{k-1}\}) u(\{\pi_1, \ldots, \pi_{k-1}, \neg \pi_k\}),$$

such that $w_c(I) = W_c(I) v(I)$.

Theorem 3. *The following recursive relation holds.*

$$v(I) = \begin{cases} 1, & \text{if } I = \emptyset, \\ \sum_{i \in I \text{ s.t. } I - i \cup \neg i \in \mathcal{P}} V_{intern}(I - i) \\ \quad u(I - i \cup \neg i) v(I - i), & \text{otherwise.} \end{cases}$$

Proof. This can be shown by induction: if we fill in our definition of $v(I)$ in the recursive formula we get

$$\sum_{i \in I \text{ s.t. } I - i \cup \neg i \in \mathcal{P}} V_{intern}(I - i) u(I - i \cup \neg i) \sum_{\pi \in \Pi(I - i)} \prod_{k=1}^{|I|-1} V_{intern}(\{\pi_1, \ldots, \pi_{k-1}\}) u(\{\pi_1, \ldots, \neg \pi_k\})$$

Both sums together sum exactly over all possible permutations of the items; the product is exactly over all terms of every permutation. □

A summary of our algorithm is given in Algorithm 1. The main idea is to apply the recursive formulas for $u(I)$ and $v(I)$ to perform dynamic programming in two phases: one bottom-up phase to compute the $u(I)$ values, and one top-down phase to compute the $v(I)$ values. Given appropriate data structures to perform the look-up of sub- and supersets of itemsets I, this procedure has complexity $\mathcal{O}(|\mathcal{P}|\delta C)$. As $|\mathcal{P}| = \mathcal{O}(n2^m)$, where n is the number of examples in the training data and m the number of attributes, this algorithm is exponential in the number of attributes.

After the run of this algorithm, for a test example we can compute $q_c(\vec{x}') = \sum_{I \subseteq \vec{x}'} w_c(I)$ for every c. We can easily compute the exact class probability estimates from this: $P(y' = c|\vec{x}', \mathbf{X}, \vec{y}) = \frac{q_c(\vec{x}')}{\sum_{c'} q_{c'}(\vec{x}')}$.

To compute the set $\mathcal{P}$ of paths in feasible trees, we can modify a frequent itemset miner (Goethals & Zaki, 2003), as indicated in our earlier work (Nijssen & Fromont, 2007). We replace the itemset lattice post-processing method of (Nijssen & Fromont, 2007) by the algorithm for computing Bayes optimal weights.

Compared to the OB1 algorithm of Cleary & Trigg (1998), the main advantage of our method is its clear link to frequent itemset mining. OB1 is based on the use of option trees, which have a worst case complexity of $O(nm!)$ instead of $O(n2^m)$. Cleary et al. suggest that sharing subtrees in option trees could improve performance; this exactly what our approach achieves in a fundamental way. The link between weighted rule-based and Bayes optimal classification was also not made by Cleary et al., making the classification phase either more time or space complex. We can interpret predictions by our approach by listing the (maximal) itemsets that contribute most weight to a prediction.

5. Experiments

We do not perform a feasibility study here, as we did such a study in earlier work (Nijssen & Fromont, 2007).

We performed several experiments to determine the importance of the α and β parameters of the size prior. We found that the differences between values $\alpha, \beta \in \{0.5, 0.6, 0.7, 0.8, 0.9, 0.95\}$ were often not significant and choose $\alpha = 0.80$ and $\beta = 0.80$ as defaults. We also experimented with a uniform prior. We choose $\vec{\alpha} = (1.0, \ldots, 1.0)$ as default for the Dirichlet prior. This setting is common in the literature.

All comparisons were tested using a corrected, two-tailed, paired $t-$test with a 95% confidence interval.

Artificial Data In our first set of experiments we use generated data. We use this data to confirm the influence of priors and the ability of the Bayes optimal classifier to recognize that data can best be represented by an ensemble of multiple trees.

A common approach is to generate data from a model and to compute how well a learning algorithm recovers this original model. In our setting this approach is however far from trivial, as it is hard to generate a realistic lattice of itemsets: Calders (2007) showed that it is NP-hard to decide if a set of itemset frequencies can occur at all in data. Hence we used an alternative approach. The main idea is that we wish to generate data such that different trees perform best on different parts of the data. We proceed as follows: we first generate n tree structures (in our experiments, all trees are complete trees of depth 7; the trees do not yet have class labels in their leaves); from these n trees we randomly generate a database of given size (4000 examples with 15 binary attributes in our experiments, without class labels). We make sure that every leaf in every tree has at least γ examples (3% of the training data in our experiments). Next, we iterate in a fixed order over these trees to assign classes to the examples in one leaf of each tree; in each tree we pick the leaf which has the largest number of examples without class, and assign a class to these examples, taking care that two adjacent leaves get different majority classes. We aim for pure leaves, but these are less likely for higher numbers of generating trees.

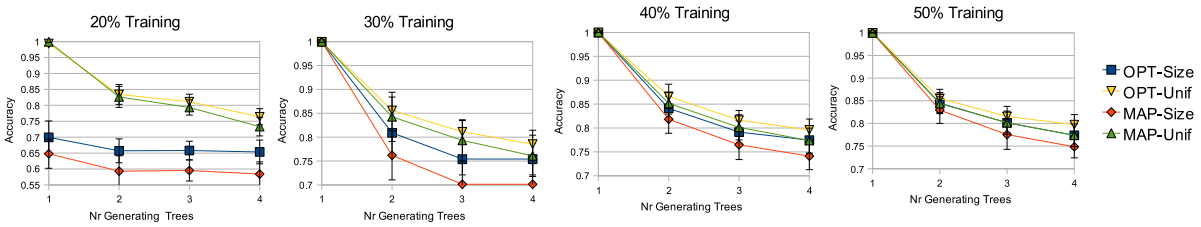

Figure 1. Results on artificial data.

The results of our experiments are reported in Figure 1. The accuracies in these experiments are computed for 20 randomly generated datasets. Each figure represents a different fraction of examples used as training data; remaining examples were as test data. The learners were run using the same depth and support constraints as used to generate the data.

We can learn the following from these experiments.

As all our datasets were created from trees with maximal height, the prior which prefers small trees performs worse than the one which assigns equal weight to all trees. If the amount of training data is small, the size prior forces the learner to prefer trees which are not 100% accurate for data created from one tree.

In all cases, the Bayes optimal approach is significantly more accurate than the corresponding MAP approach, except if the data was created using a single tree; in this case we observe that a single (correct) tree is dominating the trees in the ensembles.

The more training data we provide, the smaller the differences between the approaches are. For the correct prior the optimal approach has a better learning curve.

Additional experiments (not reported here) for other tree depths, dataset sizes and less pure leaves confirm the results above, although sometimes less pronounced.

UCI Data In our next set of experiments we determine the performance of our algorithm on common benchmark data, using ten-fold cross validation.

The frequency and depth constraints in our prior influence the efficiency of the search; too low frequency or too high depth constraints can make the search infeasible. Default values for δ that we considered were 4, 6 and ∞; for γ we considered 2, 15 and 50. We relaxed the constraints as much as was computationally possible; experiments (not reported here) show that this usually does not worsen accuracy.

As our algorithm requires binary data, numeric attributes were discretized in equifrequency bins. Only a relatively small number of 4 bins was feasible in all experiments; we used this value in all datasets to avoid drawing conclusions after parameter overfitting. Where feasible within the range of parameters used, we added results for other numbers of bins to investigate the influence of discretization.

The experiments reported in Figure 1 help to provide more insight in the following questions:

(Q1) Is a single tree dominating a Bayes optimal classifier in practice?

(Q2) Are there significant differences between a uniform and a size-based prior in practice?

(Q3) Is the optimal approach overfitting more in practice than the traditional approach, in this case Weka's implementation of C4.5?

(Q4) What is the influence of the 4-bin discretization?

To get an indication about (Q1) we compare the optimal and MAP predictions. We underlined those cases where there is a significant difference between optimal and MAP predictions. We found that in many cases there is indeed no significant difference between these two settings; in particular when hard constraints impose a high bias, such as in the Segment and Vote data, most predictions turn out to be equal. If there is a significant difference, the optimal approach is always the most accurate.

To answer (Q2) we highlighted in bold for each dataset the system that performs significantly better than all other systems. In many cases, the differences between the most accurate settings are not significant; however, our results indicate that a uniform prior performs slightly better than a size prior in the Bayes optimal case; the situation is less clear in the MAP setting.

Answering (Q3), we found not many significant differences between J48's and Bayes optimal predictions in those cases where we did not have to enforce very hard constraints to turn the search feasible. This supports the claim of Domingos (2000) that Bayes optimal predictions are not really much better. However, our results also indicate that there is no higher risk of overfitting either. The optimal learner does not perform as well as J48 in those cases where the search is only feasible for high frequency or low depth constraints, and

thus quite unrealistic priors; in (Nijssen & Fromont, 2007) we found that under the same hard constraints J48 is not able to find accurate trees either, and often finds even worse trees in terms of accuracy.

To provide more insight in (Q4), we have added results for different discretizations. In the datasets where we used harder constraints to make the search feasible, a negative effect on accuracy is observed compared to J48. Where the same hard constraints can be used we observe similar accuracies as in J48. The experiments do not indicate that a higher number of bins leads to increased risks of overfitting.

6. Conclusions

Our results indicate that instead of constructing the optimal MAP hypothesis, it is always preferable to use the Bayes optimal setting; even though we found many cases in which the claim of Domingos (2000) is confirmed and a single tree performs equally well, in those cases where there is a significant difference, the comparison is always in favor of the optimal setting. The computation of both kinds of hypothesis remains challenging if no hard constraints are applied, while incorrect constraints can have a negative impact.

Abstract

A recent trend in exemplar based unsupervised learning is to formulate the learning problem as a convex optimization problem. Convexity is achieved by restricting the set of possible prototypes to training exemplars. In particular, this has been done for clustering, vector quantization and mixture model density estimation. In this paper we propose a novel algorithm that is theoretically and practically superior to these convex formulations. This is possible by posing the unsupervised learning problem as a single convex "master problem" with non-convex subproblems. We show that for the above learning tasks the subproblems are extremely well-behaved and can be solved efficiently.

1. Introduction

Methods for unsupervised learning aim at recovering underlying structure from data. In this paper, we are concerned with *exemplar based models* in which this structure is represented by a weighted set of points in input space. Depending on the used model, these points can be interpreted as *clusters*, *codebook vectors* or *mixture components*.

Although the representation is done by a finite point set, the structure being represented – such as a density – is defined on the entire input space by expanding a *smoothing kernel function* around each representing point. In this setting learning simply becomes deciding on the number of points and their weights, as well as their location in input space by means of a suitable *objective*. In EM-learning of mixture models and in k-means clustering one fixes the number of points and adjusts their position by performing descent steps on the objective function starting from a random initialization. This leads to well-behaved but usually non-convex learning problems. Recently, a number of *convex* approaches have been proposed. Our goal in this paper is to improve on these approaches.

In section 2 we review convex formulations for unsupervised learning tasks and discuss two recent methods. We show how convexity is achieved and derive a small experiment whose result suggests a way to improve on the established models. We describe our model in section 3 together with an algorithm and a theoretical justification. The model is validated experimentally in section 4 and we conclude in section 5.

2. Review of Convex Approaches

We now discuss two convex approaches to unsupervised learning from the literature. We will denote the training set as $X = \{\boldsymbol{x}_i\}_{i=1,\ldots,N}$, with $\boldsymbol{x}_i \in \mathcal{X}$ and usually $\mathcal{X} = \mathbb{R}^d$.

Kernel Vector Quantization (Tipping & Schölkopf, 2001) learns a small set of codebook vectors such that the minimum distance from any training sample to its nearest codebook vector is bounded above by a given *maximum distortion* h. In (Tipping & Schölkopf, 2001), this is done by formulating a linear programming problem, of which the following problem is an equivalent reformulation.[1]

$$\begin{aligned} \max_{\boldsymbol{q},\rho} \quad & \rho \\ \text{sb.t.} \quad & K\boldsymbol{q} \geq \rho\mathbf{1}, \\ & \|\boldsymbol{q}\|_1 = 1, \\ & \boldsymbol{q} \geq \mathbf{0}. \end{aligned} \tag{1}$$

Here K is a (N, N) matrix with $K_{i,j} = I(\|\boldsymbol{x}_i - \boldsymbol{x}_j\| \leq h)$, where $I(\cdot)$ evaluates to one if the predicate is true and to zero otherwise, therefore, $K_{i,j}$ is one if a ball of radius h centered on $\boldsymbol{x}_j$ contains $\boldsymbol{x}_i$. In the solution of (1) the balls selected by $q_j > 0$ form a sparse covering of the training set and the distance of each sample to its closest covering ball is bounded by h.

Convex Clustering (Lashkari & Golland, 2007) was re-

[1] Subject to rescaling of $\boldsymbol{q}$.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

cently proposed for clustering. In Lashkari and Golland's model, a mixture model is fit to an observed training set, such that a candidate mixture component is centered around each training set exemplar. Using the framework of Bregman clustering (Banerjee et al., 2005), their objective maximizes the log-likelihood subject to the constraint that the resulting model is a proper mixture model. In the optimum solution of the model, a sparse set of exemplars is selected, allowing the interpretation as clusters.

Formally, Lashkari and Golland maximize $\frac{1}{N}\sum_{i=1}^{N}\log\left[\sum_{j=1}^{N} q_j e^{-\beta d_\phi(\boldsymbol{x}_i,\boldsymbol{x}_j)}\right]$ over the mixture parameters $q_j \geq 0,\ j = 1,\ldots,N$ with $\sum_{j=1}^{N} q_j = 1$. The model allows all exponential family distributions with a corresponding Bregman divergence d_ϕ (Banerjee et al., 2005). For the maximization, a multiplicative update is used, which leads to slow convergence once elements of $\boldsymbol{q}$ approach zero. We reformulate the above objective function by introducing a new set of variables γ_i, with $i = 1,\ldots,N$ as follows.

$$\max_{\boldsymbol{q},\boldsymbol{\gamma}} \quad \frac{1}{N}\sum_{i=1}^{N}\log\gamma_i \tag{2}$$

$$\text{sb.t.} \quad K\boldsymbol{q} = \boldsymbol{\gamma}, \tag{3}$$
$$\|q_j\|_1 = 1,$$
$$q_j \geq 0, \qquad j = 1,\ldots,N,$$

where K is a (N,N) matrix and $K_{i,j} = e^{-\beta d_\phi(\boldsymbol{x}_i,\boldsymbol{x}_j)}$. Clearly, problem (2) is equivalent to the previous one because constraints (3) only serve to evaluate the likelihood γ_i for each sample $\boldsymbol{x}_i$.

2.1. Where does Convexity come from?

Models as proposed in (Tipping & Schölkopf, 2001) and (Lashkari & Golland, 2007) achieve convexity by changing the problem parametrization. Instead of learning the coordinates of a fixed number of exemplars $\boldsymbol{z}_j,\ j = 1,\ldots,M$, there is now a larger set of possible candidate exemplars with fixed coordinates. Learning is performed by optimizing over indicator variables, selecting a sparse subset of the candidates.

This reparametrization makes the problem convex but also changes the regularization: whereas usually the number of exemplars M is the main regularization parameter, it is now an implicit guarantee on the quality of the solution. In (Tipping & Schölkopf, 2001) this is the maximum distortion h, whereas in (Lashkari & Golland, 2007) the regularization parameter β controls the smoothness of the density.

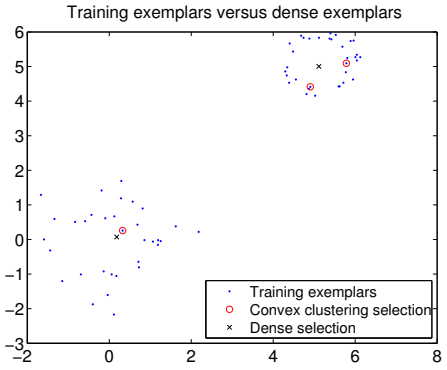

Figure 1. Exemplar selection within the training set versus the finest dense set of 900 exemplars on a regular grid. In this toy example, there are 66 data points.

2.2. Motivating Experiment: More Exemplars

Restricting the set of possible prototype candidates to the training set might result in a suboptimal solution if there is no exemplar close to the true mean of a cluster. If the data is low-dimensional, normal-distributed within each cluster, has low noise and there are enough training examples, this effect is small and can be ignored. But in high dimensions the true mean might be far away from any exemplar.

To demonstrate the effect of restricting the prototype candidate set we perform an experiment. A simple two-dimensional data set is created by sampling from an isotropic Gaussian and a ring of uniform density, forming two well-separated clusters, see Figure 1. We compare convex clustering (Lashkari & Golland, 2007) with a modified model where the objective is changed to $\frac{1}{N}\sum_{i=1}^{N}\log\left[\sum_{j=1}^{M} q_j e^{-\beta d_\phi(\boldsymbol{x}_i,\boldsymbol{z}_j)}\right]$, with N training samples $\boldsymbol{x}_i$ and M cluster center candidates $\boldsymbol{z}_j$. This convex objective still represents the log-likelihood of the training samples under a mixture model. We generate $\boldsymbol{z}_j$ by densely discretizing the $[-2;7]^2$ box on a regular grid. Our hope is that a fine discretization will increase the chance that $\{\boldsymbol{z}_j\}_{j=1,\ldots,M}$ contains exemplars close to the true center of each cluster. For both models we use an isotropic multivariate normal distribution with covariance matrix $\Sigma = \sigma^2 I$, $\sigma = 2.5$.

The clustering result is shown in Figure 1. For the cluster around the origin there is indeed a training set exemplar close to the mean of the generating Gaussian and the difference between the convex clustering and dense selection is small. However, for the ring-like structure, the training set exemplars cannot represent the cluster center adequately. This causes convex clustering to select two exemplars, while in the dense set a single good candidate is selected. A slight perturba-

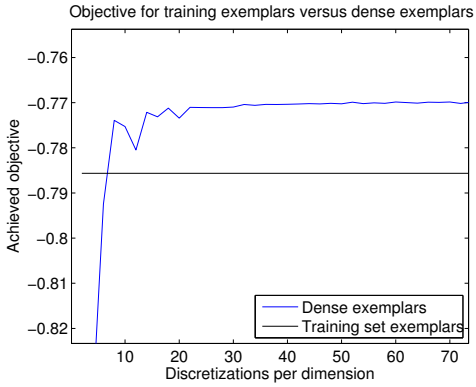

Figure 2. Training set vs. dense set log-likelihood.

tion in the training data would lead to a different selection by the convex clustering method, as all samples bordering to the interior of the ring are roughly equally bad. For this data set, the solution produced by convex clustering is not only qualitatively disappointing but also unstable. The achieved objectives are shown in Figure 2, where the convex clustering objective is drawn as horizontal line and the dense exemplar model forms a curve as the discretization becomes finer and finer. At around eight discretizations per dimension our modified model surpasses the log-likelihood of the convex clustering model. At around 30 discretizations per dimension the log-likelihood levels out and adding more cluster candidates does not improve the solution.

This experiment suggests that a larger set of candidate clusters can lead to higher quality results which are also more robust. While dense discretization is only feasible in case the input space is low-dimensional, ideally we would like to use an infinitely fine discretization and thus use the set of *all* possible input points as candidates. This idea will be the basis for our method.

3. A Decoupled Model

We now introduce our model for unsupervised learning together with an efficient solution algorithm. Essential to the solution is the ability to solve a certain subproblem which we analyze in detail.

3.1. Model

Our model for unsupervised learning generalizes convex clustering (Lashkari & Golland, 2007) and kernel vector quantization (Tipping & Schölkopf, 2001). Let $k_{\boldsymbol{z}}(\cdot)$ be a non-negative smoothing kernel centered at $\boldsymbol{z} \in \mathcal{Z}$, with $\mathcal{Z} \subseteq \mathcal{X}$. Let $\{\boldsymbol{x}_i\}_{i=1,\dots,N}$, $\boldsymbol{x}_i \in \mathcal{X}$ denote the training set. The following semi-infinite convex programming problem learns a convex combination of response functions such that an objective is minimized.

$$\min_{\boldsymbol{q},\gamma,\rho} \quad \Omega(\boldsymbol{\gamma}, \rho) \tag{4}$$

$$\text{sb.t.} \quad \int_{\mathcal{Z}} q_{\boldsymbol{z}} k_{\boldsymbol{z}}(\boldsymbol{x}_i)\, d\boldsymbol{z} = \gamma_i : \alpha_i,\ i = 1, \dots, N \tag{5}$$

$$\rho \le \gamma_i : \omega_i, \quad i = 1, \dots, N, \tag{6}$$

$$q_{\boldsymbol{z}} \ge 0 : \mu_{\boldsymbol{z}}, \quad \forall \boldsymbol{z} \in \mathcal{Z}, \tag{7}$$

$$\int_{\mathcal{Z}} q_{\boldsymbol{z}}\, d\boldsymbol{z} = 1 : \sigma, \tag{8}$$

where $\boldsymbol{\alpha}$, $\boldsymbol{\omega}$, $\boldsymbol{\mu}$ and σ are the Lagrange multipliers for the respective constraints. Before discussing the choice of objective function Ω, let us discuss the purpose of the constraints.

- Constraint (5) evaluates a convex combination of responses for each sample. γ_i contains the combined response for sample $\boldsymbol{x}_i$.
- Constraint (6) identifies – if $\nabla_\rho \Omega(\boldsymbol{\gamma}, \rho) < 0$ – the lowest response among all samples. The value of the lowest combined response is ρ.
- Constraints (7) and (8) define the combination simplex of the response functions.

For the special case where $\mathcal{Z}$ is a finite set of points in $\mathcal{X}$, we can replace the integrals and infinite constraints with a finite sum and finite set of constraints, respectively. Constraints (5) can then be compactly written as $K\boldsymbol{q} = \boldsymbol{\gamma}$, where K is a $(N, |\mathcal{Z}|)$ matrix storing the kernel responses. The dual problem of (4) can be derived from the conjugate function $\Omega^*(\boldsymbol{\alpha}, \sigma, \boldsymbol{\omega}, \boldsymbol{\mu})$ and its respective domain (Boyd & Vandenberghe, 2004, result (5.11)). The dual problem is

$$\max_{\boldsymbol{\alpha},\sigma,\boldsymbol{\omega},\boldsymbol{\mu}} \quad -\Omega^*(\boldsymbol{\alpha}, \sigma, \boldsymbol{\omega}, \boldsymbol{\mu}) - \sigma \tag{9}$$

$$\text{sb.t.} \quad (\boldsymbol{\alpha}, \sigma, \boldsymbol{\omega}, \boldsymbol{\mu}) \in \mathbf{dom}(\Omega^*),$$

$$\sum_{i=1}^{N} \alpha_i k_{\boldsymbol{z}}(\boldsymbol{x}_i) \ge \mu_{\boldsymbol{z}} - \sigma, \quad \forall \boldsymbol{z} \in \mathcal{Z}$$

$$\boldsymbol{\omega} \ge \mathbf{0} \tag{10}$$

$$\mu_{\boldsymbol{z}} \ge \mathbf{0}, \quad \forall \boldsymbol{z} \in \mathcal{Z}$$

We propose the following choices of convex objective functions $\Omega(\boldsymbol{\gamma}, \rho)$.

1. $\Omega(\boldsymbol{\gamma}, \rho) = -\rho$

   The objective states that the lowest response among all samples is to be maximized. All other samples have equal or higher responses but are ignored by this objective, hence a single exemplar can have a large influence on the overall objective. The KVQ problem (1) corresponds to this

objective with K chosen as discussed in section 2. The conjugate is $\Omega^*(\boldsymbol{\alpha}, \sigma, \boldsymbol{\omega}, \boldsymbol{\mu}) = 0$ and domain $\mathbf{dom}(\Omega^*) = \{(\boldsymbol{\alpha}, \sigma, \boldsymbol{\omega}, \boldsymbol{\mu}) : \boldsymbol{\omega} + \boldsymbol{\alpha} \leq \mathbf{0}, \boldsymbol{\omega}^\top \mathbf{1} = 1\}$. With (10) we have $\boldsymbol{\alpha} \leq \mathbf{0}$.

2. $\Omega(\boldsymbol{\gamma}, \rho) = -\frac{1}{N} \sum_{i=1}^N \log(\gamma_i)$

   This objective maximizes $\prod_{i=1}^N \gamma_i$. For the special case where the columns of K correspond to evaluations of probability density functions at the training samples this objective maximizes the log-likelihood of the samples under a mixture model, resulting in convex clustering (2). A single exemplar can have a significant effect on the overall objective, but all sample responses are considered, contrasting the previous objective function. The conjugate is $\Omega^*(\boldsymbol{\alpha}, \sigma, \boldsymbol{\omega}, \boldsymbol{\mu}) = -\frac{1}{N} \sum_{i=1}^N \log(-\alpha_i) + \log(N)$ with domain $\mathbf{dom}(\Omega^*) = \{(\boldsymbol{\alpha}, \sigma, \boldsymbol{\omega}, \boldsymbol{\mu}) : \boldsymbol{\alpha} < \mathbf{0}, \boldsymbol{\omega} = \mathbf{0}\}$.

3. $\Omega(\boldsymbol{\gamma}, \rho) = -\rho + \frac{C}{N} \sum_{i=1}^N (\gamma_i - \rho)^2$

   The objective maximizes the margin ρ while penalizing large deviations from the margin, where the penalty strength is determined by $C \geq 0$. The objective may prefer a smaller margin if the corresponding choice of $\boldsymbol{q}$ leads to a more uniform γ_i. This *margin-minus-variance* (MMV) objective was first proposed in (Rückert & Kramer, 2006) for supervised learning.

4. $\Omega(\boldsymbol{\gamma}, \rho) = -\frac{1}{N} \sum_{i=1}^N \gamma_i + \frac{C}{N} \sum_{i=1}^N (\gamma_i - \frac{1}{N} \sum_{i=1}^N \gamma_i)^2$

   The objective maximizes the mean response while penalizing large deviations from it, where the penalty strength is determined by $C \geq 0$. This maximizes the *mean-minus-variance* popular in applications such as portfolio optimization, see for example (Cornuejols & Tütüncü, 2007).

In order to be able to compare our method with established methods from the literature we only use the first two objectives in the experiments.

3.1.1. Relation to existing methods.

Most relevant for our approach is Boosting Density Estimation (Rosset & Segal, 2002). We note the following differences, i) our model includes different objectives, ii) in our solution algorithm, we will use totally-corrective weight updates[2] instead of a simple line-search procedure, and iii) we identify each *weak learner* uniquely with a point in input space. Also related is the hard-margin case of 1-class Boosting (Rätsch et al., 2001). With exemplar-based weak learners it is a special case of our model with the first objective.

[2]Totally-corrective steps update all weights individually in each iteration, leading to faster convergence.

Algorithm 1 Infinite Exemplar Column Generation

$(Z, \boldsymbol{q}) = \textsc{Infex}(X, \epsilon, k, Z_0)$
Input:
  Sample set $X = \{\boldsymbol{x}_i\}_{i=1,\dots,N}$, $\boldsymbol{x}_i \in \mathcal{X}$
  Convergence tolerance $\epsilon > 0$
  Non-negative smoothing kernel $k_{\boldsymbol{z}} : \mathcal{Z} \times \mathcal{X} \to \mathbb{R}_+$
  Initial exemplar set $Z_0 = \{\boldsymbol{z}_j\}_{j=1,\dots,|Z_0|}$, $\boldsymbol{z}_j \in \mathcal{Z}$
Output:
  Column exemplar set $Z = \{\boldsymbol{z}_j\}_{j=1,\dots,R}$, $\boldsymbol{z}_j \in \mathcal{Z}$
  Weightings $q_{\boldsymbol{z}_j} \in \mathbb{R}_+$, $j = 1, \dots, R$
Algorithm:
$\boldsymbol{\alpha} \leftarrow -\frac{1}{N}\mathbf{1}$, $Z \leftarrow Z_0$, $R \leftarrow |Z_0| + 1$, $\delta \leftarrow \infty$, $\sigma^* \leftarrow 0$
loop
  $\boldsymbol{z}_R \leftarrow \operatorname{argmax}_{\boldsymbol{z} \in \mathcal{Z}} - \sum_{i=1}^N \alpha_i k_{\boldsymbol{z}}(\boldsymbol{x}_i)$ {(SP)}
  $\delta \leftarrow \sigma^* - \sum_{i=1}^N \alpha_i k_{\boldsymbol{z}_R}(\boldsymbol{x}_i)$ {Compute $\nabla_{\boldsymbol{z}_R}$}
  if $\delta < \epsilon$ **then**
    break {convergence to tolerance}
  end if
  $Z \leftarrow Z \cup \{\boldsymbol{z}_R\}$
  $K \leftarrow \left[k_{\boldsymbol{z}_j}(\boldsymbol{x}_i)\right]_{i=1,\dots,N,\ j=1,\dots,R}$ {response matrix}
  p_R^*, $(\boldsymbol{q}_R^*, \boldsymbol{\gamma}^*, \rho^*)$, $(\boldsymbol{\alpha}^*, \boldsymbol{\omega}^*, \boldsymbol{\mu}_R^*, \sigma^*) \leftarrow$
    objective value, primal- and dual-solution to problem (4) with finite (N, R) matrix K.
  $R \leftarrow R + 1$
end loop

3.2. Algorithm

To solve problem (4), we propose Algorithm 1 (INFEX), a delayed column generation algorithm. The algorithm works with a finite and usually small set of candidate prototypes $\boldsymbol{z}_j$. This set is iteratively enlarged by adding good candidates. Selecting the candidates to add in each iteration becomes a subproblem, which we define now.

Problem 1 (Subproblem (SP)) *Given a set of samples $\boldsymbol{x}_i \in \mathcal{X}$, $i = 1, \dots, N$, a corresponding non-positive sample weighting $\alpha_i \leq 0$, $i = 1, \dots, N$ and a non-negative smoothing kernel $k_{\boldsymbol{z}}(\boldsymbol{x}) : \mathcal{Z} \times \mathcal{X} \to \mathbb{R}_+$, obtain $\boldsymbol{z}^*$ as the solution of*

$$\boldsymbol{z}^* = argmax_{\boldsymbol{z} \in \mathcal{Z}} - \sum_{i=1}^N \alpha_i k_{\boldsymbol{z}}(\boldsymbol{x}_i).$$

The solution to this subproblem provides a candidate $\boldsymbol{z}^*$ that, when added to the set of considered candidates, will reduce the global objective.[3] We will now rigorously derive the subproblem from global optimality conditions of problem (4).

[3]In the optimization literature such columns are referred to as having *negative reduced cost*. The overall decoupled solution approach is closely related to the generalized Benders decomposition (Geoffrion, 1972).

Theorem 1 *Assume that the subproblem (SP) can be solved exactly in each iteration. Then Algorithm 1 solves problem (4) globally to the desired accuracy ϵ.*

Proof. Consider a slightly modified version of problem (4), where a part of the constraints (7) is replaced by equality constraints. We replace (7) by the following constraint set, parametrized by a finite set of points $Z_R = \{\boldsymbol{z}_1, \ldots, \boldsymbol{z}_{|Z_R|}\}$.

$$q_{\boldsymbol{z}} \geq 0 : \mu_{\boldsymbol{z}}, \qquad \forall \boldsymbol{z} \in Z_R, \tag{11}$$
$$q_{\boldsymbol{z}} = v_{\boldsymbol{z}} : \mu_{\boldsymbol{z}}, \qquad \forall \boldsymbol{z} \in \mathcal{Z} \setminus Z_R, \tag{12}$$

where $v_{\boldsymbol{z}} = 0$ is constant for all $\boldsymbol{z} \in \mathcal{Z} \setminus Z_R$. Together, constraints (11) and (12) restrict problem (4) such that only a finite subset of the variables $\boldsymbol{q}$ are used.

For a given finite Z_R, we can obtain an optimal primal $(\boldsymbol{q}^*, \boldsymbol{\gamma}^*, \rho^*)$, and dual $(\boldsymbol{\alpha}^*, \boldsymbol{\omega}^*, \boldsymbol{\mu}^*, \sigma^*)$ solution to the modified problem by solving a finite problem in the restricted set of variables $\{q_{\boldsymbol{z}} : \boldsymbol{z} \in Z_R\}$. Let the optimal function value of this solution be denoted by $p(\boldsymbol{v})$. Because the optimal solution must be feasible, we have $q^*_{\boldsymbol{z}} = v_{\boldsymbol{z}} = 0$ for all $\boldsymbol{z} \in \mathcal{Z} \setminus Z_R$. How would the objective function value $p(\boldsymbol{v})$ change if we force a $q^*_{\boldsymbol{z}}$ to become non-zero? That is, if we increase $v_{\boldsymbol{z}}$ by a very small amount can we improve the solution? The sensitivity theorem (Bertsekas, 1999, Proposition 3.3.3) provides a definite answer, namely we have for all $\boldsymbol{z} \in \mathcal{Z} \setminus Z_R$ the following.

$$\nabla_{v_{\boldsymbol{z}}} p(\boldsymbol{v}) = -\mu^*_{\boldsymbol{z}}.$$

If we have for all $\boldsymbol{z} \in \mathcal{Z} \setminus Z_R$ that $\nabla_{v_{\boldsymbol{z}}} p(\boldsymbol{v}) \geq 0$, then this implies that we can not decrease $p(\boldsymbol{v})$ by making $q_{\boldsymbol{z}} > 0$. Conversely, this observation provides us with a *global optimality condition*: if and only if Z_R contains all relevant (positive $q_{\boldsymbol{z}}$) exemplars, we have $\forall \boldsymbol{z} \in \mathcal{Z} \setminus Z_R : \mu^*_z \leq 0$. Given Z_R and a primal-dual optimal solution we can find an alternative expression for $\mu^*_{\boldsymbol{z}}$. Consider the Lagrangian of the modified problem.

$$\begin{aligned}\mathcal{L}(\boldsymbol{q}, \boldsymbol{\gamma}, \rho, \boldsymbol{\alpha}, \boldsymbol{\omega}, \boldsymbol{\mu}, \sigma) &= \Omega(\boldsymbol{\gamma}, \rho) \\ &+ \sum_{i=1}^{N} \alpha_i \left(\int_{\mathcal{Z}} q_{\boldsymbol{z}} k_{\boldsymbol{z}}(\boldsymbol{x}_i)\, d\boldsymbol{z} - \gamma_i \right) + \boldsymbol{\omega}^\top (\rho \mathbf{1} - \boldsymbol{\gamma}) \\ &- \sum_{\boldsymbol{z} \in Z_R} \mu_{\boldsymbol{z}} q_{\boldsymbol{z}} + \int_{\mathcal{Z} \setminus Z_R} \mu_{\boldsymbol{z}} q_{\boldsymbol{z}}\, d\boldsymbol{z} \\ &+ \sigma\Big(\sum_{\boldsymbol{z} \in Z_R} q_{\boldsymbol{z}} + \int_{\mathcal{Z} \setminus Z_R} q_{\boldsymbol{z}}\, d\boldsymbol{z} - 1 \Big)\end{aligned}$$

Because of optimality of the solution, it must satisfy the Karush-Kuhn-Tucker necessary conditions (Bertsekas, 1999), therefore we must have a zero gradient with respect to the primal variables. Specifically, for all $\boldsymbol{z} \in \mathcal{Z} \setminus Z_R$ we must have $\nabla_{q_{\boldsymbol{z}}} \mathcal{L}(\boldsymbol{q}^*, \boldsymbol{\gamma}^*, \rho^*, \boldsymbol{\alpha}^*, \boldsymbol{\omega}^*, \boldsymbol{\mu}^*, \sigma^*) = \sum_{i=1}^{N} \alpha^*_i k_{\boldsymbol{z}}(\boldsymbol{x}_i) + \mu^*_{\boldsymbol{z}} + \sigma^* = 0$. This allows us to express $\mu^*_{\boldsymbol{z}}$ as

$$\mu^*_{\boldsymbol{z}} = \sigma^* - \sum_{i=1}^{N} \alpha^*_i k_{\boldsymbol{z}}(\boldsymbol{x}_i). \tag{13}$$

Therefore, if for all $\boldsymbol{z} \in \mathcal{Z} \setminus Z_R$ we have dual feasible $\mu^*_z \leq 0$, then the current solution is optimal, despite the restrictions imposed by constraints (12). If we satisfy the optimality condition, then replacing (12) with constraints (11), does not change the solution, which remains optimal in the original problem (4).

What remains to be shown is that Algorithm 1 makes progress in each iteration and thus in the limit will satisfy the optimality condition. Consider the case where the above optimality condition is violated for one or more $\boldsymbol{z} \in \mathcal{Z} \setminus Z_R$. Then, let $\boldsymbol{z}^* = \operatorname{argmax}_{\boldsymbol{z} \in \mathcal{Z} \setminus Z_R} \left(\sigma^* - \sum_{i=1}^{N} \alpha^*_i k_{\boldsymbol{z}}(\boldsymbol{x}_i) \right)$ be the sample corresponding to the most negative partial derivative $\nabla_{v_{\boldsymbol{z}^*}} p(v) < 0$. Because of the sensitivity theorem, adding $\boldsymbol{z}^*$ to Z_R – making $q_{\boldsymbol{z}^*}$ a free variable – and re-solving (4) will reduce the objective value. Therefore, *either* no $\boldsymbol{z}^*$ with $\nabla_{v_{\boldsymbol{z}^*}} p(v) < -\epsilon$ is found and convergence to the tolerance is established, *or* a strict decrease in the objective is obtained. □

Note that in practice, we can add multiple exemplars in each iteration. Suppose during solving the subproblem (SP) we obtain a number of good local maximizers. Then, we can add all these local maximizers in order to obtain a faster convergence. Adding redundant exemplars with $\nabla_{v_{\boldsymbol{z}}} p(v) > 0$ does not have an effect as they will receive a zero weight $q_{\boldsymbol{z}} = 0$.

3.3. On the Nature of the Subproblem

The subproblem (SP) is completely determined by the negative weighting of the training set and the shape of the smoothing kernel function. For further discussion let us define $\eta_i = -\alpha_i$ and rewrite the subproblem as $\operatorname{argmax}_{\boldsymbol{z} \in \mathcal{Z}} \sum_{i=1}^{N} \eta_i k(\boldsymbol{x}_i, \boldsymbol{z})$. From the definition it follows that all η_i are non-negative. Clearly, this problem is non-concave whenever k is non-concave in $\boldsymbol{z}$ which is true for all smoothing functions we consider.

However, for kernel functions of the form $k_{\boldsymbol{z}}(\boldsymbol{x}) = k(\|\boldsymbol{x} - \boldsymbol{z}\|)$, the optima of the subproblem, thus the new candidates, are located at the *modes* of the expansion $\sum_{i=1}^{N} \eta_i k_{\boldsymbol{z}}(\boldsymbol{x}_i)$. It is this fact that can be exploited to efficiently solve the subproblem by standard hill-climbing algorithms. Such algorithms start at a point $\boldsymbol{z}^{(0)}$ in input space and generate iteratively better candidates such that $\sum_{i=1}^{N} \eta_i k_{\boldsymbol{z}^{(t+1)}}(\boldsymbol{x}_i) > \sum_{i=1}^{N} \eta_i k_{\boldsymbol{z}^{(t)}}(\boldsymbol{x}_i)$. In this paper, we use the *weighted*

mean shift procedure which was introduced by (Fukunaga & Hostetler, 1975; Cheng, 1995) and gained popularity due to (Comaniciu & Meer, 2002). Given an initial starting point $\boldsymbol{z}^{(0)}$ the iterates are produced by

$$\boldsymbol{z}^{(t+1)} = \frac{\sum_{i=1}^{N} \alpha_i g\left(\left\|\frac{\boldsymbol{z}^{(t)}-\boldsymbol{x}_i}{h}\right\|^2\right)\boldsymbol{x}_i}{\sum_{i=1}^{N} \alpha_i g\left(\left\|\frac{\boldsymbol{z}^{(t)}-\boldsymbol{x}_i}{h}\right\|^2\right)}, \qquad (14)$$

where $g : \mathbb{R}_+ \to \mathbb{R}_+$ is the negative derivative of the so called *kernel profile*. If for a continuous kernel the function g is convex and non-increasing, then the mean shift procedure is guaranteed to converge to a local maxima (Comaniciu & Meer, 2002). For each of the common continuous smoothing kernels, a unique function g exists and some popular kernels and their profile derivatives are discussed in section 4. For the Gaussian kernel, g is a scaled version of the original kernel profile and thus particularly easy to maximize.[4] Mean shift is popular in computer vision, where specialized procedures have been developed to efficiently find globally good modes, for example the *annealed mean shift* procedure (Shen et al., 2007).

If the smoothing kernel function is a reproducing Hilbert kernel (Schölkopf & Smola, 2002), then problem (SP) is known as the *pre-image problem* (Schölkopf et al., 1999). An important difference which simplifies our subproblem considerably is that all our weights $\boldsymbol{\alpha}$ are of the same sign. In the general pre-image problem the sign is not fixed and procedures such as the one of (Schölkopf et al., 1999) can be unstable and do not have a convergence guarantee.

3.4. Optimality Bound

The proof of global optimality of the solution obtained by Algorithm 1 was based on the assumption that the subproblem (SP) can be solved globally. We now show that even without this assumption, the method can be no worse than methods using a fixed exemplar set.

Theorem 2 *Given $\Omega(\boldsymbol{\gamma}, \rho)$, a set $X = \{\boldsymbol{x}_i\}_{i=1,\dots,N}$, $\boldsymbol{x}_i \in \mathcal{X}$ and a finite set of exemplars $Z_F = \{\boldsymbol{z}_j\}_{j=1,\dots,M}$, the solution obtained by solving problem (4) with $\mathcal{Z} = Z_F$ can not achieve a better objective than the solution obtained by Algorithm 1 with $\mathcal{Z} = \mathcal{X}$, $Z_0 = Z_F$.*

[4]The Gaussian kernel has received special attention in the literature. In (Carreira-Perpiñán, 2000) it was conjectured that the number of modes in a Gaussian mixture is bounded above by the number of components. While this is true in the univariate case, this has been proven wrong in general in (Carreira-Perpiñán & Williams, 2003). See also the counter-example at `http://www.inference.phy.cam.ac.uk/mackay/gaussians/`.

Proof. Let Algorithm 1 be called with $Z_0 = Z_F$. In the first iteration of Algorithm 1, the solved problem is identical to problem (4) with $\mathcal{Z} = Z_F$. Therefore, after the first iteration, the objective of Algorithm 1 is equal to the one obtained by solving problem (4). In all later iterations, the objective can only improve. □

4. Experiments and Results

For the following experiments, we solve the restricted master problem (4) using IpOpt (Wächter & Biegler, 2006), a modern primal-dual interior point solver for non-linear programming available as open-source. For each master problem, we obtain accurate convergence in a few dozen solver iterations. We use tolerances 10^{-10} for the restricted master problem and 10^{-7} for the subproblems for all experiments.[5]

As smoothing kernels we use the unnormalized Gaussian, the unnormalized Epanechnikov, and a simple uniform disc kernel. All are parametrized by a bandwidth parameter h. The following are the kernel functions k and profiles g used in the mean shift procedure.

1. Gaussian, bandwidth h
$$k_{\boldsymbol{z}}(\boldsymbol{x}) = e^{-\frac{1}{2}\left\|\frac{\boldsymbol{x}-\boldsymbol{z}}{h}\right\|^2}, \quad g(y) = \frac{1}{2}e^{-\frac{1}{2}y}$$
2. Epanechnikov, bandwidth h
$$k_{\boldsymbol{z}}(\boldsymbol{x}) = \begin{cases} 1 - \left\|\frac{\boldsymbol{x}-\boldsymbol{z}}{h}\right\|^2 & \left\|\frac{\boldsymbol{x}-\boldsymbol{z}}{h}\right\| \le 1 \\ 0 & \text{otherwise} \end{cases}$$
$$g(y) = \begin{cases} 1 & 0 \le y \le 1 \\ 0 & y > 1 \end{cases}$$
3. Uniform disc, maximum distortion h
$$k_{\boldsymbol{z}}(\boldsymbol{x}) = \begin{cases} 1 & \left\|\frac{\boldsymbol{x}-\boldsymbol{z}}{h}\right\| \le 1 \\ 0 & \text{otherwise} \end{cases}$$

The first two kernels are common in non-parametric density estimation, whereas the last one is used by (Tipping & Schölkopf, 2001) for vector quantization. We use the mean shift procedure (14) started from all training samples to solve the subproblem (SP) for the Gaussian and Epanechnikov kernels. We collect the result of each run and add the set of unique local maximizers to the restricted master problem.

However, mean shift cannot be used to solve subproblem (SP) for the non-continuous uniform disc kernel. Instead, when using the uniform disc kernel, we find new codebook candidates by solving the subproblem with the Epanechnikov kernel instead. This is a reasonable approximation as the Epanechnikov kernel response lower bounds the uniform disc kernel response and its maximum lies in the center of the disc.

[5]Our implementation is available at `http://www.kyb.mpg.de/bs/people/nowozin/infex/`.

4.1. Comparison with KVQ

In the first experiment we compare the original Kernel Vector Quantization formulation (1) with all training exemplars as possible prototypes with our Algorithm 1, where the initial set is empty, $Z_R = \emptyset$. We use the first objective $\Omega(\boldsymbol{\gamma}, \rho) = -\rho$ and the uniform disc kernel. As dataset we use a subset of 1100 exemplars from the USPS digit machine learning dataset, with all labels removed and each class sampled equally such that there are 110 exemplars from each class. We evaluate by selecting the maximum allowed distortion h from $\{800, 1000, 1200, 1400, 1600, 1800, 2000\}$, where $\approx$ 2000 is the mean inter-class L_2-distance in the dataset. We compare the achieved margin $\rho^*_{\text{KVQ}}(h)$ with $\rho^*_{\text{INFEX}}(h)$, and the number of codebook vectors $\|\boldsymbol{q}^*_{\text{KVQ}}\|_0$ with $\|\boldsymbol{q}^*_{\text{INFEX}}\|_0$. Figures 3 and 4 show these as the maximum allowed distortion is varied.

The proposed method outperforms KVQ, selecting a smaller number of codebook vectors and achieving a better objective value. Especially for larger allowed distortions, the benefit of selecting an arbitrary point in input space is substantial as due to the high dimensionality of the data set all input samples are relatively far away from each other. Because we use $Z_R = \emptyset$ to initialize our method, the results show that our subproblem approximation using the Epanechnikov kernel is an effective way to find good codebook candidates.

4.2. Comparison with Gaussian Mixture EM

In the second experiment we consider mixture model density estimation and compare our method with Convex Clustering and a homoscedastic Gaussian mixture ($\Sigma = \sigma^2 I$) learned with Expectation Maximization (EM).[6] The log-likelihood objective and the same USPS dataset as before is used. The experimental protocol is as follows. For a range of bandwidths our model and convex clustering are run once per bandwidth. For each run, the number of components of our model is used to fix the number of components in the Gaussian mixture model, which is trained by EM starting 20 times from random initial sample points.

The results are shown in Table 1. Clearly, a single run of our model is consistently the best. The best EM run is always close to our result and Convex Clustering is always the worst. (Lashkari & Golland, 2007) mention that their solution "can be improved in practice with a few extra steps of the EM algorithm". From Table 1, we conclude that the results of convex clustering are qualitatively inferior to plain EM and such *refitting* is actually essential for obtaining good results.

[6] A similar experiment is in (Lashkari & Golland, 2007).

4.3. Subproblem Modes

In the last experiment we show the qualitative behavior of our model with the Epanechnikov kernel with $h = 1500$ and the log-likelihood objective. Because the Epanechnikov kernel has finite support, if we start with $Z_0 = \emptyset$ we could have some samples $\boldsymbol{x}_i$ which have zero response because $k_{\boldsymbol{z}_j}(\boldsymbol{x}_i) = 0$ for all j. Then, the restricted variables $\boldsymbol{q}_j$ are too few and problem (4) would be infeasible. Thus, in order to ensure feasibility of the initial master problems, we use $Z_0 = X$. Some subproblem modes are shown in Figure 5. The modes approximate the "natural" clusters well except for classes such as 3, 8 and 9, which seem to be explained by one joint region with many local modes in it, for example in the first and second row.

5. Discussion and Conclusion

We presented a unifying perspective on existing exemplar based methods that aim at density estimation, clustering and vector quantization. Existing methods were either non-convex or achieved convexity by severe restrictions. In contrast, our approach – although still non-convex as a whole – is provable better than all existing methods. This is achieved by isolating a non-convex but still efficient solvable subproblem. The non-convex subproblem is embedded into a convex master problem steering towards an optimal solution.

One limitation of our model is that one cannot fix $\|\boldsymbol{q}^*\|_0$, the number of components. For problems where guarantees such as maximum distortion or smoothness are more natural constraints, this is not an issue.

There are open questions that result from our work:

1. Does there exists a response function k that is useful for unsupervised learning and at the same time yields a globally solvable subproblem?
2. What is the relation between objective Ω, kernel k and number of components $\|\boldsymbol{q}^*\|_0$?

Table 1. Achieved log-likelihoods. CC is Convex Clustering; for EM the best and mean of 20 runs are shown.

Abstract

For two-class classification, it is common to classify by setting a threshold on class probability estimates, where the threshold is determined by ROC curve analysis. An analog for multi-class classification is learning a new class partitioning of the multiclass probability simplex to minimize empirical misclassification costs. We analyze the interplay between systematic errors in the class probability estimates and cost matrices for multi-class classification. We explore the effect on the class partitioning of five different transformations of the cost matrix. Experiments on benchmark datasets with naive Bayes and quadratic discriminant analysis show the effectiveness of learning a new partition matrix compared to previously proposed methods.

1. Introduction

Many classifiers first estimate class probabilities $\hat{p}_k(x)$ for each class $k \in \{1, \ldots, K\}$, then classify a test sample x as the class $\hat{y}(x)$ that minimizes the expected misclassification costs:

$$\hat{y}(x) = \arg \min_{i=1,\ldots,K} \sum_{j=1}^{K} c_{i|j} \hat{p}_j(x) \doteq g(\hat{p}(x); c), \qquad (1)$$

where $c_{i|j}$ is the i^{th} row, j^{th} column element of the cost matrix c, and the cost of classifying as class i when the true class is j. We define the function g to use as short-hand for this minimization.

Such probability-based classifiers can be interpreted as mapping each test sample to a point on the $\hat{p}$-simplex, where each corner of the simplex has $\hat{p}_j = 1$ for some j, and $\hat{p}_i = 0$ for all $i \neq j$; and that the cost matrix c induces a partitioning of the $\hat{p}$-simplex into regions assigned to each of the K classes. However, the probability estimation can suffer from systematic errors, e.g. oversmoothing the estimate towards class prior probabilities. The main contribution of this paper is an analytic and experimental investigation of how changing the partitioning of the $\hat{p}$-simplex can reduce the effect of such systematic errors on classification loss, analogous to ROC analysis for two-class classification.

First, we discuss systematic probability estimation errors and show how these errors can cause classification errors. Then in Section 3 we review methods to reduce the effect of such errors. In Section 4 we establish properties that describe how changing c affects the class-partitioning of the $\hat{p}$-simplex. In Section 5, we propose learning a partitioning of the $\hat{p}$-simplex that seeks to minimize the empirical misclassification costs for the given c, and we provide experimental evidence of the effectiveness of our approach in Section 6.

2. Systematic Error in Multi-class Probability Estimation

Friedman uses the term *oversmoothing* for cases where the probability estimates are systematically smoothed towards the class prior probabilities, and *undersmoothing* for cases where the class probability estimates produced are too confident, such as 1-NN (Friedman, 1997). Other systematic errors in the probability estimates can occur; Niculescu-Mizil and Caruana have documented the systematic errors introduced by various methods of probability estimation for two-class classification (Niculescu-Mizil & Caruana, 2005). Here we provide illustrative examples of over- and under-smoothing in multiclass tasks.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

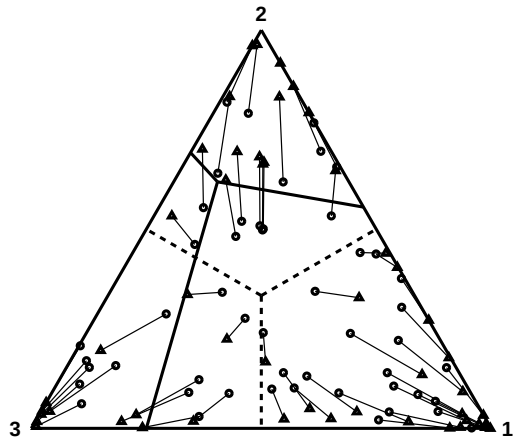
2.1. A Naive Bayes' Example

Consider a three-class problem with discrete features. We estimate class probabilities for test samples using naive Bayes (Hastie et al., 2001). The three classes are equally likely, and the feature vector consists of two identical copies of the same feature. Thus the naive Bayes' assumption of independent features is clearly violated. Figure 1(a) shows pairings of a true class probability (marked with an attached circle) and the associated naive Bayes' estimated probability (marked with a triangle). The incorrect feature-independence assumption *undersmooths* the probability estimates, pushing them towards the edges of the simplex.

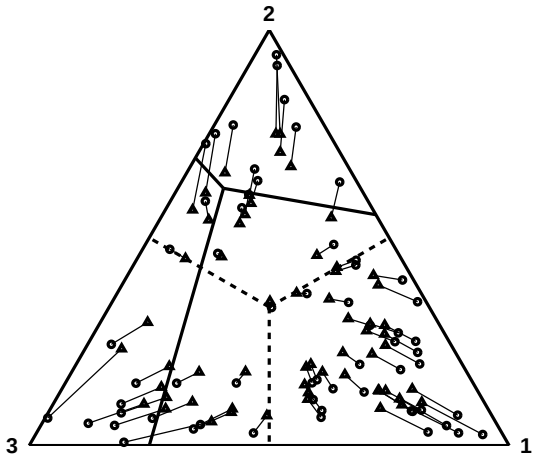
When an estimated probability and the corresponding true probability fall in the same class partition, the undersmoothing does not cause any classification error. When the line attaching a triangle to a circle crosses a class partition line, a classification error occurs. One sees that undersmoothing does not cause errors given the 0/1 cost matrix (dashed lines), but causes many errors given an asymmetric cost matrix (solid lines).

2.2. A k-NN Example

Let N be the number of training samples. Then for the k-NN classifier as the number of nearest neighbors $k \rightarrow N$, the probability estimates are smoothed towards the class prior probabilities. Figure 1(b) illustrates an extreme example: $k = 2000$, $N = 3000$, and the samples are drawn iid and with equal probability from one of three class-conditional normal distributions. The oversmoothing does not cause errors given the 0/1 cost matrix (dashed lines), but causes many errors given an asymmetric cost matrix (solid lines).



(a) Naive Bayes example



(b) k-NN example

Figure 1. Circles mark the true probabilities, triangles mark the estimated probabilities, and each line connects a true probability to the corresponding estimate. The dashed lines mark the class partitioning of the $\hat{p}$-simplex induced by the 0-1 cost matrix, and the solid lines mark the class partitioning induced by an asymmetric cost matrix.

3. Related Work

Approaches to deal with the systematic errors in probability estimation can be analyzed in terms of the classification rule given in (1). Such approaches generally either change the partitioning of the $\hat{p}$-simplex, or change the probability estimates.

3.1. Related Work in Two-class Classification

For the two-class case, the $\hat{p}$-simplex is a line segment from $\hat{p}_1(x) = 0$ to $\hat{p}_1(x) = 1$, and a scalar threshold t partitions the two class regions. The optimal threshold $t^\star$ derived with respect to (1) is,

$$t^\star = \frac{c_{1|2} - c_{2|2}}{c_{1|2} + c_{2|1} - c_{1|1} - c_{2|2}}. \qquad (2)$$

Classification errors can be reduced by changing the class-partitioning by specifying a threshold t that reduces the effect of systematic errors of the class probability estimates. The most common approach uses the receiver operating characteristic (ROC) curves (Egan, 1975; Hanley & McNeil, 1982). An ROC curve plots estimates of the probabilities $P_{\hat{Y}|Y}(2|2)$ versus $P_{\hat{Y}|Y}(2|1)$ for thresholds $t, 0 \leq t \leq 1$, where the estimates are derived from training or validation data. For a given cost matrix the desired point on the ROC curve is chosen and the associated threshold t is used for the classifier (Noe, 1983; Provost & Fawcett, 2001).

Other methods fix the threshold at the theoretical optimal $t^\star$ given by (2), and seek to improve classification by improving the probability estimates. Friedman considered adding a scalar a to the probability estimates

for class 1 (Friedman, 1997); it is easy to show that this method is equivalent to using a threshold $\tilde{t} = t^\star - a$.

Zadrozny and Elkan use monotonic functions of the probability estimate $\hat{p}_1$ to give a *calibrated* estimate and show great improvements in cost-sensitive classification when the calibrated probability estimates are used in place of the original estimates (Zadrozny & Elkan, 2001; Zadrozny & Elkan, 2002). One of their approaches builds on Platt's earlier work to transform support vector machine (SVM) scores into probability estimates using a sigmoid function (Platt, 2000). The same approach can be applied to probability estimates rather than SVM scores. Zadrozny and Elkan propose two other approaches to perform the calibration: *binning* and *pair-adjacent violators*.

Binning takes the probability estimates obtained using cross-validation, orders these values and then groups them into B bins so that there are an equal number of samples in each bin (Zadrozny & Elkan, 2001). The upper and lower boundaries of each bin are determined, and for any test sample with a probability estimate falling in bin b, the updated probability estimate for class 1 is given by the fraction of validation samples in bin b that belong to class 1.

Pair-adjacent violators (PAV) monotonically transform the probability estimates using isotonic regression (Ayer et al., 1955). It has been shown that applying threshold $t^\star$ from (2) to the calibrated probability estimates obtained using PAV is equivalent to using a threshold chosen by ROC analysis on the original probabilities (O'Brien, 2006).

3.2. Related Work in Multi-class Classification

Zadrozny and Elkan extended their two-class solutions to multi-class problems by breaking the classification task into a number of binary classification tasks and using error correcting output codes (ECOC) to obtain multi-class probability estimates (Zadrozny & Elkan, 2002).

Other methods seek to extend the ROC thresholding approach to K-class classification. Instead of choosing a scalar threshold t, a partition of the $(K-1)$-dimensional $\hat{p}$-simplex must be specified. Mossman proposed a method for three class tasks using a very restrictive partitioning of the simplex (Mossman, 1999):

$$\hat{y}(x) = \begin{cases} 1 & \text{if} \quad \hat{p}_3(x) \leq \delta_1 \text{ and } \hat{p}_2(x) - \hat{p}_1(x) \leq \delta_2 \\ 2 & \text{if} \quad \hat{p}_3(x) \leq \delta_1 \text{ and } \hat{p}_2(x) - \hat{p}_1(x) > \delta_2 \\ 3 & \text{if} \quad \hat{p}_3(x) > \delta_1. \end{cases} \tag{3}$$

Lachiche and Flach proposed an alternative to the minimum expected misclassification cost assignment of (1) (Lachiche & Flach, 2003):

$$\hat{y}(x) = \arg\max_i w_i^* \hat{p}_i, \tag{4}$$

where the w_i^* are chosen by minimizing costs on the training set:

$$w^* = \arg\min_w \sum_{n=1}^{N} c_{(\arg\max_i w_i \hat{p}_i(x_n))|y_n}, \tag{5}$$

and x_n, y_n are the nth training sample and its associated class label. We refer to (4) and (5) as the *LF method*. Mossman's method and the LF method can both be viewed as learning a new partitioning for the $\hat{p}$-simplex. In Section 5, we show how these partitions can be achieved by using different cost matrices in equation (1).

MetaCost is a wrapper method that can be used with any classification algorithm and reduces the variance of the probability estimates by bootstrapping (Domingos, 1999). MetaCost reduces the variance of probability estimates, but is not designed to overcome systematic probability estimation errors.

4. The Effect of the Cost Matrix on the Class-Decision Boundaries

In this section we establish how different changes in the cost matrix affect the class partitioning of the $\hat{p}$-simplex enacted by (1). In Section 5 we use these properties to propose a new method to reduce the effect of systematic errors in probability estimation.

For a particular cost matrix c, and any two classes i, k that are adjacent in the partition of the $\hat{p}$-simplex, the partition-boundary between them is described by the hyperplane,

$$\sum_{j=1}^{K} c_{i|j} \hat{p}_j = \sum_{j=1}^{K} c_{k|j} \hat{p}_j. \tag{6}$$

We restrict attention to cost matrices where the cost of correct assignment is always less than the cost of incorrect assignment, that is, $c_{j|j} < c_{i|j}$, $\forall i \neq j$.

Property 1: *For any $\hat{p}$, the assigned class is the same for cost matrices c and αc for any scalar α.*

Proof: The minimization in (1) is unaffected by replacing $c_{i|j}$ by $\alpha c_{i|j}$, $\forall i, j$.

Property 2: *If the cost matrix c is full rank, then there is a point ζ^e where all two class boundaries as described by (6) intersect, and ζ^e may occur outside*

the probability simplex. We term ζ^e the "equal risk point".

Proof: If c is full rank then the solution is $\zeta^e = c^{-1}\mathbf{1}/\|c^{-1}\mathbf{1}\|_1$ that will solve (6) for all classes. However, it can happen that $\|c^{-1}\mathbf{1}\|_1 = 0$, in which case the equal risk point can be said to be at infinity.

If c is not full rank there may still be an unique equal risk point. In general, ζ^e must solve $\left[\begin{array}{c|c} c & \mathbf{-1} \\ \hline \mathbf{1}^T & 0 \end{array}\right] \left[\begin{array}{c} \zeta^e \\ \hline \gamma \end{array}\right] = \left[\begin{array}{c} \mathbf{0} \\ \hline 1 \end{array}\right]$ for some $\gamma \in \mathbb{R}$. If the above matrix is full rank then there is a unique point solution for ζ^e, otherwise the above system is underdetermined and there is a hyperplane of solutions, or the above system can be overdetermined and there is no solution.

Property 3: *Adding a constant to all costs for a particular true class (equivalently, adding a constant to each term in any column of the cost matrix) does not affect the assignment.*

Proof: The minimization in (1) is unaffected by changing $c_{i|j}$ to $c_{i|j} + \alpha_j$, $\forall i$.

Property 4: *The class-partitioning produced by any cost matrix c can equivalently be produced by some cost matrix $\tilde{c}$ where $\tilde{c}_{i|i} = 0$ and $\tilde{c}_{i|j} > 0$ for $i \neq j$.*

Proof: Follows directly from Property 3.

Property 5: (See Fig. 2b) *Adding a constant α to the cost of assignment to class i irrespective of the true class (that is, adding α to each term in row i of a cost matrix), produces a new class-partitioning with partition boundaries parallel to those of the original.*

Proof: This change only affects the two-class boundary equations specified by (6) for class i and each class k:

$$\sum_{j=1}^{K}(c_{i|j} + \alpha)\hat{p}_j = \sum_{j=1}^{K} c_{k|j}\hat{p}_j = \sum_{j=1}^{K} c_{i|j}\hat{p}_j + \alpha.$$

Thus the new boundary between class i and k is parallel to the original boundary between class i and k. To maintain $c_{j|j} < c_{i|j}$, $\forall i \neq j$ requires $\max_{k\neq i}(c_{k|k} - c_{i|k}) < \alpha < \min_{k\neq i}(c_{k|i} - c_{i|i})$.

Property 6: (See Fig. 2c) *Scaling all costs where the true class is ℓ by a positive constant α (that is, multiplying column ℓ of c by α) moves an equal risk point along the line joining it to the corner of the simplex where $\hat{p}_\ell = 1$. The intersections of the class boundaries with the $\hat{p}_\ell = 0$ plane are unchanged.*

Proof: To prove that the new equal risk point $\tilde{\zeta}^e$ is on the line joining the original equal risk point ζ^e and the corner of the simplex where $\hat{p}_\ell = 1$, we show that there exists a constant β such that

$$\tilde{\zeta}^e_j = \beta\zeta^e_j + (1-\beta)\mathcal{I}_{(j=\ell)}, \tag{7}$$

for all j, and where $\mathcal{I}$ is the indicator function.

From (6), multiplying column ℓ by α, and requiring equal risk for classes ℓ and k:

$$\sum_{j=1, j\neq\ell}^{K}(c_{i|j} - c_{k|j})\tilde{\zeta}^e_j + (c_{i|\ell} - c_{k|\ell})(\alpha\tilde{\zeta}^e_\ell) = 0. \tag{8}$$

First note that if $\zeta^e_\ell = 0$, then ζ^e remains an equal risk point for the transformed cost matrix. Otherwise, for any ζ^e, we write $\zeta^e_j = s_j\zeta^e_\ell$. Comparing (6) and (8), there exists $\tilde{\zeta}$ such that $\tilde{\zeta}^e_j = \alpha(s_j\tilde{\zeta}^e_\ell)$, $\forall j \neq \ell$. Thus,

$$\tilde{\zeta}^e_j = \left(\frac{\alpha\tilde{\zeta}^e_\ell}{\zeta^e_\ell}\right)\zeta^e_j. \tag{9}$$

Let $\beta = \alpha\tilde{\zeta}^e_\ell/\zeta^e_\ell$, then (9) establishes (7) $\forall j \neq \ell$. Also,

$$\sum_{j\neq\ell}\tilde{\zeta}^e_j = \beta\sum_{j\neq\ell}\zeta^e_j \tag{10}$$

$$\Rightarrow 1 - \tilde{\zeta}^e_\ell = \beta(1-\zeta^e_\ell), \tag{11}$$

where (11) follows from (10) since components of $\tilde{\zeta}^e$ and ζ^e both sum to 1. This establishes (7) for ℓ.

Lastly, by setting $\hat{p}_\ell = 0$ in equation (6), it is evident that changes in $c_{i|\ell}$ and $c_{j|\ell}$ will not effect the intersections of the class boundaries with the $\hat{p}_\ell = 0$ plane.

Property 7: (See Fig. 2d) *Scaling all costs where the assigned class is i by a positive constant α (that is, multiplying all elements in row i by α) moves an equal risk point ζ^e along the hyper-plane where all classes but class i have equal expected misclassification costs.*

Proof: Let $\tilde{c}_{j|k} = c_{j|k}$ for all $j \neq i$, and let $\tilde{c}_{i|k} = \alpha c_{i|k}$. Then the equal risk point $\tilde{\zeta}^e$ produced by $\tilde{c}$ solves the same set of class boundary equations (6) specifying ζ^e, except

$$\sum_{j=1}^{K}(c_{i|j} - c_{K|j})\zeta^e_j = 0 \quad \Rightarrow \quad \sum_{j=1}^{K}(\alpha c_{i|j} - c_{K|j})\tilde{\zeta}^e_j = 0.$$

Because the constraints specifying that the other classes have equal misclassification costs still apply, the new equal risk point $\tilde{\zeta}^e$ must occur along the hyperplane specified by that subset of the constraints.

5. Learning the Partition Matrix

We propose changing the class partitions so that the class-partitioning corrects for the systematic error in the probability estimates. Changing the partition of the multi-class $\hat{p}$-simplex is analogous to the two-class practice of changing the threshold on $\hat{p}_1(x)$.

We split the cost matrix's role into two separate entities: a partition matrix (which partitions the $\hat{p}$-simplex with linear boundaries), and the misclassification cost matrix that specifies how misclassification errors are to be scored. From now on we will use the term *partition matrix* for the former role, and the term *cost matrix* only for the latter role.

Given a training set $\{(x_1, y_1), (x_2, y_2), ..., (x_N, y_N)\}$, where x_n has class probability estimate vector $\hat{p}(x_n)$, we propose to use a partition matrix $a^\star$ that solves

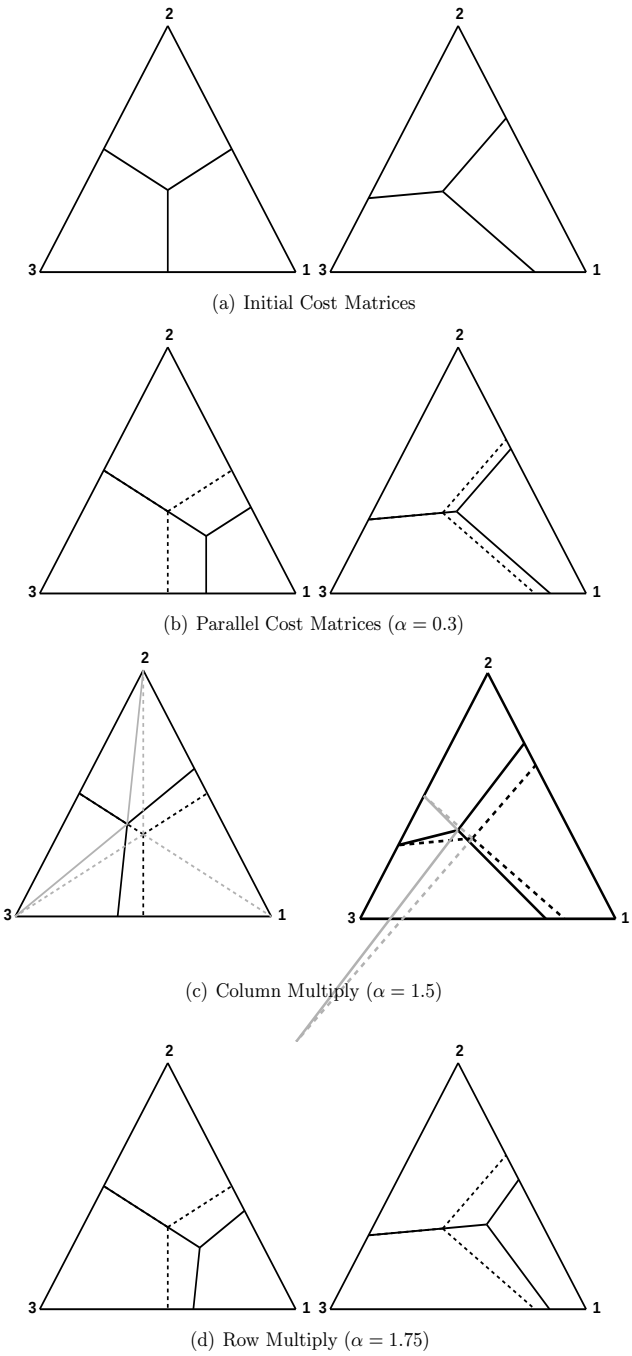
$$a^\star = \arg\min_a \sum_n c_{g(\hat{p}(x_n);a)|y_n}, \tag{12}$$

where the function g in (12) is defined in (1). To avoid the issue of overfitting in learning a partition matrix, we restrict the partition to have linear boundaries that are parallel to the original decision boundaries produced by the cost matrix (see Fig. 2b). We have also considered learning partition matrices with different constraints, including partition matrices with all $K^2 - K$ free parameters, partition matrices that are column-multiply modifications of the original cost matrix (see Fig. 2c), and row-multiply modifications (see Fig. 2d). We found these different constraints resulted in similar performance, with the parallel partitioning working consistently well (O'Brien, 2006).

By Property 4 stated in Section 4, without loss of generality we consider only partition matrices a where $a_{i|i} = 0$ and $a_{i|j} > 0$ for $i \neq j$. From Property 5, adding α_i to row i of the cost matrix will yield a partition matrix with partition boundaries parallel to the partition boundaries induced by c. To maintain the requirement that $a_{i|i} = 0$ we subtract the same constant from column i without affecting the partition boundaries (Property 3). Thus given the cost matrix c, the partition matrix is a where $a_{i|j} = c_{i|j} + \alpha_i - \alpha_j$. This approach requires learning the parameters α_i for $i = 1, \ldots, K$.

Related methods can also be viewed as applications of (12) but with different restrictions on a. Mossman's method for three classes (Mossman, 1999) implicitly requires a to be of the form

$$\begin{bmatrix} 0 & 1 & L - \frac{\delta_2}{1-\delta_2} \\ \frac{1+\delta_2}{1-\delta_2} & 0 & L \\ \frac{\delta_1}{1-\delta_1} L & \frac{\delta_1}{1-\delta_1} L & 0 \end{bmatrix}, \tag{13}$$



(a) Initial Cost Matrices

(b) Parallel Cost Matrices ($\alpha = 0.3$)

(c) Column Multiply ($\alpha = 1.5$)

(d) Row Multiply ($\alpha = 1.75$)

Figure 2. This figure illustrates Properties 5, 6, and 7 described in Section 4 for a three-class classification. The partition produced by the cost matrix is marked by solid lines: a 0/1 cost matrix for the left figures, and an asymmetric cost matrix for the right figures. The corners of the simplex are marked such that $\hat{p}_j = 1$ at corner j, and if a test sample has estimated class probability $\hat{p}$ that falls in the region including corner j, then the estimated class label is j. For each of the figures, manipulations are applied to the class 1 elements of the cost matrix. The dashed lines show the initial cost matrix partitions, the gray lines help to illustrate the properties.

where the δ terms are those used in (3) and $L \gg 1$. The LF method (Lachiche & Flach, 2003) is equivalent to choosing a partition matrix a such that $a_{i|j} = w_j z_{i|j}$ where $z_{i|j}$ is the 0-1 cost matrix and w_j is the weight used in equations (4) and (5). Thus the LF method is equal to a column-multiply of a 0-1 cost matrix (see Property 5 stated in Section 4, and Fig 2c), whereas our proposed method enacts a parallel shift based on the actual cost matrix c.

5.1. Optimizing the Partition Matrix

We learn the new partition matrix by minimizing an empirical loss calculated on a validation set of labeled samples using a greedy approach. The new partition matrix a is initialized to the cost matrix c. Then each free parameter is updated in turn. Let a denote the current partition matrix, and the new partition matrix $\tilde{a}$ will have $\tilde{a}_{i|j} = a_{i|j} + \alpha_i$ and $\tilde{a}_{j|i} = a_{j|i} - \alpha_i$ for all $j \neq i$. Suppose $\alpha_i = -\infty$ and interpret $\tilde{a}$ as a cost matrix – then there would be an infinitely negative cost to assigning a sample as class i, and thus every training sample would be assigned to class i. Suppose one increased α_i from negative infinity. For different values of α_i it would become more cost-effective to classify each of the training samples as a different class, call this classification choice $g^i(\hat{p}(x_n))$, where $g^i(\hat{p}(x_n)) = \arg\min_{k \neq i} \sum_{j=1}^{K} a_{k|j} \hat{p}_j(x)$. Let α_{in} denote the changepoint value – for $\alpha_i < \alpha_{in}$ training sample n would be assigned to class i and for $\alpha_i > \alpha_{in}$ training sample n would be assigned to class $g^i(\hat{p}(x_n))$.

We find these N changepoints α_{in} for $n = 1, \ldots, N$, by solving the N equations,

$$\sum_{j=1}^{K} \left(a_{g^i(\hat{p}(x_n))|j}\right) \hat{p}_j(x_n) = \sum_{j=1}^{K} \left(a_{i|j} + \alpha_{in}\right) \hat{p}_j(x_n).$$

Re-order the training data by their changepoints, so that $\{x_k, y_k\}$ denotes the training point with the kth largest changepoint. Then select N^* where,

$$N^* = \arg \min_{N_0 = 1,2,\ldots,N} \sum_{n < N_0} c_{g^i(\hat{p}(x_n))|y_n} + \sum_{n \geq N_0} c_{i|y_n}. \tag{14}$$

Note that α_{iN^*} to α_{iN^*+1} defines the range of α_i that would yield the empirical cost given in (14); we set the parameter α_i to be the geometric mean of α_{iN^*} and α_{iN^*+1}. Since we require that $\tilde{a}_{j|j} < \tilde{a}_{k|j}$, for all $k \neq j$, it must be that $a_{j|j} < a_{i|j} + \alpha_i$ and $a_{i|i} + \alpha_i < a_{k|i}$, for all $j, k \neq i$, and so α_i is clipped to satisfy these conditions. In addition, if $\alpha_{iN^*} < 0 < \alpha_{iN^*+1}$, then α_i is set equal to 0, or equivalently $\tilde{a}$ is set equal to a.

Each class's partition matrix parameter is adjusted in this manner once, and the parameters are updated in order of class size from most populous to least. Preliminary experiments provided evidence that multiple passes through the parameters did not improve the final classification performance, and that performance was fairly robust to the parameter ordering.

6. Experiments

Experiments with UCI benchmark datasets compare the proposed parallel-partition matrix method to MetaCost (MC) (Domingos, 1999) and to the LF method (Lachiche & Flach, 2003).

For two-class problems the proposed partition matrix methods are equivalent to ROC analysis and therefore only multi-class problems are considered here.

There are two basic variants of MetaCost: the first variant is that the probability estimates are based on training samples not including the sample, while the other variant is that all-inclusive estimates are made. The results reported here are the better of the two variants for each dataset.

Randomized ten-fold cross-validation was done 100 times for each method and each dataset. In the cross-validation, 1/10 of the data was set aside as test data. For MetaCost, 100 resamples were generated using the remaining nine folds. For the proposed methods and the LF method the remaining nine folds were subject to a nine-fold cross-validation so that 8/10 of the data (eight folds) were used to estimate the probabilities for each of the nine folds. Then the partition matrix a and LF parameters were estimated using the nine folds' probability estimates. Finally, the learned cost-sensitive classifier was applied to the withheld 1/10 of the test data.

Experiments were done with two different probability estimation methods. For datasets with discrete features, multinomial naive Bayes was used with Laplacian correction for estimating probabilities. Any continuous features used with naive Bayes were quantized to 21 values. For datasets with continuous features, regularized quadratic discriminant analysis (QDA) (Friedman, 1989) was used. Each class's estimated covariance matrix was regularized as,

$$\hat{\Sigma} = (1 - \gamma - \lambda)\hat{\Sigma}_{ML} + \lambda\bar{\Sigma} + \lambda \frac{\text{trace}\left(\hat{\Sigma}_{ML}\right)}{d} I,$$

where $\hat{\Sigma}_{ML}$ is the maximum likelihood estimate of the full covariance matrix, $\bar{\Sigma}$ is the pooled maximum likelihood estimate, d is the dimensionality of the feature vector, and γ and λ were increased from zero until the condition number of $\hat{\Sigma}$ was less than 10^6.

Experiments were run with two different cost scenarios. In practical situations it is often the rare events that are of greatest interest, and therefore the cost of misclassifying samples from rare classes is higher. To simulate this situation, we set $c_{i|i} = 0$ and,

$$c_{i|j} = \frac{N_i}{N_i + N_j},$$

where N_i is the number of training samples labeled class i. For the second set of experiments, we set $c_{i|i} = 0$, and each element $c_{j|k}$ for $j \neq k$ was drawn randomly and uniformly from $[1, 10]$.

6.1. Discussion of Results

Results are presented in Tables 1 and 2 in terms of the mean increase in performance over the baseline of using the partitioning induced by the cost matrix. The datasets in the results tables are ordered by increasing geometric-mean class size for the training set. The results show that MetaCost did not consistently improve over the baseline. The LF method performed better and usually improved performance, but caused large increases in error in two cases: image segmentation with QDA, and dermatology with naive Bayes. In contrast, learning a new parallel partitioning showed a mean improvement of 10.8% for the rarity-based cost matrix and a mean improvement of 8.9% with the random cost matrix.

The LF method and proposed partition-learning method are designed to correct for systematic errors in the probability estimates. Such systematic errors can be interpreted as a bias that can cause the classifier to be wrong in the same way on average over many training sets. Thus, we expected to see a greater increase in performance for the LF method and proposed partition-learning method for larger datasets (further down in the tables) because performance given a large training sets is more likely to suffer from problems of bias than estimation variance. With smaller datasets, estimation variance is generally a larger concern, and the bias reduction offered by the LF and proposed method may not be very helpful. In addition, for small datasets it is harder to learn the systematic error from only a few training samples, and there is an increased risk of overfitting the learned parameters.

The datasets *iris* and *dermatology* had very low misclassification loss for the original probability estimates. For these datasets there was not much improvement possible, and we hypothesize that the methods that learned parameters were likely to overfit to small improvements in the training data.

We used a greedy optimization approach to learn the new partition matrix for our method, but in some cases this leads only to a locally optimal solution. The LF method also uses a greedy search. However, Deng et al.'s results (Deng et al., 2006) show that improving the optimization of the LF objective can lead to an improvement in results. Similarly, we hypothesize that finding a globally optimal solution would also lead to an improvement in costs.

7. Discussion

We analyzed how changes in the cost matrix affect the partitioning of the $\hat{p}$-simplex due to the cost matrix. Based on this analysis, we explored correcting for systematic probability estimation errors by learning a partitioning of the $\hat{p}$-simplex that minimizes empirical misclassification costs on the training set. To reduce overfitting, we only considered partitionings parallel to the original partitioning induced by the cost matrix. Experiments with two standard classifiers showed that this post-processing worked best when the number of training samples per class is relatively large, and when the estimation error with the original cost matrix is large.

Abstract

We present a discriminative online algorithm with a bounded memory growth, which is based on the kernel-based Perceptron. Generally, the required memory of the kernel-based Perceptron for storing the online hypothesis is not bounded. Previous work has been focused on discarding part of the instances in order to keep the memory bounded. In the proposed algorithm the instances are not discarded, but projected onto the space spanned by the previous online hypothesis. We derive a relative mistake bound and compare our algorithm both analytically and empirically to the state-of-the-art Forgetron algorithm (Dekel et al, 2007). The first variant of our algorithm, called Projectron, outperforms the Forgetron. The second variant, called Projectron++, outperforms even the Perceptron.

1. Introduction

One of the most important aspects of online learning methods is their ability to work in an open-ended fashion. Autonomous agents, for example, need to learn continuously from their surroundings, to adapt to the environment and maintain satisfactory performances. A recent stream of work on artificial cognitive systems have signaled the need for life-long learning methods and the promise of discriminative classifiers for this task (Orabona et al., 2007, and references therein).

Kernel-based discriminative online algorithms have been shown to perform very well on binary classification problems (see for example (Kivinen et al., 2004; Crammer et al., 2006)). Most of them can be seen as belonging to the Perceptron algorithm family. They construct their classification function incrementally, keeping a subset of the instances called *support set*. Each time an instance is misclassified it is added to the support set, and the classification function is defined as a kernel combination of the observations in this set. It is clear that if the problem is not linearly separable, they will never stop updating the classification function. This leads eventually to a memory explosion, and it concretely limits the usage of these methods for all those applications where data must be acquired continuously in time.

Several authors tried in the past to address this problem, mainly by bounding a priori the memory requirements. The first algorithm to overcome the unlimited growth of the support set was proposed by Crammer et al. (2003). The algorithm was then refined by Weston et al. (2005). The idea of the algorithm was to discard a vector of the solution, once the maximum dimension has been reached. The strategy was purely heuristic and no mistake bounds were given. A similar strategy has been used also in NORMA (Kivinen et al., 2004) and SILK (Cheng et al., 2007). The very first online algorithm to have a fixed memory "budget" and at the same time to have a relative mistake bound has been the Forgetron (Dekel et al., 2007). A stochastic algorithm that on average achieves similar performances, and with a similar mistake bound has been proposed by Cesa-Bianchi et al. (2006).

In this paper we take a different route. We modify the Perceptron algorithm so that the number of stored samples is always bounded. Instead of fixing a priori the maximum dimension of the solution, we introduce a parameter that can be tuned by the user, to trade accuracy for sparseness, depending on the needs of the task at hand. We call the algorithm, that constitutes the first contribution of this paper, *Projectron*. The Projectron is an online, Perceptron-like method that is bounded in space and in time complexity. We derive for it a mistake bound, and we show experimentally that it outperforms consistently the Forgetron algorithm. The second contribution of this paper is the

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

derivation of a second algorithm, that we call *Projectron++*. It achieves better performances than the Perceptron, retaining all the advantage of the Projectron listed above. Note that this is opposite to previous budget online learning algorithms, delivering performances at most as good as the original Perceptron.

The rest of the paper is organized as follows: in Section 2 we state the problem and we introduce the necessary background theory. Section 3 introduces the Projectron, Section 4 derives its properties and Section 4.1 derives the Projectron++. We report experiments in Section 5, and we conclude the paper with an overall discussion.

2. Problem Setting

The basis of our study is the well known Perceptron algorithm (Rosenblatt, 1958). The Perceptron algorithm learns the mapping $f : \mathcal{X} \to \mathbb{R}$ based on a set of examples $S = \{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)\}$, where $\mathbf{x}_t \in \mathcal{X}$ is called an *instance* and $y_t \in \{-1, +1\}$ is called a *label*. We denote the prediction of Perceptron as $\text{sign}(f(\mathbf{x}))$ and we interpret $|f(\mathbf{x})|$ as the confidence in the prediction. We call the output f of the Perceptron algorithm a *hypothesis*, and we denote the set of all attainable hypotheses by $\mathcal{H}$. In this paper we assume that $\mathcal{H}$ is a Reproducing Kernel Hilbert Space (RKHS) with a positive definite kernel function $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ implementing the inner product $\langle \cdot, \cdot \rangle$. The inner product is defined so that it satisfies the reproducing property, $\langle k(\mathbf{x}, \cdot), f(\cdot) \rangle = f(\mathbf{x})$

The Perceptron algorithm is an online algorithm, in which the learning takes place in rounds. At each round a new hypothesis function is estimated, based on the previous one. We denote the hypothesis estimated after the t-th round by f_t. The algorithm starts with the zero hypothesis $f_0 = \mathbf{0}$. On each round t, an instance $\mathbf{x}_t \in \mathcal{X}$ is presented to the algorithm. The algorithm predicts a label $\hat{y}_t \in \{-1, +1\}$ by using the current function, $\hat{y}_t = \text{sign}(f_t(\mathbf{x}_t))$. Then, the correct label y_t is revealed. If the prediction $\hat{y}_t$ differs from the correct label y_t, it updates the hypothesis $f_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$, otherwise the hypothesis is left intact, $f_t = f_{t-1}$. Practically, the hypothesis f_t can be written as a kernel expansion (Schölkopf et al., 2000),

$$f_t(\mathbf{x}) = \sum_{i \in \mathcal{S}_t} \alpha_i k(\mathbf{x}_i, \mathbf{x}) \ , \tag{1}$$

where $\alpha_i = y_i$ and $\mathcal{S}_t$ is defined to be the set of instance indices for which an update of the hypothesis occurred, i.e., $\mathcal{S}_t = \{0 \le i \le t \,|\, \hat{y}_i \ne y_i\}$. The set $\mathcal{S}_t$ is called the support set. The Perceptron algorithm is summarized in Algorithm 1.

Algorithm 1 Perceptron Algorithm

Initialize: $\mathcal{S}_0 = \emptyset$, $f_0 = \mathbf{0}$
for $t = 1, 2, \ldots, T$ **do**
  Receive new instance $\mathbf{x}_t$
  Predict $\hat{y}_t = \text{sign}(f_{t-1}(\mathbf{x}_t))$
  Receive label y_t
  if $y_t \ne \hat{y}_t$ **then**
    $f_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$
    $\mathcal{S}_t = \mathcal{S}_{t-1} \cup \{t\}$
  else
    $f_t = f_{t-1}$
    $\mathcal{S}_t = \mathcal{S}_{t-1}$
  end if
end for

Although the Perceptron is a very simple algorithm, it is considered to produce very good results. Our goal is to derive and analyze a new algorithm which attains the same results as the Perceptron but with a minimal size of support set. In the next section we present our Projectron algorithm.

3. The Projectron Algorithm

Let us first consider a finite dimensional RKHS $\mathcal{H}$ induced by a kernel such as the polynomial kernel. Since $\mathcal{H}$ is finite dimensional, there is a finite number of linearly independent hypotheses in this space. Hence, any hypothesis in this space can be expressed using a finite number of examples. We can modify the Perceptron algorithm to use only one set of independent instances as follows. On each round the algorithm receives an instance and predicts its label. On a prediction mistake, if the instance can be spanned by the support set, namely, $\mathbf{x}_t = \sum_{i=1}^{t-1} d_i \mathbf{x}_i$, it is not added to the support set. Instead, the coefficients $\{\alpha_i\}$ in the expansion Eq. (1) are not merely y_i, $i \in \mathcal{S}_{t-1}$, but they are changed to reflect the addition of this instance to the hypothesis, that is, $\alpha_i = y_i + y_t d_i$, $1 \le i \le t-1$. If the instance and the support set are linearly independent, the instance is added to the set with $\alpha_t = y_t$ as before. This technique reduces the size of the support set without changing the hypothesis in any way, and was used by Downs at al. (2001) to simplify Support Vector Machine solutions.

Let us consider now the more elaborate case of an infinite dimensional RKHS $\mathcal{H}$ induced by kernels such as the Gaussian kernel. In this case, it is not possible to find a finite number of linearly independent vectors which span the whole space, and hence there is no guarantee that the hypothesis can be expressed by a finite number of instances. However, we can approximate the concept of linear independence with a

Algorithm 2 Projectron Algorithm

Initialize: $\mathcal{S}_0 = \emptyset$, $f_0 = \mathbf{0}$
for $t = 1, 2, \ldots, T$ **do**
  Receive new instance $\mathbf{x}_t$
  Predict $\hat{y}_t = \text{sign}(f_{t-1}(\mathbf{x}_t))$
  Receive label y_t
  if $y_t \neq \hat{y}_t$ **then**
    $f'_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$
    $f''_t = f'_t$ projected onto the space $\mathcal{S}_{t-1}$
    $\delta_t = f''_t - f'_t$
    if $\|\delta_t\| \leq \eta$ **then**
      $f_t = f''_t$
      $\mathcal{S}_t = \mathcal{S}_{t-1}$
    else
      $f_t = f'_t$
      $\mathcal{S}_t = \mathcal{S}_{t-1} \cup \{t\}$
    end if
  else
    $f_t = f_{t-1}$
    $\mathcal{S}_t = \mathcal{S}_{t-1}$
  end if
end for

finite number of vectors (Csató & Opper, 2001; Engel et al., 2002; Orabona et al., 2007). In particular assume that at round t of the algorithm there is a prediction mistake and the mistaken instance $\mathbf{x}_t$ should be added to the support set. Before adding the instance to the support, we construct two hypotheses: a temporal hypothesis f'_t using the function $k(\mathbf{x}_t, \cdot)$, that is, $f'_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$, and a projected hypothesis f''_t, which is the projection of f'_t onto the space spanned by $\mathcal{S}_{t-1}$. That is, the projected hypothesis is a hypothesis from the support set $\mathcal{S}_{t-1}$ which is the closest to the temporal hypothesis. Denote by δ_t the distance between the hypotheses $\delta_t = f''_t - f'_t$. If the norm of distance $\|\delta_t\|$ is below some threshold η, we use the projected hypothesis as our next hypothesis, i.e., $f_t = f''_t$, otherwise we use the temporal hypothesis as our next hypothesis, i.e., $f_t = f'_t$. As we show in the next section, this strategy assures that the maximum size of the support set is always finite, regardless of the dimension of the RKHS $\mathcal{H}$. Guided by these considerations we can design a new Perceptron-like algorithm that projects the solution onto the space spanned by the previous support vectors whenever possible. We call this algorithm Projectron. The algorithm is given in Algorithm 2.

In our algorithm the parameter η plays an important role. If η is equal to zero, we obtain exactly the same solution of the Perceptron algorithm. In this case, however, the Projectron solution can still be sparser when some of the instances are linearly dependent or when the kernel induces a finite dimensional RKHS $\mathcal{H}$. In case η is greater than zero we trade precision for sparseness. Moreover, as shown in the next section, this implies a bounded algorithmic complexity, namely, the memory and time requirements for each step are bounded. We will also derive mistake bounds to analyze the effect of η on the classification accuracy.

We now consider the problem of deriving the projected hypothesis f''_t in a Hilbert space $\mathcal{H}$, induced by a kernel function $k(\cdot, \cdot)$. Denote by $P_{t-1} f_t$ the projection of $f_t \in \mathcal{H}$ onto the subspace $\mathcal{H}_{t-1} \subset \mathcal{H}$ spanned by the set $\mathcal{S}_{t-1}$. The projected hypothesis f''_t is defined as $f''_t = P_{t-1} f'_t$. Expanding f'_t we have

$$f''_t = P_{t-1} f'_t = P_{t-1} \left(f_{t-1} + y_t k(\mathbf{x}_t, \cdot) \right) . \quad (2)$$

The projection is an idempotent ($P^2_{t-1} = P_{t-1}$) and linear operator, hence,

$$f''_t = f_{t-1} + y_t P_{t-1} k(\mathbf{x}_t, \cdot) . \quad (3)$$

Recall that $\delta_t = f''_t - f'_t$. Substitute f''_t from Eq. (3) and f'_t we have

$$\delta_t = f''_t - f'_t = y_t P_{t-1} k(\mathbf{x}_t, \cdot) - y_t k(\mathbf{x}_t, \cdot) . \quad (4)$$

Recall that the projection of $f'_t \in \mathcal{H}$ onto a subspace $\mathcal{H}_{t-1} \subset \mathcal{H}$ is the hypothesis in $\mathcal{H}_{t-1}$ closest to f'_t. Hence, let $\sum_{j \in \mathcal{S}_{t-1}} d_j k(\mathbf{x}_j, \cdot)$ be an hypothesis in $\mathcal{H}_{t-1}$, where $(d_1, \ldots, d_{t-1})$ is a set of coefficients. The closest hypothesis is the one for which

$$\|\delta_t\|^2 = \min_{(d_1, \ldots, d_{t-1})} \left\| \sum_{j \in \mathcal{S}_{t-1}} d_j k(\mathbf{x}_j, \cdot) - k(\mathbf{x}_t, \cdot) \right\|^2 . \quad (5)$$

Expanding Eq. (5) we get

$$\|\delta_t\|^2 = \min_{(d_1, \ldots, d_{t-1})} \Bigg(\sum_{i,j \in \mathcal{S}_{t-1}} d_j d_i k(\mathbf{x}_j, \mathbf{x}_i) - 2 \sum_{j \in \mathcal{S}_{t-1}} d_j k(\mathbf{x}_j, \mathbf{x}_t) + k(\mathbf{x}_t, \mathbf{x}_t) \Bigg) . \quad (6)$$

Define $\mathbf{K}_{t-1}$ to be the matrix generated by the instances in the support set $\mathcal{S}_{t-1}$, that is, $\{\mathbf{K}_{t-1}\}_{i,j} = k(\mathbf{x}_i, \mathbf{x}_j)$ for every $i, j \in \mathcal{S}_{t-1}$. Define $\mathbf{k}_t$ to be the vector whose i-th element is $\mathbf{k}_{t_i} = k(\mathbf{x}_i, \mathbf{x}_t)$. We have

$$\|\delta_t\|^2 = \min_{\mathbf{d}} \left(\mathbf{d}^T \mathbf{K}_{t-1} \mathbf{d} - 2 \mathbf{d}^T \mathbf{k}_t + k(\mathbf{x}_t, \mathbf{x}_t) \right) , \quad (7)$$

where $\mathbf{d} = (d_1, \ldots, d_{t-1})^T$. Solving Eq. (7), that is, applying the extremum conditions with respect to $\mathbf{d}$, we obtain

$$\mathbf{d}^\star = \mathbf{K}^{-1}_{t-1} \mathbf{k}_t \quad (8)$$

and, by substituting Eq. (8) into Eq. (7),

$$\|\delta_t\|^2 = k(\mathbf{x}_t, \mathbf{x}_t) - \mathbf{k}_t^T \mathbf{d}^\star \ . \tag{9}$$

Furthermore, substituting Eq. (8) into Eq. (3) we get

$$f_t'' = f_{t-1} + y_t \sum_{j \in \mathcal{S}_{t-1}} \mathbf{d}_j^\star \, k(\mathbf{x}_j, \cdot) \ . \tag{10}$$

We have shown how to calculate both the distance δ_t and the projected hypothesis f_t''. In summary, one needs to compute $\mathbf{d}^\star$ according to Eq. (8), plug the result either into Eq. (9) and obtain δ_t or into Eq. (10) and obtain the projected hypothesis.

In order to make the computation more tractable, we introduce an efficient method to calculate the matrix inversion $\mathbf{K}_t^{-1}$ iteratively. This method was first introduced in (Cauwenberghs & Poggio, 2000), and we give it here only for completeness. We would like to note in passing that the matrix $\mathbf{K}_{t-1}$ can be safely inverted since, by incremental construction, it is always full-rank. After the addition of a new sample, $\mathbf{K}_t^{-1}$ becomes

$$\begin{bmatrix} & & & 0 \\ & \mathbf{K}_{t-1}^{-1} & & \vdots \\ & & & 0 \\ 0 & \cdots & 0 & 0 \end{bmatrix} + \frac{1}{\|\delta_t\|^2} \begin{bmatrix} \mathbf{d}^\star \\ -1 \end{bmatrix} \begin{bmatrix} \mathbf{d}^{\star T} & -1 \end{bmatrix} \tag{11}$$

where $\mathbf{d}^\star$ and $\|\delta_t\|^2$ are already evaluated during the previous steps of the algorithm. Thanks to this incremental evaluation, the time complexity of the linear independence check is $O(|\mathcal{S}_{t-1}|^2)$, as one can easily see from Eq. (8).

4. Analysis

In this section we analyze the performance of the Projectron algorithm in the usual framework of online learning with a competitor. First, we present a theorem which states that the size of the support set is bounded.

Theorem 1. *Let $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ a continuous Mercer kernel, with $\mathcal{X}$ a compact subset of a Banach space. Then, for any training sequence $(\mathbf{x}_i, y_i), i = 1, \cdots, \infty$ and for any $\eta > 0$, the size of the support set of the Projectron algorithm is finite.*

The proof of this theorem goes along the same lines as the proof of Theorem 3.1 in (Engel et al., 2002), and we omit it for brevity. Note that this theorem guarantees that the size of the support set is bounded, however it does not state that the size of the support set is fixed or can be estimated before training.

The next theorem provides a mistake bound. The main idea is to bound the maximum number of mistakes of the algorithm, relatively to the best hypothesis $g \in \mathcal{H}$ chosen in hindsight. Let us define D_1 as

$$D_1 = \sum_{t=1}^{T} \ell(g(\mathbf{x}_t), y_t) \tag{12}$$

where $\ell(g(\mathbf{x}_t), y_t)$ is the hinge loss suffered by the function g on the example $(\mathbf{x}_t, y_t)$, that is, $\max\{0, 1 - y_t g(\mathbf{x}_t)\}$. With these definitions we can state the following bound for the Projectron Algorithm.

Theorem 2. *Let $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_T, y_T)$ be a sequence of instance-label pairs where $\mathbf{x}_t \in \mathcal{X}$, $y_t \in \{-1, +1\}$, and $k(\mathbf{x}_t, \mathbf{x}_t) \leq R$ for all t. Let g be an arbitrary function in $\mathcal{H}$. Assume that the Projectron algorithm is run with $0 \leq \eta < \frac{2-R^2}{2\|g\|}$. Then the number of prediction mistakes the Projectron makes on the sequence is at most*

$$\frac{\|g\|^2 + 2D_1}{2 - R^2 - 2\eta\|g\|}$$

The proof of this theorem is based on the following lemma.

Lemma 1. *Let $(\mathbf{x}, y)$ be an example, with $\mathbf{x} \in \mathcal{X}$ and $y \in \{+1, -1\}$. Denote by f an hypothesis in $\mathcal{H}$, such that $yf(\mathbf{x}) < 1$. Let $f' = f + \tau y q(\cdot)$, where $q(\cdot) \in \mathcal{H}$. Then the following bound holds for any $\tau \geq 0$:*

$$\begin{aligned} \|f - g\|^2 - \|f' - g\|^2 \geq \tau\big(&2\ell(f(\mathbf{x}), y) - 2\ell(g(\mathbf{x}), y) \\ &-\tau\|q(\cdot)\|^2 - 2\langle f, q(\cdot) - k(\mathbf{x}, \cdot)\rangle - 2\|q(\cdot) - k(\mathbf{x}, \cdot)\| \cdot \|g\|\big) \end{aligned}$$

Proof.

$$\begin{aligned} &\|f - g\|^2 - \|f' - g\|^2 = 2\tau y\langle g - f, q(\cdot)\rangle - \tau^2\|q(\cdot)\|^2 \\ &= 2\tau y(g(x) - f(x)) - \tau^2\|q(\cdot)\|^2 \\ &\qquad + 2\tau y\langle g - f, q(\cdot) - k(x, \cdot)\rangle \\ &\geq \tau\big(2\ell(f(\mathbf{x}), y) - 2\ell(g(\mathbf{x}), y) - \tau\|q(\cdot)\|^2 \\ &\qquad - 2y\langle f, q(\cdot) - k(x, \cdot)\rangle - 2\|q(\cdot) - k(x, \cdot)\| \cdot \|g\|\big) \end{aligned}$$

□

With this bound we are ready to prove Thm. 2.

Proof. Define the relative progress in each round as $\Delta_t = \|f_{t-1} - g\|^2 - \|f_t - g\|^2$. We bound the progress from above and below. On rounds in which there is no mistake Δ_t is 0. On rounds in which there is a mistake there are two possible updates: either $f_t = f_{t-1} + y_t P_{t-1} k(\mathbf{x}_t, \cdot)$ or $f_t = f_{t-1} + y_t k(\mathbf{x}_t, \cdot)$. In the following we bound the progress from below, when the update is of the former type (the same bound can be obtained for the latter type as well, but the derivation is omitted). In particular we set $q(\cdot) = P_{t-1} k(\mathbf{x}_t, \cdot)$ in

Lemma 1 and use $\delta_t = y_t P_{t-1} k(\mathbf{x}_t, \cdot) - y_t k(\mathbf{x}_t, \cdot)$ from Eq. (4)

$$\begin{aligned}\Delta_t &= \|f_{t-1} - g\|^2 - \|f_t - g\|^2 \\ &\geq \tau_t \Big(2\ell(f_{t-1}(\mathbf{x}_t), y_t) - 2\ell(g(\mathbf{x}_t), y_t) \\ &\quad - \tau_t \|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2 - 2\langle f_{t-1}, \delta_t \rangle - 2\|\delta_t\| \|g\| \Big) \ .\end{aligned}$$

Note that $\langle f_{t-1}, \delta_t \rangle = 0$, because f_{t-1} belongs to the space spanned by the functions indexed by $\mathcal{S}_{t-1}$. Moreover, on every projection update $\|\delta_t\| \leq \eta$ and using the theorem assumption $\|P_{t-1} k(\mathbf{x}_t, \cdot)\| \leq R$, we then have

$$\Delta_t \geq \tau_t \Big(2 \left(\ell(f_{t-1}(\mathbf{x}_t), y_t) - \ell(g(\mathbf{x}_t), y_t) \right) - \tau_t R^2 - 2\eta \|g\| \Big) \ .$$

We can further bound Δ_t by noting that on every prediction mistake $\ell(f_{t-1}(\mathbf{x}_t), y_t) \geq 1$. Overall we have

$$\begin{aligned}&\|f_{t-1} - g\|^2 - \|f_t - g\|^2 \geq \\ &\qquad \tau_t \Big(2 \left(1 - \ell(g(\mathbf{x}_t), y_t) \right) - \tau_t R^2 - 2\eta \|g\| \Big) \ .\end{aligned}$$

We sum over t both sides. Let τ_t be an indicator function for a mistake on the t-th round, that is, τ_t is 1 if there is a mistake on round t and 0 otherwise, hence it can be upper bounded by 1. The left hand side of the equation is a telescopic sum, hence it collapses to $\|f_0 - g\|^2 - \|f_T - g\|^2$, which can be upper bounded by $\|g\|^2$, using the fact that $f_0 = \mathbf{0}$ and that $\|f_T - g\|^2$ is non-negative. Finally, we have

$$\|g\|^2 + 2D_1 \geq M \left(2 - R^2 - 2\eta \|g\| \right) \ ,$$

where M is the number of mistakes. □

To compare with other similar algorithms it can be useful to change the formulation of the algorithm in order to use the maximum norm of g as parameter instead of η. Hence we can fix an upper bound, U, on $\|g\|$ and then we set η to have a positive progress. Specifically, on each round we set η to be

$$\frac{1}{2U} \Big(2\ell(f_{t-1}(\mathbf{x}_t), y_t) - \|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2 - 0.5 \Big) \ . \quad (13)$$

The next corollary, based on Thm. 2, provides a mistake bounds in terms of U rather than η.

Corollary 1. *Let $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_T, y_T)$ be a sequence of instance-label pairs where $\mathbf{x}_t \in \mathcal{X}$, $y_t \in \{-1, +1\}$, and $k(\mathbf{x}_t, \mathbf{x}_t) \leq 1$ for all t. Let g be an arbitrary function in $\mathcal{H}$, whose norm $\|g\|$ is bounded by U. Assume that the Projectron algorithm is run with a parameter η, which is set in each round according to Eq. (13). Then, the number of prediction mistakes the Projectron makes on the sequence is at most*

$$2\|g\|^2 + 4D_1 \ .$$

Notice that the bound in Corollary 1 is similar to Thm. 5.1 in (Dekel et al., 2007) of the Forgetron algorithm. The difference is in the assumptions made: in the Forgetron, the size of the support set is guaranteed to be less than a fixed size B that depends on U, while in the Projectron we choose the value of η or, equivalently, U, and there is no guarantee on the exact size of the support set. However, the experimental results suggest that, with the same assumptions used in the derivation of the Forgetron bound, the Projectron needs a smaller support set and produces less mistakes.

It is also possible to give yet another bound by slightly changing the proof of Thm. 2. This theorem is a worst-case mistake bound for the Projectron algorithm. We state it here without the proof, leaving it for a long version of this paper.

Theorem 3. *Let $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_T, y_T)$ be a sequence of instance-label pairs where $\mathbf{x}_t \in \mathcal{X}$, $y_t \in \{-1, +1\}$, and $k(\mathbf{x}_t, \mathbf{x}_t) \leq R$ for all t. Let g an arbitrary function in $\mathcal{H}$. Assume that the Projectron algorithm is run with $0 \leq \eta < \frac{1}{\|g\|}$. Then, M, the number of prediction mistakes the Projectron makes on the sequence is at most*

$$\left(\frac{R\|g\| + \sqrt{R^2 \|g\|^2 + 4D_1}}{2(1 - \eta\|g\|)} \right)^2$$

The last theorem suggests that the performance of the Projectron are slightly worse than the Perceptron (Shalev-Shwartz & Singer, 2005). Specifically the degradation in the performance of Projectron compared to the Perceptron are related to $1/(1-\eta\|g\|)^2$. In the next subsection we present a variant to the Projectron algorithm, which attains even better performance.

4.1. Going Beyond the Perceptron

The proof of Thm. 2 and Corollary 1 direct us how to improve the Projectron algorithm to go beyond the performance of the Perceptron algorithm, while maintaining a bounded support set.

Let us start from the algorithm in Corollary 1. We change it so an update takes place not only if there is a prediction mistake, but also when the prediction is correct with a low confidence. We indicate this latter case as a *margin error*, that is, $0 < y_t f_{t-1}(\mathbf{x}_t) < 1$. This strategy improves the classification rate but also increases the size of the support set (Crammer et al., 2006). A possible solution to this obstacle is not to update every round a margin error occurs, but also when the new instance *can be projected* onto the support set. Hence, the update on margin error rounds

would be in the general form

$$f_t = f_{t-1} + y_t \tau_t P_{t-1} k(\mathbf{x}_t, \cdot) \ , \qquad (14)$$

with $0 < \tau_t \leq 1$. The last constraint comes from proofs of Thm. 2 and Corollary 1 in which we upper bound τ_t by 1. Note that setting τ_t to 0 is equivalent to leave the hypothesis unchanged. The bound in Corollary 1 becomes

$$M \leq 2(\|g\|^2 + 2D_1 - \sum_{\{t:0<y_t f_{t-1}(\mathbf{x}_t)<1\}} \beta_t) \ , \qquad (15)$$

where β_t bounds the progress made on margin error round t. In particular it is easy to see from Lemma 1 that β_t is

$$\tau_t \big(2\ell(f_{t-1}(\mathbf{x}_t), y_t) - \tau_t \|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2 - 2U\|\delta_t\|\big) \ , \qquad (16)$$

for $0 < \tau_t \leq 1$, and is 0 when there is no update. Whenever β_t is non-negative the worst-case number of mistakes in Eq. (15) decreases, hopefully along with the classification error rate of the algorithm. Hence, we determine the optimal τ_t which maximizes β_t. In particular, the expression of β_t in Eq. (16) is quadratic in τ_t, and is maximized for $\tau_t = \ell(f_{t-1}(\mathbf{x}_t), y_t)/\|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2$. Constraining τ_t to be less than or equal to 1, we have[1]

$$\tau_t = \min\{\ell(f_{t-1}(\mathbf{x}_t), y_t)/\|P_{t-1} k(\mathbf{x}_t, \cdot)\|^2, 1\} \ . \qquad (17)$$

In summary, at every round t with margin error we calculate τ_t according to Eq. (17), and check that β_t is non-negative. If so we update the hypothesis using Eq. (14), otherwise we leave it untouched.

With this modification we expect better performance, that is, fewer mistakes, but without any increase of the support set size. We can even expect solutions with a smaller support set, since new instances can be added to the support set only if misclassified, hence having less mistakes should result in a smaller support set. We name this variant Projectron++, and in the next section we compare it to the original version.

5. Experimental Results

In this section we present experimental results that demonstrate the effectiveness of the Projectron and the Projectron++. We compare both algorithms to the Perceptron and to the budget algorithms Forgetron (Dekel et al., 2007) and Randomized Budget Perceptron (RBP) (Cesa-Bianchi et al., 2006). For the Forgetron, we choose the state-of-the-art "self-tuned" variant, which outperforms its other variants. We also use two other baseline algorithms: the first one is a Perceptron algorithm which stops updating the solution once the support size has reached some limit, and it is used to verify that the Projectron is better than just stop learning. We name it *Stoptron*. The second baseline algorithm is the PA-I variant of the Passive-Aggressive learning algorithm (Crammer et al., 2006), which gives an upper bound to the classification performance that Projectron++ can reach.

We tested the algorithms with two standard machine learning datasets: *Adults9* and *Vehicle*[2] and a synthetic dataset, all of them with more than 10000 samples. The synthetic dataset is built in the same way as in (Dekel et al., 2007). It is composed with samples taken from two separate bi-dimensional Gaussian distributions. The means of the positive and negative samples are $(1, 1)$ and $(-1, -1)$, respectively, while the covariance matrix for both is diagonal matrix with $(0.2, 2)$ as its diagonal. Then the labels are flipped with a probability of 0.1 to introduce noise.

All the experiments were performed over 5 different permutations of the training set. All algorithms used a Gaussian kernel with σ^2 equals 25, 4, and 0.5 for *Adults9*, *Vehicle*, and the synthetic datasets, respectively. The C parameter of the PA-I was set to 1, to have an update similar to the Perceptron and Projectron. Due to the different nature of our algorithm compared to the budget ones, we cannot select the support set size in hindsight. Hence, we compared them using the proper conditions to obtain the same bounds. That is, we selected the maximum support size B for the Forgetron algorithm, which implies a maximum value U, the norm of g, for its bound to hold. In particular U is equal to $1/4\sqrt{(B+1)/\log(B+1)}$ (Dekel et al., 2007), where B is the budget parameter that sets the maximum size of the support set. We then selected the parameter η in the Projectron in each round according to Eq. (13). Hence the final size of the Projectron solution will depend on U and on the particular classification problem at hand. We have set B on each dataset roughly to 1/2 and 1/4 of the size of the Perceptron support set, for a total of 6 experiments. Note that Projectron can also be used without taking into account the norm of the competitor and considering η just as a parameter. In particular η should be set to trade accuracy for sparseness.

In Tables 1–3 we summarize the results of our experiments. The cumulative number of mistakes as percentage of the training size (mean ± std) and the size of the

[1] This update rule gives $\tau_t = 1$ on rounds in which there is a mistake.

support set are reported. In all the experiments both the Projectron and the Projectron++ outperform the Forgetron and the RBP with a smaller support size. Moreover, the Projectron++ always outperforms the Projectron and has smaller support set. Due to its theoretically derived formulation, it achieves better results even if being bounded, and it has better performance than the Perceptron. In particular it gets closer to the classification rate of the PA-I, without paying the price of a large support set. It is interesting to note the performances of the Stoptron: it has an accuracy close to the other bounded algorithms in average, but with much bigger variance. This indicates that all the examined strategies for bounded learning are always better than the simple procedure to stop learning, at least to have stable performances.

Last, we show the behavior of the algorithms over time. In Fig. 1 we show the average online error rate, that is, the total numbers of errors on the examples seen as a function of the number of samples for all algorithms on the Adult9 dataset with $B = 1500$. Note how the Projectron algorithm closely tracks the Perceptron. On the other hand the Forgetron and the RBP stop improving after reaching the support set size B, around 7500 samples. The growth of the support set as a function of the number of samples is depicted in Fig. 2. While for PA-I and Perceptron the growth is clearly linear, it is sub-linear for Projectron and for the Projectron++ and they will reach a maximum size and then they will stop growing (as stated in Thm. 1). In Fig. 3 we show the average online error rate as a function of the size of the support set. It is clear that the Projectron and the Projectron++ outperform the Perceptron with smaller support set.

6. Discussion

This paper presented two different versions of a bounded online learning algorithm. The algorithms depend on a parameter that allows to trade accuracy for sparseness of the solution. The size of the solution is always guaranteed to be bounded, therefore it solves the memory explosion problem of the Perceptron and similar algorithms. Although the size of the support set is guaranteed to be bounded, the actual size of the support set cannot be determined in advance, like in the Forgetron algorithm, and it is not fixed. Practically, the size of the support set of the Projectron algorithms is much smaller than that of the budget algorithms.

Compared to budget algorithms it has the advantage of a bounded support set size without removing or scaling instances in the set. This keeps performance high. We call this algorithm Projectron. Its second variant, the Projectron++, always outperforms the standard Perceptron algorithm, while assuring a bounded solution. Another advantage over budget algorithms is the possibility to obtain bounded batch solutions using standard online-to-batch conversion. In fact using the averaging conversion (Cesa-Bianchi et al., 2004) we get a bounded solution. This is not true for budget algorithms, where more sophisticated techniques have to be used (Dekel & Singer, 2005). A similar approach has been used in (Csató & Opper, 2001) in the framework of the Gaussian Processes. However in that

Learning Dissimilarities by Ranking: From SDP to QP

Hua Ouyang HOUYANG@CC.GATECH.EDU

Alex Gray AGRAY@CC.GATECH.EDU
College of Computing, Georgia Institute of Technology

Abstract

We consider the problem of learning dissimilarities between points via formulations which preserve a specified ordering between points rather than the numerical values of the dissimilarities. *Dissimilarity ranking (d-ranking)* learns from instances like "A is more similar to B than C is to D" or "The distance between E and F is larger than that between G and H". Three formulations of d-ranking problems are presented and new algorithms are presented for two of them, one by semidefinite programming (SDP) and one by quadratic programming (QP). Among the novel capabilities of these approaches are out-of-sample prediction and scalability to large problems.

1. Introduction

Ranking or sometimes referred as *ordinal regression*, is a statistical learning problem which gained much attention recently (Cohen et al., 1998; Herbrich et al., 1999; Joachims, 2002). This problem learns from relative comparisons like "A ranks lower than B" or "C ranks higher than D". The goal is to learn an explicit or implicit function which gives *ranks* over an sampling space $\mathbb{X}$. In most of these tasks, the sampled instances to be ranked are vector-valued data in $\mathbb{R}^D$, while the ranks are real numbers which can be either discrete or continuous. If the problem is to learn a real valued ranking function, it can be stated as: given a set $\mathcal{S}$ of pairs $(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{S}$ (which indicates that the rank of $\mathbf{x}_i$ is lower than $\mathbf{x}_j$), learn a real valued $f : \mathbb{X} \to \mathbb{R}$ that satisfies $f(\mathbf{x}_m) < f(\mathbf{x}_n)$ if the rank of $\mathbf{x}_m$ is lower than $\mathbf{x}_n$.

In this paper we investigate a special ranking problem: *dissimilarity ranking* (*d-ranking*). Unlike ranking, this problem learns from instances like "A is more similar to B than C is to D" or "The distance between E and F is larger than that between G and H". Note that the dissimilarities here are not necessarily distances. Other than real vectors in conventional ranking problems, the data to be ranked here are dissimilates of pairwised data vectors. This problem can be stated as: learning an explicit or implicit function which gives ranks over a space of dissimilarities $d(\mathbb{X}, \mathbb{X}) \in \mathbb{R}$. Based on different requirements of applications, this learning problem can have various formulations. We will present some of them in Section 2.

D-ranking can be regarded as a special instance of dissimilarity learning (or metric learning). Different dissimilarity learning methods have different goals. We highlight some previous work as below.

- In metric learning methods (Hastie & Tibshirani, 1996; Xing et al., 2002), the purpose of learning a proper Mahalanobis distance is to achieve better class/cluster separations.
- In kernel learning methods (Lanckriet et al., 2004; Micchelli & Pontil, 2005), learning a proper kernel is equivalent to learning a good inner-product function which introduces a dissimilarity in the input space. The purpose is to maximize the performance of a kernel-based learning machine.
- Multidimensional scaling (MDS) (Borg & Groenen, 2005) and Isomap (Tenenbaum et al., 2000) can also be regarded as learning an implicity function $f : \mathbb{R}^D \to \mathbb{R}^L$. The purpose of learning an embedding is to preserve distances in a low-dimensional Euclidean space $\mathbb{R}^L$.

In our d-ranking problems, the purpose of learning a proper dissimilarity is to *preserve the ranks* of dissimilarities, not the absolute values of them (which is the case in MDS and Isomap). For example, if we know

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

that "The distance between A and B is smaller than that between C and D", the problem can be formulated as: find a dissimilarity function d, such that $d(A, B) < d(C, D)$.

Unlike conventional learning and ranking problems, d-ranking hasn't received intensive studies in previous research. One of the most important related work is the nonmetric multidimensional scaling (NMDS) (Borg & Groenen, 2005). Given a symmetric proximity (similarity or dissimilarity) matrix $\Delta = [\delta_{mn}]$, NMDS tries to find a low dimensional embedding space $\mathbb{R}^L$ such that $\forall \mathbf{x}_i, \mathbf{x}_j, \mathbf{x}_k, \mathbf{x}_l \in \mathbb{R}^L$, $\|\mathbf{x}_i - \mathbf{x}_j\|_2^2 < \|\mathbf{x}_k - \mathbf{x}_l\|_2^2 \Leftrightarrow \delta_{ij} < \delta_{kl}$. NMDS was recently extended to the generalized NMDS (GNMDS) (Agarwal, 2007). GNMDS does not need to know the absolute values of proximities δ_{mn}. Instead it only need a set $\mathcal{S}$ of quadruples $(i, j, k, l) \in \mathcal{S}$, which indicate that $\delta_{ij} < \delta_{kl}$.

Both NMDS and GNMDS learn an embedding space instead of learning an explicit ranking function, thus they are unable to handle out-of-sample problems. Schultz et. al. gave a solution to these problems by proposing to learn a distance metric from relative comparisons (Schultz & Joachims, 2003). They choose to learn a Mahalanobis distance which can preserve ranks of distances. Since the learned distance functions are parameterized, they can be used to handle new samples. The proposed formulation was solved in a similar manner as SVM. Nonetheless, the regularization term was not well justified.

Many applications in biology, computer vision, web search, social science etc. can be put into the framework of d-ranking problems. Take document classification as an instance. Without adequate domain knowledge, it is hard to accurately determine the quantitative dissimilarities between two documents. However, comparing the dissimilarities between every three or four documents can be easily done, either automatically or manually. Generally speaking, d-ranking is especially useful when the quantized dissimilarities are not reliable.

In Section 2, we propose three formulations of d-ranking problems. Section 3 gives the numerical solutions for solving d-ranking by SDP. Section 4 shows how to solve d-ranking by QP. The proposed methods are evaluated in Section 5. Section 6 concludes the paper.

2. Three Formulations of D-Ranking

D-ranking problems can have various formulations depending on specific requirements or settings of applications. Next we will give three formulations.

Formulation 2.1. ***(F1) Inputs**: a set $\mathcal{S}$ of ordered quadruples $(i, j, k, l) \in \mathcal{S}$, indicating that $d(\boldsymbol{x}_i, \boldsymbol{x}_j) \leq d(\boldsymbol{x}_k, \boldsymbol{x}_l)$, where $d(\cdot, \cdot)$ is a fixed but unknown dissimilarity function; **Outputs**: coefficients of embedded samples $\boldsymbol{x}_i', \boldsymbol{x}_j', \boldsymbol{x}_k', \boldsymbol{x}_l' \in \mathbb{R}^L$; **Criteria**: $(i, j, k, l) \in \mathcal{S} \Leftrightarrow \|\boldsymbol{x}_i' - \boldsymbol{x}_j'\|_2^2 \leq \|\boldsymbol{x}_k' - \boldsymbol{x}_l'\|_2^2$.*

As proposed by Agarwal et. al. (Agarwal, 2007), in **F1** we neither assume any geometry of the input space, nor assume any form of dissimilarities in it. We do not need to know the coefficients of input samples. Only ordering information is provided. Nonetheless we assume a Euclidean metric in the embedding space, which is often of low dimensions (e.g. $L = 2$, or 3). As shown in Section 3, **F1** can be formed as a problem of semidefinite programming (SDP).

Formulation 2.2. ***(F2) Inputs**: a set $\mathcal{S}$ of ordered quadruples $(i, j, k, l) \in \mathcal{S}$, indicating that $d(\boldsymbol{x}_i, \boldsymbol{x}_j) \leq d(\boldsymbol{x}_k, \boldsymbol{x}_l)$, where $d(\cdot, \cdot)$ is a fixed but unknown dissimilarity function; corresponding coefficients in the input Euclidean space $\boldsymbol{x}_i, \boldsymbol{x}_j, \boldsymbol{x}_k, \boldsymbol{x}_l \in \mathbb{R}^D$; **Outputs**: dissimilarity functions $\hat{d}(\cdot, \cdot) : \mathbb{R}^D \times \mathbb{R}^D \to \mathbb{R}$; **Criteria**: $(i, j, k, l) \in \mathcal{S} \Leftrightarrow \hat{d}(\boldsymbol{x}_i, \boldsymbol{x}_j) \leq \hat{d}(\boldsymbol{x}_k, \boldsymbol{x}_l)$.*

Unlike learning an embedding space as in **F1**, **F2** learns an explicit dissimilarity function $\hat{d}(\cdot, \cdot)$ which preserves the ranks of dissimilarities. We will show in Section 4 that **F2** can be handled in a very similar manner as support vector machines, where the quadratic programming (QP) problem can be solved efficiently by specialized sequential optimization methods. If in some cases we need to find a low dimensional Euclidean embedding of the input samples, we can then use the classical multidimensional scaling (MDS) to preserve the learned dissimilarities.

Formulation 2.3. ***(F3) Inputs**: a set $\mathcal{S}$ of ordered quadruples $(i, j, k, l) \in \mathcal{S}$, indicating that $d(\boldsymbol{x}_i, \boldsymbol{x}_j) \leq d(\boldsymbol{x}_k, \boldsymbol{x}_l)$, where $d(\cdot, \cdot)$ is a fixed but unknown dissimilarity function; corresponding coefficients in the input Euclidean space $\boldsymbol{x}_i, \boldsymbol{x}_j, \boldsymbol{x}_k, \boldsymbol{x}_l \in \mathbb{R}^D$; **Outputs**: projection function $f : \mathbb{R}^D \to \mathbb{R}^L$, $\boldsymbol{x}_i', \boldsymbol{x}_j', \boldsymbol{x}_k', \boldsymbol{x}_l' \in \mathbb{R}^L$; **Criteria**: $(i, j, k, l) \in \mathcal{S} \Leftrightarrow \|\boldsymbol{x}_i' - \boldsymbol{x}_j'\|_2^2 \leq \|\boldsymbol{x}_k' - \boldsymbol{x}_l'\|_2^2$.*

Although we formulate **F3** as a function learning problem, currently we have not found any efficient method to solve it. This formulation will remains as our future work.

3. Solving F1 by SDP

F1 was studied by Agarwal et. al. (Agarwal, 2007). The authors proposed GNMDS which can be solved as

a SDP, as shown in Eq.(1).

$$\begin{aligned} &\text{GNMDS:} \\ \min\ & \sum_{ijkl\in\mathcal{S}} \xi_{ijkl} + \lambda \mathrm{tr(K)}, \\ \text{s.t. } & (K_{kk} - 2K_{kl} + K_{ll}) - (K_{ii} - 2K_{ij} + K_{jj}) \\ & + \xi_{ijkl} \geq 1, \\ & \sum_{ab} K_{ab} = 0,\ \xi_{ijkl} \geq 0,\ K \succeq 0, \\ & \text{for all } (i,j,k,l) \in \mathcal{S}. \end{aligned} \tag{1}$$

The main idea of GNMDS is to learn a positive semidefinite Gram matrix $K = X^T X$ which can be eigen-decomposed to recover the embedded samples. The relation between Euclidian distances and the Gram matrix is used:

$$\|\mathbf{x}_i - \mathbf{x}_j\|_2^2 = K_{ii} - 2K_{ij} + K_{jj}. \tag{2}$$

Nonetheless, the constraints that contain order information of dissimilarities are not sufficient to determine a unique K, since any rotation, translation or scaling can also satisfies these constraints. To reduce these ambiguities, they use $\sum_{ab} K_{ab} = 0$ to center all the embedded samples at the origin.

It is preferable in many applications to find low dimensional embedding spaces, e.g. 2D or 3D Euclidean space. Thus a low-rank K is desired. Unfortunately, minimizing rank(K) subject to linear inequality constraints is NP-Hard (Vandenberghe & Boyd, 1996). Thus the objective function is relaxed heuristically as minimizing trace(K), which is a convex envelope of the rank.

Figure 1 shows the result of GNMDS on a toy problem. The inputs are 990 pairwise ranks of distances between 10 European cities. The outputs are the recovered 2D coefficients. It can be observed that the recovered locations of the cities do not correspond to the true locations. Actually only 789 out of 990 pairs of ranks are preserved by the learned 2D embedding, i.e. 20.3% error rate. Figure 2 shows the 10 sorted eigenvalues of the Gram matrix K. Although the original space is a 2D Euclidean space, the first 2 eigenvalues only account for 49.4% of the total variation.

There are at least two reasons that account for the poor performance of GNMDS. Firstly, there is no guarantee on the quality of the solution of the relaxed problem compared with the original problem. There may exist some higher dimensional spaces which satisfy all the constants while have smaller traces than lower dimensional spaces. Secondly, due to the introduction of

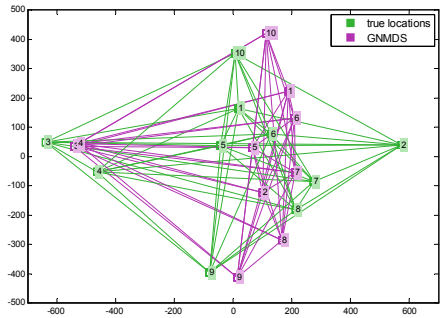

Figure 1. d-ranking toy problem: locations of ten European cities. Purple: true locations. Green: locations recovered by GNMDS. All the coefficients have been scaled before plotting.

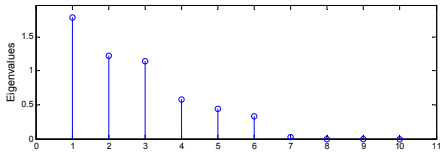

Figure 2. 10 sorted eigenvalues of the Gram matrix K learned by GNMDS.

slack variables ξ_{ijkl} in the inequality constraints, the learned embedding tends to push all the samples to the same point. The first problem can be solved by introducing better heuristics of the convex envelope of the rank. The second problem can be solved by the following slight modification of GNMDS:

$$\begin{aligned} &\text{Modified GNMDS:} \\ \min\ & \sum_{ijkl\in\mathcal{S}} \xi_{ijkl} + \lambda \mathrm{tr(K)}, \\ \text{s.t. } & (K_{kk} - 2K_{kl} + K_{ll}) - (K_{ii} - 2K_{ij} + K_{jj}) \\ & - \xi_{ijkl} \geq 1, \\ & \sum_{ab} K_{ab} = 0,\ \xi_{ijkl} \geq 0,\ K \succeq 0, \\ & \text{for all } (i,j,k,l) \in \mathcal{S}. \end{aligned} \tag{3}$$

The modified GNMDS just changes the slack variables from $+\xi_{ijkl}$ to $-\xi_{ijkl}$. This simple trick can ensure that all the differences between distances k,l and i,j are larger than 1, thus pulls the embedding samples apart. Figure 3 shows toy problem solved by the modified GNMDS. The recovered samples are closer to the true locations than those in Figure 1. There are 850 out of 990 pairs of ranks correctly preserved, i.e. 14.14% error rate, which is 6% lower than GNMDS. Figure

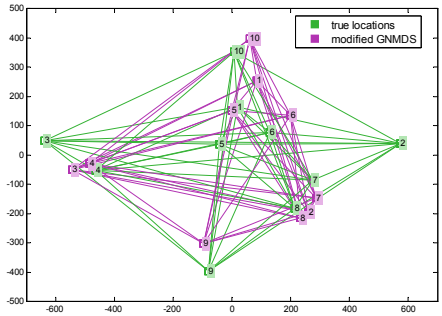

Figure 3. d-ranking toy problem: locations of ten European cities. Purple: true locations. Green: locations recovered by modified GNMDS. All the coefficients have been scaled before plotting.

4 shows the 10 eigenvalues of K learned by modified GNMDS. The first 2 eigenvalues account to 69.8% of the total variant, which is 20% higher than GNMDS.

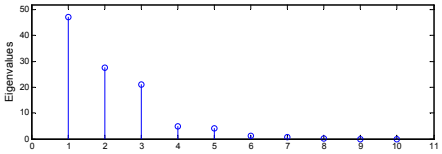

Figure 4. 10 sorted eigenvalues of the Gram matrix K learned by modified GNMDS.

4. Solving F2 by QP

As introduced in Section 2, instead of learning an embedding as in **F1**, a dissimilarity function $d(\mathbf{x}_i, \mathbf{x}_j) : \mathbb{X} \times \mathbb{X} \to \mathbb{R}$ is learned in **F2**, such that all the training ranks between $d(\cdot, \cdot)$ are preserved, and can generalize to new samples. This is indeed a dissimilarity learning problem.

Many previous metric learning methods (Hastie & Tibshirani, 1996; Goldberger et al., 2004; Kwok & Tsang, 2003) try to learn an alternative dissimilarity function by replacing the Euclidean metric with an properly learnt Mahalanobis metric, either globally or locally.

In this section we propose the *d-ranking Vector Machine* (*d-ranking-VM*) method. Unlike metric learning methods, d-ranking-VM is explicitly regularized. Thus we can have a full control over the complexity of $d(\mathbf{x}_i, \mathbf{x}_j)$. D-ranking-VM utilizes the technique of hyperkernel learning (Ong et al., 2005) which was originally proposed for learning a proper kernel.

D-ranking-VM is formulated as the following optimization problem:

$$\begin{aligned} &\text{d-ranking-VM (primal):} \\ \min\ & \frac{1}{N}\sum_{ijkl\in\mathcal{S}} \xi_{ijkl} + \lambda \|d\|^2_{\underline{\mathbb{H}}}, \\ \text{s.t. }\ & d(\mathbf{x}_k, \mathbf{x}_l) - d(\mathbf{x}_i, \mathbf{x}_j) - \xi_{ijkl} \geq 1, \\ & \xi_{ijkl} \geq 0, \\ & \text{for all } (i,j,k,l) \in \mathcal{S}. \end{aligned} \tag{4}$$

where $N = |\mathcal{S}|$. $\underline{\mathbb{H}}$ is a hyper-reproducing kernel Hilbert space (hyper-RKHS) from which the function $d : \mathbb{X} \times \mathbb{X} \to \mathbb{R}$ is drawn.

Like the representer theorem in RKHS (Kimeldorf & Wahba, 1971), there is also a representer theorem in hyper-RHKS (see (Ong et al., 2005) or (Kondor & Jebara, 2006) for the theorem and proofs):

$$d(\underline{\mathbf{x}}) = \sum_{p=1}^{M} c_p \underline{K}(\underline{\mathbf{x}}_p, \underline{\mathbf{x}}), \tag{5}$$

where $\underline{K}$ is a semidefinite hyperkernel, $\underline{\mathbf{x}}$ denotes a pair of samples $(\mathbf{x}_i, \mathbf{x}_j)$, and M is the number of distinct dissimilarity pairs provided by the training rank data $\mathcal{S}$. We denote the set of dissimilarity pairs as $\mathcal{D}$, and $M = |\mathcal{D}|$. Normally we have $M > N$ (the discussion of M and N is given in Section 5.1).

Substitute Eq.(5) into (4), we can change the primal problem to the following form:

$$\begin{aligned} \min\ & \frac{1}{N}\sum_{p\in\mathcal{S}} \xi_p + \lambda C^T \underline{K} C, \\ \text{s.t. }\ & \sum_{p=1}^{M} c_p \underline{K}(\underline{\mathbf{x}}_p; \mathbf{x}_k, \mathbf{x}_l) - \sum_{p=1}^{M} c_p \underline{K}(\underline{\mathbf{x}}_p; \mathbf{x}_i, \mathbf{x}_j) \\ & - \xi_p \geq 1, \\ & \xi_p \geq 0, \text{for all } p \in \mathcal{S}, \end{aligned} \tag{6}$$

where $C \in \mathbb{R}^M$ is a vector with the ith element being c_p, and $\underline{K} \in \mathbb{R}^{M\times M}$ is the hyper-kernel matrix.

The dual problem of (6) can be derived by using the Lagrangian technique. The solution to this optimization problem is given by the saddle point of the Lagrangian function:

$$\begin{aligned} L(C, \xi_p, \alpha_p, \zeta_p) = & \frac{1}{N}\sum_{p\in\mathcal{S}} \xi_p + \lambda C^T \underline{K} C - \sum_{p=1}^{N} \zeta_p \xi_p \\ & + \sum_{p=1}^{N} \alpha_p \left\{ \sum_{s=1}^{M} c_s \left[\underline{K}(\underline{\mathbf{x}}_s; \mathbf{x}_i, \mathbf{x}_j) - \underline{K}(\underline{\mathbf{x}}_s; \mathbf{x}_i, \mathbf{x}_j) \right] + 1 + \xi_p \right\}, \end{aligned} \tag{7}$$

where ζ_p and α_p are non-negative Lagrange multipliers. The primal problem is convex, thus there exist a strong duality between the primal and the dual. Utilizing the KKT optimality condition, we have:

$$\frac{\partial L}{\partial C} = 2\lambda \underline{K} C + \underline{K}(P-Q)A = 0, \tag{8}$$

and

$$\frac{\partial L}{\partial \xi_p} = \frac{1}{N} + \lambda_p - \zeta_p = 0, \tag{9}$$

where $A \in \mathbb{R}^N$ is a vector with the pth element being α_p. $P, Q \in \mathbb{R}^{M\times N}$ are two matrices with contain the rank information. Each column $p_{x\cdot}(x = 1 \dots N)$ of P and each column $q_{x\cdot}(x = 1 \dots N)$ of Q only contain one 1 and $M-1$ 0s. For example, if the rth training quadruples in $\mathcal{S}$ is (i, j, k, l), which means that $d(\mathbf{x}_i, \mathbf{x}_j) < d(\mathbf{x}_k, \mathbf{x}_l)$, and if the pair (i, j) is the mth element in $\mathcal{D}$, while (k, l) is the $n$the element in $\mathcal{D}$, then $p_{rm} = 1$ and $q_{rn} = 1$.

From Eq.(8) and (9) we have:

$$C = \frac{(Q-P)A}{2\lambda}, \tag{10}$$

and

$$\alpha_p = \zeta_p - \frac{1}{N} \tag{11}$$

Substitute Eq.(10) and (11) into (6), we arrive at the following *dual* problem for d-ranking-VM:

$$\begin{aligned} &\text{d-ranking-VM (dual):} \\ &\max \sum_{p=1}^{N} \alpha_p - \frac{A^T(Q-P)^T \underline{K}(Q-P)A}{4\lambda}, \\ &\text{s.t. } \alpha_p \geq 0, \\ &\text{for all } (i,j,k,l) \in \mathcal{S}. \end{aligned} \tag{12}$$

This problem is a quadratic programming (QP) problem which shares a similar form as SVM. Thus the sequential optimization techniques of SVM can be readily employed for d-ranking-VM. To perform testing, we can use the learnt dissimilarity function in Eq.(5) and make pairwise comparisons.

An important problem for kernel learning methods is the selection of proper kernels. This problem also exists in hyperkernel learning methods. Here we propose some examples of hyperkernels, which are hyperextensions of Gaussian RBF kernels and polynomial kernels. The construction of these hyperkernels are based on the following proposition.

Proposition 4.1. *Let $k_a(\cdot,\cdot)$ and $k_b(\cdot,\cdot)$ be positive definite kernels, then $\forall \boldsymbol{x}_1, \boldsymbol{x}_1', \boldsymbol{x}_2, \boldsymbol{x}_2' \in \mathbb{X}$, and $\forall \alpha, \beta > 0$, $\big(k_a(\boldsymbol{x}_1, \boldsymbol{x}_2)\big)^\alpha \big(k_b(\boldsymbol{x}_1', \boldsymbol{x}_2')\big)^\beta$ or $\alpha k_a(\boldsymbol{x}_1, \boldsymbol{x}_2) + \beta k_b(\boldsymbol{x}_1', \boldsymbol{x}_2')$ can give a hyperkernel $\underline{k}$.*

Proof. See appendix. □

Example 4.2. ***(Gaussian symmetric product hyperkernel)*** *Let k_a and k_b be the same Gaussian RBF kernel $k(\boldsymbol{x}, \boldsymbol{x}') = \exp\big(-\frac{\|\boldsymbol{x}-\boldsymbol{x}'\|^2}{2\sigma^2}\big)$, and let $\alpha = \beta = 1$, the Gaussian symmetric product hyperkernel is given by:*

$$\begin{aligned} &\underline{k}\big((\boldsymbol{x}_1, \boldsymbol{x}_1'), (\boldsymbol{x}_2, \boldsymbol{x}_2')\big) = k(\boldsymbol{x}_1, \boldsymbol{x}_1') k(\boldsymbol{x}_2, \boldsymbol{x}_2') \\ &= \exp\bigg(-\frac{\|\boldsymbol{x}_1 - \boldsymbol{x}_1'\|^2 + \|\boldsymbol{x}_2 - \boldsymbol{x}_2'\|^2}{2\sigma^2}\bigg) \end{aligned} \tag{13}$$

Example 4.3. ***(Gaussian symmetric sum hyperkernel)*** *Under the same conditions as Example 4.2, we can construct the Gaussian symmetric sum hyperkernel as:*

$$\begin{aligned} &\underline{k}\big((\boldsymbol{x}_1, \boldsymbol{x}_1'), (\boldsymbol{x}_2, \boldsymbol{x}_2')\big) = k(\boldsymbol{x}_1, \boldsymbol{x}_1') + k(\boldsymbol{x}_2, \boldsymbol{x}_2') \\ &= \exp\bigg(-\frac{\|\boldsymbol{x}_1 - \boldsymbol{x}_1'\|^2}{2\sigma^2}\bigg) + \exp\bigg(-\frac{\|\boldsymbol{x}_2 - \boldsymbol{x}_2'\|^2}{2\sigma^2}\bigg) \end{aligned} \tag{14}$$

Example 4.4. ***(polynomial symmetric product hyperkernel)*** *Let k_a and k_b be the same polynomial kernel $k(\boldsymbol{x}, \boldsymbol{x}') = \big(\langle \boldsymbol{x}, \boldsymbol{x}' \rangle + q\big)^p$, and let $\alpha = \beta = 1$, we can construct the polynomial symmetric product hyperkernel as:*

$$\underline{k}\big((\boldsymbol{x}_1, \boldsymbol{x}_1'), (\boldsymbol{x}_2, \boldsymbol{x}_2')\big) = \big(\langle \boldsymbol{x}_1, \boldsymbol{x}_1' \rangle + q\big)^p \big(\langle \boldsymbol{x}_2, \boldsymbol{x}_2' \rangle + q\big)^p \tag{15}$$

Example 4.5. ***(polynomial symmetric sum hyperkernel)*** *Under the same conditions as Example 4.4, we can construct the polynomial symmetric sum hyperkernel as:*

$$\underline{k}\big((\boldsymbol{x}_1, \boldsymbol{x}_1'), (\boldsymbol{x}_2, \boldsymbol{x}_2')\big) = \big(\langle \boldsymbol{x}_1, \boldsymbol{x}_1' \rangle + q\big)^p + \big(\langle \boldsymbol{x}_2, \boldsymbol{x}_2' \rangle + q\big)^p \tag{16}$$

5. Experiments

The proposed d-ranking methods in Section 3 and Section 4 are evaluated by several experiments.

5.1. Obtaining Ranks of Pairs from Data

To test our methods, we need to obtain pairwise distance ranks. This can be done in many ways. Generally speaking, for a problem of n data samples, the total number of available distance pairs are $M = C_n^2 = \frac{n(n-1)}{2}$ (if we take $d(\mathbf{x}_i, \mathbf{x}_j)$ and $d(\mathbf{x}_j, \mathbf{x}_i)$ as the same

distance). The total number of pairwise distance ranks are $N = C_M^2 = \frac{M(M-1)}{2} = \frac{n^4}{8} - \frac{n^3}{4} - \frac{n^2}{8} + \frac{n}{4}$ (if we take $d(\mathbf{x}_i, \mathbf{x}_j) < d(\mathbf{x}_k, \mathbf{x}_l)$ and $d(\mathbf{x}_k, \mathbf{x}_l) > d(\mathbf{x}_i, \mathbf{x}_j)$ as the same rank pair). Table 1 gives some examples of the relation between n and N. When n grows, the number of rank constraints will increase dramatically. Even solving a problem of $n > 100$ will be impossible for some optimization solvers.

Table 1. Some examples of N v.s. n.

n	2	3	4	10	20	50	100	1000
N	0	3	15	990	17955	749700	12248775	1.2475e+11

Here we reduce N by considering order transitivities, i.e. if $A > B$ and $B > C$, then the rank pair $A > C$ can be ignored (automatically satisfied) in the optimization constraints. The method is very simple. Firstly we sort the M distances decreasingly. Then we take the adjacent two distances to form one distance rank pair. By doing this, N can be reduced to $\frac{n^2}{2} - \frac{n}{2} - 1$. This is the maximum number of N which carries full rank information of all the distances. Of course in some applications, the rank information is not be fully given, and $N < \frac{n^2}{2} - \frac{n}{2} - 1$.

We test our method on three data sets: 1) 2D locations of 109 largest cities in the continental US; 2) 100 images of handwritten digits "3" and "5" from the USPS database, each of size 16×16; 3) 126 face images of 4 people from the UMist database, each of size 112×92.

For GNMDS and modified GNMDS methods, all ranks of distance pairs are fed to a SDP solver, and the recovered 2D embeddings are plotted. We used SeDuMi (Strum, 1999) to get the results given in the following subsection. For d-ranking-VM, LibSVM (Chang & Lin, 2001) is employed as our QP solver. It is implemented by employing the sequential minimal optimization (SMO) technique. The learned dissimilarities are used as a "pseudo-distances", and are fed to the classical MDS. The recovered 2D embeddings are then plotted.

5.2. Results of US Cities

In this data set, $n = 109$ and $N = 5885$. Every location of the cities is given by a 2D coefficient. Figure 5 shows the true locations. Figure 6 shows the results given by GNMDS.

It can be observed that GNMDS cannot correctly recover the embedding based on distance ranks. Most of the embedded samples are pushed to a line. 50.3% of the distances ranks are preserved, which are the results of randomness. This gives an evidence to the analysis in Section 3. Figure 7 shows the result given by the modified GNMDS. The recovered embedding roughly reflects the geometry of the cities. 74.5% of the distances ranks have been preserved. Since the distance information is not provided, there is no hope to match the true locations exactly.

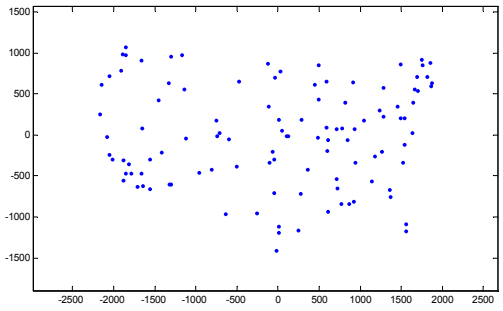

Figure 5. Locations of 109 largest cities in the continental United States.

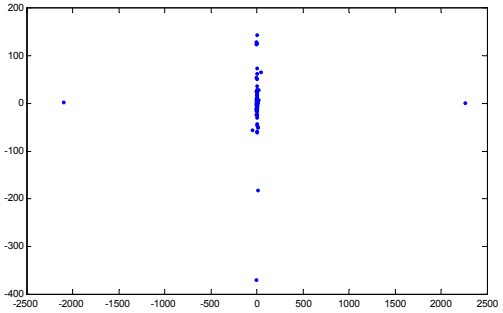

Figure 6. Recovered locations of 109 US cities given by GNMDS.

Figure 8 shows the results given by d-ranking-VM, where $\lambda = 10$, and the Gaussian symmetric product hyperkernel is used, with $\sigma = 15$. 97.9% of the distances ranks are preserved.

Table 2 shows the runtime of the above experiments.

Table 2. Runtime comparison for the three d-ranking methods.

Method	Runtime(minutes)
GNMDS	124
modified GNMDS	71
d-ranking-VM	4.5

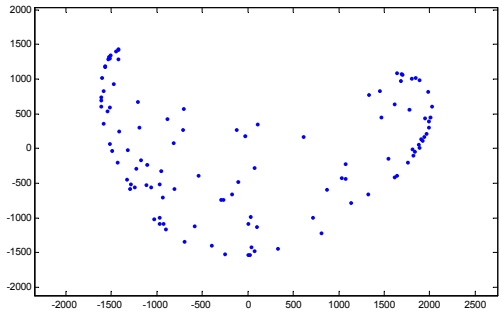

Figure 7. Recovered locations of 109 US cities given by the modified GNMDS.

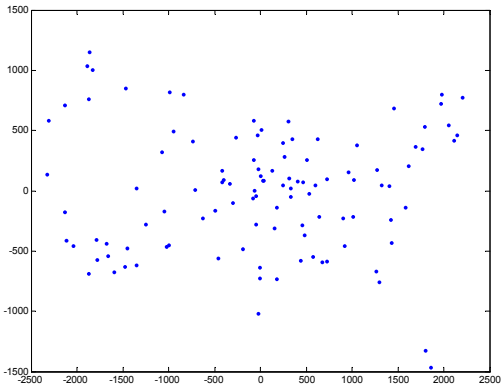

Figure 8. Recovered locations of 109 US cities given by the d-ranking-VM, using Gaussian symmetric product hyperkernel.

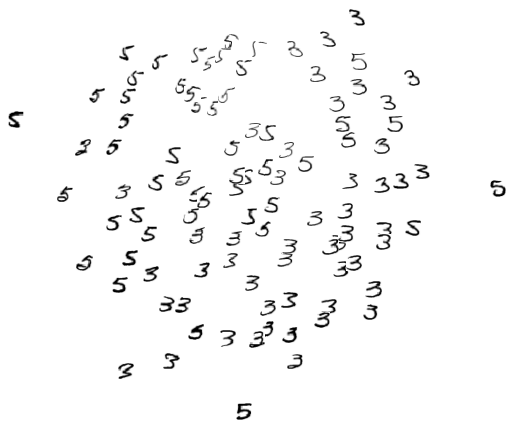

Figure 9. Recovered locations of USPS handwritten digits "3" and "5" given by d-ranking-VM.

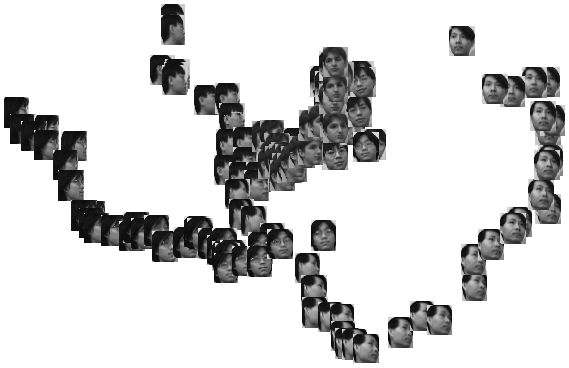

Figure 10. Recovered locations of UMist human faces given by d-ranking-VM.

5.3. Results of USPS Handwritten Digits

In this data set, $n = 100$ and $N = 4949$. The dimension every data sample is $16 \times 16 = 256$. Figure 9 shows the recovered 2D results given by RnakD-VM.

5.4. Results of UMist Human Faces

In this data set, $n = 126$ and $N = 7874$. The dimension every data sample is $112 \times 92 = 10304$. Figure 10 shows the recovered 2D results given by RnakD-VM.

6. Discussions and Conclusions

We have presented three d-ranking formulations, and give numerical solutions for two of them, namely solving d-ranking by SDP and solving d-ranking by QP. Each of them has its advantages and shortcomings. We list some pros and cons from different perspectives:

- Pros for d-ranking by SDP (GNMDS and the modified version): It can recover low dimensional embedding directly. Only ordering information is needed. There is no need to know the values of sample coefficients.
- Cons for d-ranking by SDP (GNMDS and the modified version): Solving SDP is hard, especially for large scale problems. Even sophistries SDP solver can only solve $N < 10^3$ problems with the number of constraints less than 10^5. It cannot be used to predict unseen samples.
- Pros for d-ranking by QP (d-ranking-VM): Solving QP in our case is much easier than SDP, since it can be converted to a similar form as SVM. Using sequential methods (SMO), can solve $N > 10^5$ problems. The learn dissimilarity function can be used to predict unseen samples.
- Cons for d-ranking by QP (d-ranking-VM): It can-

not recover low-dimensional embedding explicitly. One needs to use MDS or other embedding methods after learning the dissimilarities. Learning dissimilarity measure needs to know the coefficients of original samples. Like kernel methods, how to choose a good hyperkernel is crucial in solving a specific problem.

To our knowledge, this is the first work which brings out-of-sample prediction capability and large-scale scalability to d-ranking problems. Note that the technique of d-ranking-VM can also be employed in solving distances preserving problems. We will investigate the regularization properties and evaluate the performances of different hyperkernels in the following research. Finding a numerical solution for formulation **F3** will also be our future work.

7. Appendix: Proof of Proposition 4.1

We need to prove that $\underline{k}$ is a kernel on $\mathbb{X}^2$.

Denote $\bigotimes$ as the Kronecker product of two matrices $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{p\times q}$:

$$A \bigotimes B = \begin{bmatrix} a_{11}B & \cdots & a_{1n}B \\ \vdots & \ddots & \vdots \\ a_{m1}B & \cdots & a_{mn}B \end{bmatrix}, \qquad (17)$$

and define $\bigoplus$ as:

$$A \bigoplus B = \begin{bmatrix} a_{11}\mathbb{1} + B & \cdots & a_{1n}\mathbb{1} + B \\ \vdots & \ddots & \vdots \\ a_{m1}\mathbb{1} + B & \cdots & a_{mn}\mathbb{1} + B \end{bmatrix}, \qquad (18)$$

where $\mathbb{1}$ is a matrix of all ones.

Denote the kernel matrix of $k_a(\mathbf{x}_1, \mathbf{x}_2)$ as K_a, and that of $k_b(\mathbf{x}_1^{'}, \mathbf{x}_2^{'})$ as K_b. Denote the hyperkernel matrix of $\underline{k}$ as $\underline{K}$.

It is easy to verify that we can construct $\underline{K} = K_a \bigotimes K_b$. Since K_a and K_b are positive definite, their eigenvalues μ_a and μ_b are positive. Thus the eigenvalues of $\underline{K}$: $v_{ij} = \alpha\beta\mu_{ai}\mu_{bj}$ are also positive. A symmetric matrix $\underline{K}$ with positive eigenvalues is positive definite. Thus $\underline{k} = \big(k_a(\mathbf{x}_1, \mathbf{x}_2)\big)^{\alpha}\big(k_b(\mathbf{x}_1^{'}, \mathbf{x}_2^{'})\big)^{\beta}$ is a valid hyperkernel.

We can also verify that $\alpha K_a \bigoplus \beta K_b = \alpha K_a \bigotimes \mathbb{1} + \beta\mathbb{1} \bigotimes K_b$. Since K_a, K_b and $\mathbb{1}$ are all positive semidefinite and $\alpha, \beta > 0$, $\underline{K} = \alpha K_a \bigoplus \beta K_b$ is positive semidefinite. Thus $\underline{k} = \alpha k_a(\mathbf{x}_1, \mathbf{x}_2) + \beta k_b(\mathbf{x}_1^{'}, \mathbf{x}_2^{'})$ is a valid hyperkernel.

Abstract

Modeling long-term dependencies in time series has proved very difficult to achieve with traditional machine learning methods. This problem occurs when considering music data. In this paper, we introduce a model for rhythms based on the distributions of distances between subsequences. A specific implementation of the model when considering Hamming distances over a simple rhythm representation is described. The proposed model consistently outperforms a standard Hidden Markov Model in terms of conditional prediction accuracy on two different music databases.

1. Introduction

Reliable models for music would be useful in a broad range of applications, from contextual music generation to on-line music recommendation and retrieval. However, modeling music involves capturing long-term dependencies in time series, which has proved very difficult to achieve with traditional statistical methods. Note that the problem of long-term dependencies is not limited to music, nor to one particular probabilistic model (Bengio et al., 1994).

Music is characterized by strong hierarchical dependencies determined in large part by *meter*, the sense of strong and weak beats that arises from the interaction among hierarchical levels of sequences having nested periodic components. Such a hierarchy is implied in western music notation, where different levels are indicated by kinds of notes (whole notes, half notes, quarter notes, etc.) and where bars establish measures of an equal number of beats. Meter and rhythm provide a framework for developing musical melody. For example, a long melody is often composed by repeating with variation shorter sequences that fit into the metrical hierarchy (e.g. sequences of 4, 8 or 16 measures). It is well know in music theory that *distance patterns* are more important than the actual choice of notes in order to create coherent music (Handel, 1993). In this work, distance patterns refer to distances between subsequences of equal length in particular positions. For instance, measure 1 may be always similar to measure 5 in a particular musical genre. In fact, even random music can sound structured and melodic if it is built by repeating random subsequences with slight variation.

Many algorithms have been proposed for audio beat tracking (Dixon, 2007; Scheirer, 1998). Probabilistic models have also been proposed for tempo tracking and inference of rhythmic structure in musical audio (Whiteley et al., 2007; Cemgil & Kappen, 2002). The goal of these models is to align rhythm events with the metrical structure. However, simple Markovian assumptions are used to model the transitions between rhythms themselves. Hence, these models do not take into account long-term dependencies. A few generative models have already been proposed for music in general (Pachet, 2003; Dubnov et al., 2003). While these models generate impressive musical results, we are not aware of quantitative comparisons between models of music with machine learning standards, as it is done in Section 3 in terms of out-of-sample prediction accuracy. In this paper, we focus on modeling rhyth-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

mic sequences, ignoring for the moment other aspects of music such as pitch, timbre and dynamics. However, by capturing aspects of global temporal structure in music, this model should be valuable for full melodic prediction and generation: combined with an audio transcription algorithm, it should help improve the poor performance of state-of-the-art transcription systems; it could as well be included in genre classifiers or automatic composition systems (Eck & Schmidhuber, 2002); used to generate rhythms, the model could act as a drum machine or automatic accompaniment system which learns by example.

Our main contribution is to propose a generative model for distance patterns, specifically designed for capturing long-term dependencies in rhythms. In Section 2, we describe the model, detail its implementation and present an algorithm using this model for rhythm prediction. The algorithm solves a constrained optimization problem, where the distance model is used to filter out rhythms that do not comply with the inferred structure. The proposed model is evaluated in terms of conditional prediction error on two distinct databases in Section 3 and a discussion follows.

2. Distance Model

In this Section, we present a generative model for distance patterns and its application to rhythm sequences. Such a model is appropriate for most music data, where distances between subsequences of data exhibit strong regularities.

2.1. Motivation

Let $\mathbf{x}^l = (x^l_1, \ldots, x^l_m) \in \mathbb{R}^m$ be the l-th rhythm sequence in a dataset $\mathcal{X} = \{\mathbf{x}^1, \ldots, \mathbf{x}^n\}$ where all the sequences contain m elements. Suppose that we construct a *partition* of this sequence by dividing it into ρ parts defined by $y^l_i = (x^l_{1+(i-1)m/\rho}, \ldots, x^l_{im/\rho})$ with $i \in \{1, \ldots, \rho\}$. We are interested in modeling the distances between these subsequences, given a suitable metric $d(y_i, y_j) : \mathbb{R}^{m/\rho} \times \mathbb{R}^{m/\rho} \to \mathbb{R}$. As was pointed out in Section 1, the distribution of $d(y_i, y_j)$ for each specific choice of i and j may be more important when modeling rhythms (and music in general) than the actual choice of subsequences y_i.

Hidden Markov Models (HMM) (Rabiner, 1989) are commonly used to model temporal data. In principle, an HMM is able to capture complex regularities in patterns between subsequences of data, provided its number of hidden states is large enough. However, when dealing with music, such a model would lead to a learning process requiring a prohibitive amount of data: in order to learn long range interactions, the training set should be representative of the joint distribution of subsequences. To overcome this problem, we summarize the joint distribution of subsequences by the distribution of distances between these subsequences. This summary is clearly not a sufficient statistics for the distribution of subsequences, but its distribution can be learned from a limited number of examples. The resulting model, which generates distances, is then used to recover subsequences.

2.2. Decomposition of Distances

Let $D(\mathbf{x}^l) = (d^l_{i,j})_{\rho\times\rho}$ be the distance matrix associated with each sequence $\mathbf{x}^l$, where $d^l_{i,j} = d(y^l_i, y^l_j)$. Since $D(\mathbf{x}^l)$ is symmetric and contains only zeros on the diagonal, it is completely characterized by the upper triangular matrix of distances *without* the diagonal. Hence,

$$p(D(\mathbf{x}^l)) = \prod_{i=1}^{\rho-1} \prod_{j=i+1}^{\rho} p(d^l_{i,j} | S_{l,i,j}) \tag{1}$$

where

$$S_{l,i,j} = \{d^l_{r,s} | \quad (1 < s < j \text{ and } 1 \le r < s) \\ \text{or} \quad (s = j \text{ and } 1 \le r < i)\} \ . \tag{2}$$

In words, we order the elements column-wise and do a standard factorization, where each random variable depends on the previous elements in the ordering. Hence, we do not assume any conditional independence between the distances.

Since $d(y_i, y_j)$ is a metric, we have that $d(y_i, y_j) \le d(y_i, y_k) + d(y_k, y_j)$ for all $i, j, k \in \{1, \ldots, \rho\}$. This inequality is usually referred to as the *triangle inequality*. Defining

$$\begin{aligned} \alpha^l_{i,j} &= \min_{k\in\{1,\ldots,(i-1)\}} (d^l_{k,j} + d^l_{i,k}) \text{ and} \\ \beta^l_{i,j} &= \max_{k\in\{1,\ldots,(i-1)\}} (|d^l_{k,j} - d^l_{i,k}|) \ , \end{aligned} \tag{3}$$

we know that given previously observed (or sampled) distances, constraints imposed by the triangle inequality on $d^l_{i,j}$ are simply

$$\beta^l_{i,j} \le d^l_{i,j} \le \alpha^l_{i,j} \ . \tag{4}$$

One may observe that the boundaries given in Eq. (3) contain a subset of the distances that are on the conditioning side of each factor in Eq. (1) for each indexes i and j. Thus, constraints imposed by the triangle inequality can be taken into account when modeling each factor of $p(D(\mathbf{x}^l))$: each $d^l_{i,j}$ must lie in the interval imposed by previously observed/sampled distances given

in Eq. (4). Figure 1 shows an example where $\rho = 4$. Using Eq. (1), the distribution of $d^l_{2,4}$ would be conditioned on $d^l_{1,2}$, $d^l_{1,3}$, $d^l_{2,3}$, and $d^l_{1,4}$, and Eq. (4) reads $|d^l_{1,2} - d^l_{1,4}| \leq d^l_{2,4} \leq d^l_{1,2} + d^l_{1,4}$. Then, if subsequences y^l_1 and y^l_2 are close and y^l_1 and y^l_4 are also close, we know that y^l_2 and y^l_4 cannot be far. Conversely, if subsequences y^l_1 and y^l_2 are far and y^l_1 and y^l_4 are close, we know that y^l_2 and y^l_4 cannot be close.

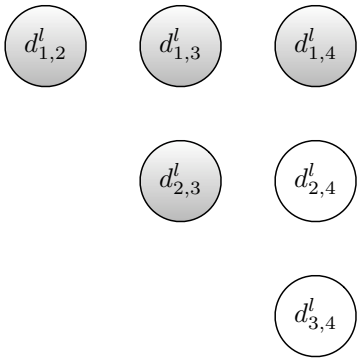

Figure 1. Each circle represents the random variable associated with the corresponding factor in Eq. (1), when $\rho = 4$. For instance, the conditional distribution for $d^l_{2,4}$ possibly depends on the variables associated to the grey circles.

2.3. Modeling Relative Distances Between Rhythms

We want to model rhythms in a music dataset $\mathcal{X}$ consisting of melodies of the same musical genre. We first quantize the database by segmenting each song in m time steps and associate each note to the nearest time step, such that all melodies have the same length m[1]. It is then possible to represent rhythms by sequences containing potentially three different symbols: 1) Note onset, 2) Note continuation, and 3) Silence. When using quantization, there is a one to one mapping between this representation and the set of all possible rhythms. Using this representation, symbol 2 can never follow symbol 3. Let $A = \{1, 2, 3\}$; in the remaining of this paper, we assume that $\mathbf{x}^l \in A^m$ for all $\mathbf{x}^l \in \mathcal{X}$.

When using this representation, $d^l_{i,j}$ can simply be chosen to be the Hamming distance (i.e. counting the number of positions on which corresponding symbols are different.) One could think of using more general edit distance such as the Levenshtein distance. However, this approach would not make sense psychoacoustically: doing an insertion or a deletion in a rhythm produces a translation that alters dramatically the nature of the sequence. Putting it another way, rhythm perception heavily depends on the *position* on which rhythmic events occur. In the remainder of this paper, $d^l_{i,j}$ is the Hamming distance between subsequences y_i and y_j.

We now have to encode our belief that melodies of the same musical genre have a common distance structure. For instance, drum beats in rock music can be very repetitive, except in the endings of every four measures, without regard to the actual beats being played. This should be accounted for in the distributions of the corresponding $d^l_{i,j}$. With Hamming distances, the conditional distributions of $d^l_{i,j}$ in Eq. (1) should be modeled by discrete distributions, whose range of possible values *must* obey Eq. (4). Hence, we assume that the random variables $(d^l_{i,j} - \beta^l_{i,j})/(\alpha^l_{i,j} - \beta^l_{i,j})$ should be identically distributed for $l = 1, \ldots, n$. As an example, suppose that measures 1 and 4 always tend to be far away, that measures 1 and 3 are close, and that measures 3 and 4 are close; Triangle inequality states that 1 and 4 should be close in this case, but the desired model would still favor a solution with the greatest distance possible *within* the constrains imposed by triangle inequalities.

All these requirements are fulfilled if we model $d_{i,j} - \beta_{i,j}$ by a binomial distribution of parameters $(\alpha_{i,j} - \beta_{i,j}, p_{i,j})$, where $p_{i,j}$ is the probability that two symbols of subsequences y_i and y_j differ. With this choice, the conditional probability of getting $d_{i,j} = \beta_{i,j} + \delta$ would be

$$B(\delta, \alpha_{i,j}, \beta_{i,j}, p_{i,j}) = \binom{\alpha_{i,j} - \beta_{i,j}}{\delta} (p_{i,j})^{\delta} (1 - p_{i,j})^{(\alpha_{i,j} - \beta_{i,j} - \delta)} \quad , \tag{5}$$

with $0 \leq p_{i,j} \leq 1$. If $p_{i,j}$ is close to zero/one, the relative distance between subsequences y_i and y_j is small/large. However, the binomial distribution is not flexible enough since there is no indication that the distribution of $d_{i,j} - \beta_{i,j}$ is unimodal. We thus model each $d_{i,j} - \beta_{i,j}$ with a binomial *mixture* distribution in order to allow multiple modes. We thus use

$$p(d_{i,j} = \beta_{i,j} + \delta | S_{i,j}) = \sum_{k=1}^{c} w^{(k)}_{i,j} B(\delta, \alpha_{i,j}, \beta_{i,j}, p^{(k)}_{i,j}) \tag{6}$$

with $w^{(k)}_{i,j} \geq 0$, $\sum_{k=1}^{c} w^{(k)}_{i,j} = 1$ for every indexes i and j, and $S_{i,j}$ defined similarly as in Eq. (2). Parameters

$$\theta_{i,j} = \{w^{(1)}_{i,j}, \ldots, w^{(c-1)}_{i,j}\} \cup \{p^{(1)}_{i,j}, \ldots, p^{(c)}_{i,j}\}$$

[1]This hypothesis is not fundamental in the proposed model and could easily be avoided if one would have to deal with more general datasets.

can be learned with the EM algorithm (Dempster et al., 1977) on rhythm data for a specific music style.

In words, we model the *difference* between the observed distance $d^l_{i,j}$ between two subsequences and the minimum possible value $\beta_{i,j}$ for such a difference by a binomial mixture.

The parameters $\theta_{i,j}$ can be initialized to arbitrary values before applying the EM algorithm. However, as the likelihood of mixture models is not a convex function, one may get better models and speed up the learning process by choosing sensible values for the initial parameters. In the experiments reported in Section 3, the k-means algorithm for clustering (Duda et al., 2000) was used. More precisely, k-means was used to partition the values $(d^l_{i,j} - \beta^l_{i,j})/(\alpha^l_{i,j} - \beta^l_{i,j})$ into c clusters corresponding to each component of the mixture in Eq. (6). Let $\{\mu^{(1)}_{i,j}, \ldots, \mu^{(c)}_{i,j}\}$ be the centroids and $\{n^{(1)}_{i,j}, \ldots, n^{(c)}_{i,j}\}$ the number of elements in each of these clusters. We initialize the parameters $\theta_{i,j}$ with

$$w^{(k)}_{i,j} = \frac{n^{(k)}_{i,j}}{n} \quad \text{and} \quad p^{(k)}_{i,j} = \mu^{(k)}_{i,j}.$$

We then follow a standard approach (Bilmes, 1997) to apply the EM algorithm to the binomial mixture in Eq. (6). Let $z^l_{i,j} \in \{1, \ldots, c\}$ be a hidden variable telling which component density generated $d^l_{i,j}$. For every iteration of the EM algorithm, we first compute

$$p(z^l_{i,j} = k | d^l_{i,j}, \alpha^l_{i,j}, \beta^l_{i,j}, \hat{\theta}_{i,j}) = \frac{\psi_{k,i,j,l}}{\sum_{t=1}^{c} \psi_{t,i,j,l}}$$

where $\hat{\theta}_{i,j}$ are the parameters estimated in the previous iteration, or the parameters guessed with k-means on the first iteration of EM, and

$$\psi_{k,i,j,l} = \hat{w}^{(k)}_{i,j} B(d^l_{i,j}, \alpha^l_{i,j}, \beta^l_{i,j}, p^{(k)}) \ .$$

Then, the parameters can be updated with

$$p^{(k)}_{i,j} = \frac{\sum_{l=1}^{n} (d^l_{i,j} - \beta^l_{i,j}) p(z^l_{i,j} = k | d^l_{i,j}, \alpha^l_{i,j}, \beta^l_{i,j}, \hat{\theta}_{i,j})}{\sum_{l=1}^{n} (\alpha^l_{i,j} - \beta^l_{i,j}) p(z^l_{i,j} = k | d^l_{i,j}, \alpha^l_{i,j}, \beta^l_{i,j}, \hat{\theta}_{i,j})}$$

and

$$w^{(k)}_{i,j} = \frac{1}{n} \sum_{l=1}^{n} p(z^l_{i,j} = k | d^l_{i,j}, \alpha^l_{i,j}, \beta^l_{i,j}, \hat{\theta}_{i,j}).$$

This process is repeated until convergence.

Note that using mixture models for discrete data is known to lead to *identifiability* problems. Identifiability refers here to the uniqueness of the representation (up to an irrelevant permutation of parameters) of any distribution that can be modeled by a mixture. Estimation procedures may not be well-defined and asymptotic theory may not hold if a model is not identifiable. However, the model defined in Eq. (6) is identifiable if $\alpha_{i,j} - \beta_{i,j} > 2c - 1$ (Titterington et al., 1985, p.40). While this is the case for most $d_{i,j}$, we observed that this condition is sometimes violated. Whatever happens, there is no impact on the estimation because we only care about what happens at the distribution level: there may be several parameters leading to the same distribution, some components may vanish in the fitting process, but this is easily remedied, and EM behaves well.

As stated in Section 1, musical patterns form hierarchical structures closely related to meter (Handel, 1993). Thus, the distribution of $p(D(\mathbf{x}^l))$ can be computed for many numbers of partitions within each rhythmic sequence. Let $\mathcal{P} = \{\rho_1, \ldots \rho_h\}$ be a set of numbers of partitions to be considered by our model, where h is the number of such numbers of partitions. The choice of $\mathcal{P}$ depends on the domain of application. Following meter, $\mathcal{P}$ may have dyadic[2] tree-like structure when modeling music (e.g. $\mathcal{P} = \{2, 4, 8, 16\}$). Let $D_{\rho_r}(\mathbf{x}^l)$ be the distance matrix associated with sequence $\mathbf{x}^l$ divided into ρ_r parts. Estimating the joint probability $\prod_{r=1}^{h} p(D_{\rho_r}(\mathbf{x}^l))$ with the EM algorithm as described in this section leads to a model of the distance structures in music datasets. Suppose we consider 16 bars songs with four beats per bar. Using $\mathcal{P} = \{8, 16\}$ would mean that we consider pairs of distances between every group of two measures ($\rho = 8$), and every single measures ($\rho = 16$).

One may argue that our proposed model for long-term dependencies is rather unorthodox. However, simpler models like Poisson or Bernoulli process (we are working in discrete time) defined over the whole sequence would not be flexible enough to represent the particular long-term structures in music.

2.4. Conditional Prediction

For most music applications, it would be particularly helpful to know which sequence $\hat{x}_s, \ldots, \hat{x}_m$ maximizes $p(\hat{x}_s, \ldots, \hat{x}_m | x_1, \ldots, x_{s-1})$. Knowing which musical events are the most likely given the past $s-1$ observations would be useful both for prediction and generation. Note that in the remaining of the paper, we refer to prediction of musical events given past observations only for notational simplicity. The distance model presented in this paper could be used to predict

[2]Even when considering non-dyadic measures (e.g. a three-beat waltz), the *very large* majority of the hierarchical levels in metric structures follow dyadic patterns (Handel, 1993) in most tonal music.

any part of a music sequence given any other part with only minor modifications.

While the described modeling approach captures long range interactions in the music signal, it has two shortcomings. First, it does not model local dependencies: it does not predict how the distances in the smallest subsequences (i.e. with length smaller than $m/\max(\mathcal{P})$) are distributed on the events contained in these subsequences. Second, as the mapping from sequences to distances is many to one, there exists several admissible sequences $\mathbf{x}^l$ for a given set of distances. These limitations are addressed by using another sequence learner designed to capture short-term dependencies between musical events. Here, we use a standard Hidden Markov Model (HMM) (Rabiner, 1989) displayed in Figure 2, following standard graphical model formalism. Each node is associated to a random variable and arrows denote conditional dependencies. Learning the parameters of the HMM can be done as usual with the EM algorithm.

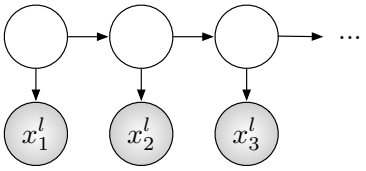

Figure 2. Hidden Markov Model. Each node is associated to a random variable and arrows denote conditional dependencies. During training of the model, white nodes are hidden while grey nodes are observed.

The two models are trained separately using their respective version of the EM algorithm. For predicting the continuation of new sequences, they are combined by choosing the sequence that is most likely according to the local HMM model, provided it is also plausible regarding the model of long-term dependencies. Let $p_{\text{HMM}}(\mathbf{x}^l)$ be the probability of observing sequence $\mathbf{x}^l$ estimated by the HMM after training. The final predicted sequence is the solution of the following optimization problem:

$$\begin{cases} \max\limits_{\tilde{x}_s,\ldots,\tilde{x}_m} & p_{\text{HMM}}(\tilde{x}_s,\ldots,\tilde{x}_m|x_1,\ldots,x_{s-1}) \\ \text{subject to} & \prod\limits_{r=1}^{h} p(D_{\rho_r}(\mathbf{x}^l)) \geq P_0 \ , \end{cases} \tag{7}$$

where P_0 is a threshold. In practice, one solves a Lagrangian formulation of problem (7), where we use log-probabilities for obvious computational reasons:

$$\begin{aligned} \max_{\tilde{x}_s,\ldots,\tilde{x}_m} [&\log p_{\text{HMM}}(\tilde{x}_s,\ldots,\tilde{x}_m|x_1,\ldots,x_{s-1}) \\ &+\lambda \textstyle\sum_{r=1}^{h} \log p(D_{\rho_r}(\mathbf{x}^l))] \ , \end{aligned} \tag{8}$$

where tuning λ has the same effect as choosing a threshold P_0 in Eq. (7) and can be done by cross-validation.

Multidimensional Scaling (MDS) is an algorithm that tries to embed points (here "local" subsequences) into a potentially lower dimensional space while trying to be faithful to the pairwise affinities given by a "global" distance matrix. Here, we propose to consider the prediction problem as finding sequences that maximize the likelihood of a "local" model of subsequences under the constraints imposed by a "global" generative model of distances between subsequences. In other words, solving problem (7) is similar to finding points between which distances are as close as possible to a given set of distances (i.e. minimizing a stress function in MDS). Naively trying all possible subsequences to maximize (8) leads to $O(|A|^{(m-s+1)})$ computations. Instead, we propose to search the space of sequences using a variant of the Greedy Max Cut (GMC) method (Rohde, 2002) that has proven to be optimal in terms of running time and performance for binary MDS optimization.

The subsequence $\hat{x}_s,\ldots,\hat{x}_m$ can be simply initialized with

$$(\hat{x}_s,\ldots,\hat{x}_m) = \max_{\tilde{x}_s,\ldots,\tilde{x}_m} p_{\text{HMM}}(\tilde{x}_s,\ldots,\tilde{x}_m|x_1,\ldots,x_{s-1}) \tag{9}$$

using the local HMM model. Then, Algorithm 1 carries on complete optimization.

Algorithm 1 Simple optimization algorithm to maximize $p(\hat{x}_i,\ldots,\hat{x}_m|x_1,\ldots,x_{i-1})$

```
Initialize x̂_s,...,x̂_m using Eq. (9)
Initialize end = false
while end = false do
  Set end = true
  for j = s to m do
    Set x̂_j = arg max_{a∈A} [log p_HMM(x*|x_1,...,x_{s-1}) +
                λ Σ_{r=1}^{h} log p(D_{ρ_r}(x_1,...,x_{s-1},x*))]
    where x* = (x̂_s,...,x̂_{j-1}, a, x̂_{j+1},...,x̂_m)
    if x̂_j has been modified in the last step then
      Set end = false
    end if
  end for
end while
Output x̂_s,...,x̂_m.
```

For each position, we try every admissible symbol of the alphabet and test if a change increases the probability of the sequence. We stop when no further change can increase the value of the utility function. Obviously, many other methods could have been used to search the space of possible sequences $\hat{x}_s, \ldots, \hat{x}_m$, such as simulated annealing (Kirkpatrick et al., 1983). We chose Algorithm 1 for its simplicity and the fact that it yields excellent results, as reported in the following section.

3. Experiments

Two rhythm databases from different musical genres were used to evaluate the proposed model. Firstly, 47 jazz standards melodies (Sher, 1988) were interpreted and recorded by the first author in MIDI format. Appropriate rhythmic representations as described in Section 2.3 have been extracted from these files. The complexity of the rhythm sequences found in this corpus is representative of the complexity of common jazz and pop music. We used the last 16 bars of each song to train the models, with four beats per bar. Two rhythmic observations were made for each beat, yielding observed sequences of length 128. We also used a subset of the Nottingham database [3] consisting of 53 traditional British folk dance tunes called "hornpipes". In this case, we used the first 16 bars of each song to train the models, with four beats per bar. Three rhythmic observations were made for each beat, yielding observed sequences of length 192. The sequences from this second database contain no silence (i.e. rests), leading to sequences with binary states.

The goal of the proposed model is to predict or generate rhythms *given* previously observed rhythm patterns. As pointed out in Section 1, such a model could be particularly useful for music information retrieval, transcription, or music generation applications. Let $\varepsilon_i^t = 1$ if $\hat{x}_i^t = x_i^t$, and 0 otherwise, with $\mathbf{x}^t = (x_1^t, \ldots, x_m^t)$ a test sequence, and $\hat{x}_i^t$ the output of the evaluated prediction model on the i-th position when given $(x_1^t, \ldots, x_s^t)$ with $s < i$. Assume that the dataset is divided into K folds $T_1, \ldots, T_K$ (each containing different sequences), and that the k-th fold T_k contains n_k test sequences. When using cross-validation, the accuracy *Acc* of an evaluated model is given by

$$Acc = \frac{1}{K} \sum_{k=1}^{K} \frac{1}{n_k} \sum_{t \in T_k} \frac{1}{m-s} \sum_{i=s+1}^{m} \varepsilon_i^t \ . \qquad (10)$$

Note that, while the prediction accuracy is simple to estimate and to interpret, other performance criteria, such as ratings provided by a panel of experts, should be more appropriate to evaluate the relevance of music models. We plan to define such an evaluation protocol in future work. We used 5-fold double cross-validation to estimate the accuracies. Double cross-validation is a recursive application of cross-validation that enables to jointly optimize the hyper-parameters of the model and evaluate its generalization performance. Standard cross-validation is applied to each subset of $K-1$ folds with each hyper-parameter setting and tested with the best estimated setting on the remaining hold-out fold. The reported accuracies are the averages of the results of each of the K applications of simple cross-validation during this process.

For the baseline HMM model, double cross-validation optimizes the number of possible states for the hidden variables. 2 to 20 possible states were tried in the reported experiments. In the case of the model with distance constraints, referred to as the global model, the hyper-parameters that were optimized are the number of possible states for hidden variables in the local HMM model (i.e. 2 to 20), the Lagrange multiplier λ, the number of components c (common to all distances) for each binomial mixture, and the choice of $\mathcal{P}$, i.e. which partitions of the sequences to consider. Values of λ ranging between 0.1 and 4 and values of c ranging between 2 and 5 were tried during double cross-validation. Since music data commonly shows strong dyadic structure following meter, many subsets of $\mathcal{P} = \{2, 4, 8, 16\}$ were allowed during double cross-validation.

Note that the baseline HMM model is a poor benchmark on this task, since the predicted sequence, when prediction consists in choosing the most probable subsequence given previous observations, only depends on the state of the hidden variable in position s, where s is the index of the last observation. This observation implies that the number of possible states for the hidden variables of the HMM upper-bounds the number of different sequences that the HMM can predict. However, this behavior of the HMM does not harm the validity of the reported experiments. The main goal of this quantitative study is to measure to what extent distance patterns are present in music data and how well these dependencies can be captured by the proposed model. What we really want to measure is how much gain we observe in terms of out-of-sample prediction accuracy when using an arbitrary model if we impose additional constraints based on distance patterns. That being said, it would be interesting to measure the effect of appending distance constraints to more complex music prediction models (Pachet, 2003; Dubnov

[3] `http://www.cs.nott.ac.uk/~ef/music/database.htm`.

Table 1. Accuracy (the higher the better) for best models on the jazz standards database.

Observed	Predicted	HMM	Global
32	96	34.5%	54.6%
64	64	34.5%	55.6%
96	32	41.6%	47.2%

Table 2. Accuracy (the higher the better) for best models on the hornpipes database.

Observed	Predicted	HMM	Global
48	144	75.1%	83.0%
96	96	75.6%	82.1%
144	48	76.6%	80.1%

et al., 2003) in future work.

Results in Table 1 for the jazz standards database show that considering distance patterns significantly improves the HMM model. One can observe that the baseline HMM model performs much better when trying to predict the last 32 symbols. This is due to the fact that this database contains song endings. Such endings contain many silences and, in terms of accuracy, a useless model predicting silence at any position performs already well. On the other hand, the endings are generally different from the rest of the rhythm structures, thus harming the performance of the global model when just trying to predict the last 32 symbols.

Results in Table 2 for the hornpipes database again show that the prediction accuracy of the global model is consistently better than the prediction accuracy of the HMM, but the difference is less marked. This is mainly due to the fact that this dataset only contains two symbols, associated to note onset and note continuation. Moreover, the frequency of these symbols is quite unbalanced, making the HMM model much more accurate when almost always predicting the most common symbol.

In Table 3, the set of partitions $\mathcal{P}$ is not optimized by double cross-validation. Results are shown for different fixed sets of partitions. The best results are reached with "deeper" dyadic structure. This is a good indication that the basic hypothesis underlying the proposed model is well-suited to music data, namely that dyadic distance patterns exhibit strong regularities in music data. We did not compute accuracies for $\rho > 16$ because it makes no sense to estimate distribution of distances between too short subsequences.

Table 3. Accuracy over the last 64 positions for many sets of partitions $\mathcal{P}$ on the jazz database, given the first 64 observations. The higher the better.

$\mathcal{P}$	Global
$\{2\}$	49.3%
$\{2, 4\}$	49.3%
$\{2, 4, 8\}$	51.4%
$\{2, 4, 8, 16\}$	55.6%

4. Conclusion

The main contribution of this paper is the design and evaluation of a generative model for distance patterns in temporal data. The model is specifically well-suited to music data, which exhibits strong regularities in dyadic distance patterns between subsequences. Reported conditional prediction accuracies show that such regularities are present in music data and can be effectively captured by the proposed model. Moreover, learning distributions of distances between subsequences really helps for accurate rhythm prediction. Rhythm prediction can be seen as the first step towards full melodic prediction and generation. A promising approach would be to apply the proposed model to melody prediction. It could also be readily used to increase the performance of transcription algorithms, genre classifiers, or even automatic composition systems.

The choice of the HMM to initialize the model is not optimal. However, this has no impact on the validity of the reported results, since our goal was to show the importance of distance patterns between subsequences in rhythm data. In order to sample to models to generate subjectively good results (Pachet, 2003; Dubnov et al., 2003), one could use other benchmark and initialization techniques, such as repetition of common patterns.

Finally, besides being fundamental in music, modeling distance between subsequences should also be useful in other application domains, such as in natural language processing. Being able to characterize and constrain the relative distances between various parts of a sequence of bags-of-concepts could be an efficient means to improve performance of automatic systems such as machine translation (Och & Ney, 2004). On a more general level, learning constraints related to distances between subsequences can boost the performance of "short memory" models such as the HMM.

On the Chance Accuracies of Large Collections of Classifiers

Mark Palatucci MARKMP@CMU.EDU
Andrew Carlson ACARLSON@CS.CMU.EDU
Carnegie Mellon University, Pittsburgh, PA 15213 USA

Abstract

We provide a theoretical analysis of the chance accuracies of large collections of classifiers. We show that on problems with small numbers of examples, some classifier can perform well by random chance, and we derive a theorem to explicitly calculate this accuracy. We use this theorem to provide a principled feature selection criterion for sparse, high-dimensional problems. We evaluate this method on microarray and fMRI datasets and show that it performs very close to the optimal accuracy obtained from an oracle. We also show that on the fMRI dataset this technique chooses relevant features successfully while another state-of-the-art method, the False Discovery Rate (FDR), completely fails at standard significance levels.

1. Introduction

There are many real world problems in which a large number of *experts* predict the outcome of a small number of events. For example, we may ask one hundred football fans to predict the outcome of twenty games, or we may ask fifty political pundits to predict the outcome of ten elections.

With only a small number of events to predict, there may be a reasonable chance that some expert may predict all the outcomes perfectly, even if the outcomes are chosen at random.

For example, suppose we ask a person to predict the outcome of five coin flips where the probability of obtaining heads is 0.5. Since the flips are independent, this person has a $(0.5)^5 = \frac{1}{32}$ chance of guessing the outcome of all flips correctly. Now, if we ask ten people to predict the outcome of the five flips, there is a much higher chance that *someone* will predict all outcomes perfectly. With thirty-two people, someone would (in expectation) guess correctly each time.

Suppose we repeated this experiment again but asked our participants to predict the outcome of thirty coin flips. In this case, the chance of obtaining a perfect prediction would be nearly 1 in 1 billion. Given any number of participants less than 1 billion, we would not expect any participant to perfectly predict all the outcomes. But some participant will predict a series of outcomes that is most similar to the true flips.

How accurate should we expect this participant's predictions to be?

We consider this question and its relevance to machine learning. In our setting, we consider *experts* that are not people, but rather classification algorithms that predict labels for a set of examples.

When a large number of classifiers predict labels for a small number of examples, some classifiers will predict the labels well purely by random chance. This may lead us to believe that a subset of the classifiers are actually good predictors, when in fact they may be just guessing randomly.

This effect is commonly seen in discriminative feature selection, where a feature is selected based on the accuracy of a classifier trained on that single feature and tested on a held-out set of validation examples. In modern high-dimensional machine learning applications such as fMRI or microarray analysis, there are typically thousands of features with less than one hundred examples. Classification tasks in such settings often have *sparse* solutions, meaning that only a small subset of the features are useful for predicting the correct class.

To determine which features are relevant, it would be useful to know how well *some* classifier could perform if all classifiers just chose labels at random. We would like to know how this accuracy changes with both the number of features and number of examples. This pa-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

per poses and answers the following question:

Given M classifiers that each produce labels randomly for N examples, what is the highest accuracy that we would expect some classifier to achieve?

1.1. Related Work

Our work is closely related to the multiple-testing problem in the statistics community. In statistics, hypothesis tests are the standard way to test if some assertion is true with high probability. While a single test has a low probability of making an error, when multiple hypothesis tests are performed simultaneously, the probability of at least one of the tests making an error can be much higher. It is common to *correct* the tests by making them more conservative to compensate.

Two of the most popular methods for correcting multiple tests are the Bonferroni Correction and the False Discovery Rate (Benjamini & Hochberg, 1995). We can apply these methods to the problem of feature selection, but in practice they are often too conservative at standard significance levels (e.g. 5%). See Wong et al. (2002) and Frank and Witten (1998). With many high-dimensional classification problems they may simply state that no feature is significant. This is not particularly helpful when building a classifier.

We could lower the significance level so more features are considered relevant, but it is unclear what significance level to choose. Since different learning algorithms have different tolerances to noisy, irrelevant features, there is no single significance level that is appropriate for all learning algorithms.

This fact, along with the large number of available tests and correction methods, makes hypothesis testing a difficult task for non-experts.

In our work, we approach the problem of significance from a different angle. Using *order statistics*, we explicitly model small chance events in a group setting. These techniques are relatively unknown in the machine learning literature although the *multiple comparison procedures* described in Jensen (2000) are similar in spirit.

We feel an order statistic approach is much more intuitive than hypothesis testing, and is well suited to problems in machine learning.

One such problem is discriminative feature selection. This feature selection technique is often called a *wrapper* method in contrast to more recent *embedded* methods like the $\mathcal{L}_1$ regularized Lasso (Tibshirani, 1996). While a full comparison of wrapper and embedded methods is beyond the scope of this paper, we believe that wrapped methods will continue to play a role in machine learning due to their simplicity and tractability. An excellent overview of the feature selection literature is available in Guyon (2003).

The work most similar to ours is by Li and Grosse (2003), which uses extreme value distribution theory to choose a significance threshold for selecting relevant features. While the general theme is similar, we do not use asymptotic results of extreme value theory, nor do we use simulation to compute moments of order statistics. By contrast, we focus on classification problems and show exact solutions that do not require any simulation.

2. Preliminaries

2.1. Order Statistics

We use *order statistics* extensively in this paper, thus we begin with a small introduction to define some basic concepts and notation. Consider M samples (i.i.d.) drawn from some distribution: $X_1, \ldots, X_M \sim F_X(x)$. If we order these samples from smallest to largest we obtain:

$$X_{(1)} \leq X_{(2)} \leq \ldots \leq X_{(M)}$$

and we use the notation $X_{(r)}$ to denote the r^{th} smallest sample which we call the r^{th} order statistic. $X_{(1)}$ and $X_{(M)}$ have special meaning which we call the *extreme values*:

$$\begin{aligned} X_{(1)} &= \min(X_1, X_2, \ldots, X_M) \\ X_{(M)} &= \max(X_1, X_2, \ldots, X_M) \end{aligned}$$

Each order statistic $X_{(r)}$ is also a random variable and can be described by a cumulative distribution function $F_{(r)}(x)$ or a density function $f_{(r)}(x)$. We will refer to an order statistic's *parent distribution*, which is the original distribution from which the M unordered samples were drawn. In our example this is $F_X(x)$.

We will use the notation $\mu_{r:M}$ to denote the mean of the r^{th} order statistic for M samples drawn from the parent distribution.

3. Expected Chance Accuracies

Using order statistics we can now answer the question we posed earlier:

Given M classifiers that each produce labels randomly for N examples, what is the highest accuracy that we would expect some classifier to achieve?

To answer this question, first consider a classifier that labels some collection of examples at random. If the classifier labels an example incorrectly with probability p_{err}, we can model the number of errors the classifier makes as a binomial random variable. Formally, let X be defined as the number of errors the classifier makes on some true labeling of N examples. Then:

$$X \sim \text{Binomial}(N, p_{err})$$

and the mean and variance of X are:

$$\begin{aligned}\mathbb{E}[X] &= N \cdot p_{err} \\ \mathbb{V}[X] &= N \cdot p_{err} \cdot (1 - p_{err})\end{aligned}$$

Now, suppose instead we have M independent classifiers where each produces a set of N labels at random. Once again, the probability that each classifier makes a mistake on a single example is p_{err}. Let X_i be the number of errors made by the ith classifier. We then have:

$$X_1, X_2, \ldots, X_M \sim \text{Binomial}(N, p_{err})$$

One of these classifiers will have the minimal number of errors. Using our order statistic notation we have:

$$X_{(1)} = \min(X_1, X_2, \ldots, X_M)$$

and the expected minimum number of errors is:

$$\mu_{1:M} = \mathbb{E}[X_{(1)}]$$

If we knew the density function of $X_{(1)}$ for M samples from a Binomial(N, p_{err}) we could compute the mean $\mu_{1:M}$ directly:

$$\mu_{1:M} = \sum_{x=0}^{\infty} x f_{(1)}(x)$$

If the parent distribution were a continuous variable, obtaining $f_{(1)}$ would not be difficult and many references show simple methods to compute the density for any order statistic of a continuous distribution (Casella & Berger, 2002). Since our parent distribution is the discrete binomial, computing $f_{(1)}$ and more importantly $\mu_{1:M}$ is more difficult.

We could resort to simulation to find the mean, but this can be quite time consuming for large collections of variables. We will show later, however, that an exact solution does exist.

3.1. The Multiplicity Gap

For any problem with M classifiers and N examples there is a risk that some classifier will perform well by random chance. *What is a good measure of this risk?*

As we showed earlier, $\mathbb{E}[X_{(1)}]$ is the minimum number of errors that we should expect *some* classifier to make. We also know that $\mathbb{E}[X]$ is the expected number of errors an *individual* classifier will make.

Thus, one natural measure of this risk is the difference between these two values. We define the *multiplicity gap* $\mathcal{G}_{M,N}$ for M classifiers and N examples as:

$$\mathcal{G}_{M,N} = \mathbb{E}[X] - \mathbb{E}[X_{(1)}]$$

Reducing the number of examples N or increasing the number of classifiers M *increases* the risk.

4. Derivation

Theorem 4.1. *Highest Chance Accuracy*
Consider a classification problem with M classifiers and N examples. If the probability that a classifier makes a mistake on a single example is p_{err}, the highest expected accuracy $\mathcal{A}_H$ of any classifier is given by:

$$\mathbb{E}[\mathcal{A}_H] = 1 - \frac{1}{N} \sum_{i=0}^{N-1} I_{p_{err}}(i+1, N-i)^M \quad (1)$$

where $I_p(a,b)$ is the incomplete beta function[1]*:*

$$I_p(a,b) = \frac{1}{\beta(a,b)} \int_0^p t^{a-1}(1-t)^{b-1} dt$$

Proof. Let X_i, $(1 \le i \le M)$ be the total number of errors classifier i makes on some true labeling of N examples. If the probability that a classifier makes a mistake on a single example is p_{err}, then:

$$X_1, X_2, \ldots, X_M \sim \text{Binomial}(N, p_{err})$$

Therefore, the expected minimum number of errors is:

$$\mu_{1:M} = \mathbb{E}[X_{(1)}]$$

To compute the value of $\mu_{1:M}$ we utilize a useful result from Feller (1957) that relates the mean of a discrete random variable to its distribution function:

$$\mu_X = \sum_{i=0}^{\infty} [1 - F_X(i)]$$

therefore

$$\mu_{1:M} = \sum_{i=0}^{\infty} [1 - F_{(1)}(i)]$$

[1] Some texts refer to this form as the regularized incomplete beta function.

A result from David and Nagaraja (2003) shows that is equivalent to:

$$\mu_{1:M} = \sum_{i=0}^{\infty} [1 - F_X(i)]^M \tag{2}$$

Now, for a Binomial(N, p_{err}), $F_X(i) = 1$ when $i \geq N$. Therefore, the upper limit of the sum becomes $N-1$:

$$\mu_{1:M} = \sum_{i=0}^{N-1} [1 - F_X(i)]^M$$

Note that the incomplete beta function $I_p(a,b)$ has an expansion that looks similar to the distribution function of a binomial:

$$I_p(a,b) = \sum_{j=a}^{a+b-1} \frac{(a+b-1)!}{j!(a+b-1-j)!} p^j (1-p)^{a+b-1-j}$$

Using this expansion and a few algebraic manipulations we can express the tail of the distribution function in terms of the incomplete beta function[2]:

$$\begin{aligned} 1 - F_X(i) &= \mathbb{P}(X \geq i+1) \\ &= \sum_{j=i+1}^{N} \frac{N!}{j!(N-j)!} (p_{err})^j (1-p_{err})^{N-j} \\ &= I_{p_{err}}(i+1, N-i) \end{aligned}$$

Substituting this form into (2) we have:

$$\mu_{1:M} = \sum_{i=0}^{N-1} I_{p_{err}}(i+1, N-i)^M$$

To put our answer in terms of accuracy rather than errors we rearrange:

$$\begin{aligned} \frac{1}{N}(N - \mu_{1:M}) &= 1 - \frac{1}{N}\mu_{1:M} \\ &= 1 - \frac{1}{N} \sum_{i=0}^{N-1} I_{p_{err}}(i+1, N-i)^M \end{aligned}$$

Note that this theorem depends on the number of classes only through p_{err}. It does not require any modification to adapt to many classes. □

[2]We feel it is numerically advantageous to use the incomplete beta function rather than computing the binomial CDF directly. Many numerical computing environments have fast implementations of the incomplete beta function $I_p(a,b)$. For example, the `betainc(p,a,b)` command in MATLAB can implement Equation 1 in one line of code.

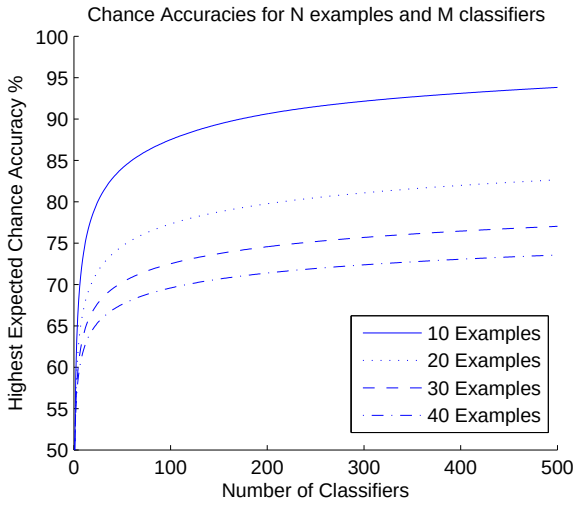

Figure 1. The highest expected chance accuracy as a function of the number of examples and classifiers. Each line represents a different number of examples. The x-axis is the number of classifiers and the y-axis is the accuracy.

Example 4.1 Predicting NFL games
Consider an office football pool with 200 participants betting on the outcome of 20 games. If each participant selects the outcome of a game according to a fair coin flip, how well would we expect the "winner" to perform?

To answer this question, we apply Equation 1 where $M = 200$, $N = 20$, and $p_{err} = 0.5$. In this case, the highest expected accuracy of some participant is 80%.

Although the chance probability of obtaining a *perfect* labeling is extremely small, in this case only $1/2^{20} = 1/1,048,576$, the chance of obtaining a *very good* labeling is much higher. Exactly 1,048,576 participants would be needed for us to expect one to obtain a perfect labeling. Yet, with only 200 participants, the expected accuracy of the top performer is 80%.

This effect can be seen by plotting Equation 1 for a two class problem where $p_{err} = 0.5$ (see Figure 1). The graph shows the highest expected chance accuracy (y-axis) for a given number of classifiers (x-axis). Each line represents a different number of examples N. As we increase the number of examples, the *multiplicity gap* closes, and highest expected chance accuracy for some classifier approaches the expected chance accuracy for a single classifier.

With small numbers of examples and large numbers of classifiers, the chance of obtaining a very good labeling may be very high, even if the chance of obtaining a perfect labeling is very low.

5. Case Study: Discriminative Feature Selection in Sparse, High-Dimensional Problems

A simple and popular method for finding relevant features in a classification task is discriminative feature selection. This method evaluates how well individual features discriminate between different classes and selects features with high predictive accuracy.

For example, if we have M features in a classification task, we train M distinct classifiers, where each classifier is trained using a single feature. After training, we evaluate all the classifiers on a set of *validation examples* and select the top performing features according to some criterion. A final classifier is then trained using only these top performing features, and then evaluated on some set of test examples.

This method is popular because it is simple to implement and often performs well in practice. The main difficulty is: *What are appropriate criteria for selecting significant features?*

One approach is to run a *cross-validation* loop, testing different significance thresholds to find one that has high empirical performance. This loop is computationally expensive and also requires additional validation examples. To avoid these difficulties in practice, it is common to choose some arbitrary threshold, and hope that performance is sufficient for the classification task.

Besides being pedantically unsatisfying, choosing an arbitrary threshold in a high-dimensional problem with a small number of examples is very risky. For example, a simple threshold might choose all features that perform better than 80% accuracy. As we showed earlier, many features may exceed this seemingly high threshold purely by random chance.

In high-dimensional problems with small numbers of examples, the accuracy required for statistical significance is often much higher than intuition might suggest.

A more principled approach for determining significance is to use a hypothesis test. With a hypothesis test, one tries to disprove a certain assertion. For example, one might assume that a classifier performs with a true accuracy of 50%. This assumption is called the *null hypothesis*. The goal then is to reject the null hypothesis if the evidence (e.g. the discriminative accuracy) is sufficiently strong.

Hypothesis testing has a vast literature in the statistics community. A good introduction can be found in Wasserman (2005). The Wald, "t", binomial, permutation, and χ^2 tests are just a few of the possible testing methods available. It is difficult, however, for a non-expert to know when to apply a particular test. To complicate matters, adjustments must be made when multiple tests are considered simultaneously. This is known in the statistics community as the *multiple testing problem*. Several methods such as the Bonferroni correction, family-wise error rate, and the false discovery rate (FDR) are used to compensate for multiple tests (Benjamini & Hochberg, 1995).

For the problem of discriminative feature selection, the use of a binomial test along with a false discovery rate adjustment is an appropriate choice. As we mentioned earlier, however, hypothesis tests require the choice of a significance level α. As is common in the scientific literature, the level $\alpha = 0.05$ is typically considered statistically significant.

For the purpose of feature selection, however, an appropriate choice of α is highly dependent on the classification algorithm used. Some classifiers are more tolerant to irrelevant features than others. Thus, there is no single α value appropriate for all classifiers. We could use a cross-validation loop to search for an appropriate α, but then we could have avoided the hypothesis test altogether and searched empirically for an appropriate threshold.

5.1. The Multiplicity Gap Midpoint (MGM) Method

Earlier in Equation 1 we derived the highest expected chance accuracy of some classifier assuming all classifiers choose their labels according to random chance. In some sense, this accuracy is a *natural significance threshold*, since we would not expect any classifer to perform better than this threshold by random chance.

While this may seem like an intuitive threshold for feature selection, in practice the threshold is overly conservative for several reasons. First, this threshold assumes all features are independent. This rarely holds in practice, and in many high-dimensional datasets it is very common to see strong correlations between features.

Further, the threshold assumes that all features are irrelevant and produce labels at random. In practice, some subset of the features will actually be significant, thereby lowering the effective number of random features. There is also no guarantee that errors for a feature can be modeled as a binomial random variable.

These violations of independence and irrelevance effectively lower the highest expected chance accuracy

(and increase the expected minimum number of errors). While this threshold may be overly conservative, it effectively serves as an upper bound on the highest expected chance accuracy.

At the other extreme, we might consider any feature significant that performs better than the expected chance accuracy of a *single* feature. As we showed before, this will clearly allow many irrelevant features to be considered significant. Note that these two extremes are the endpoints of the multiplicity gap that we defined earlier. If we model the number of errors made by a classifier as a binomial random variable, and we have M classifiers and N examples then the multiplicity gap $\mathcal{G}_{M,N} = \mathbb{E}[X] - \mathbb{E}[X_{(1)}]$

We conjecture that the optimal threshold should fall within the multiplicity gap.

In practice, we can choose any threshold between these two extremes. If we believe that our classifier is sensitive to irrelevant features, we should choose a threshold closer to $\mathbb{E}[X_{(1)}]$. Similarly, if our classifier is robust to irrelevant features, we should choose a threshold closer to $\mathbb{E}[X]$.

Without any knowledge of the particular classifier it is impossible to know what the optimal threshold should be. Therefore, as a simple heuristic we propose the *multiplicity gap midpoint* method, which chooses the midpoint of the extremes of the multiplicity gap. This yields a threshold τ_{MGM} on the maximum number of errors a classifier could make and still be considered significant:

$$\tau_{MGM} = \frac{\left(\mathbb{E}[X] + \mathbb{E}[X_{(1)}]\right)}{2}$$

where $\mathbb{E}[X_{(1)}]$ is computed as in Equation 1:

$$\mathbb{E}[X_{(1)}] \quad = \quad \mu_{1:M} = \sum_{i=0}^{N-1} I_{p_{err}}(i+1, N-i)^M$$

and $\mathbb{E}[X]$ is the number of examples N multiplied by the probability p_{err} that a classifier makes an error on a particular example: $\mathbb{E}[X] = N \cdot p_{err}$

To use this threshold, we perform a discriminative feature selection and select all features that make less than τ_{MGM} errors on a validation set with N examples.

5.2. Experimental Methodology

We perform discriminative feature selection experiments on two high-dimensional classification tasks that have few relevant features and limited training data:

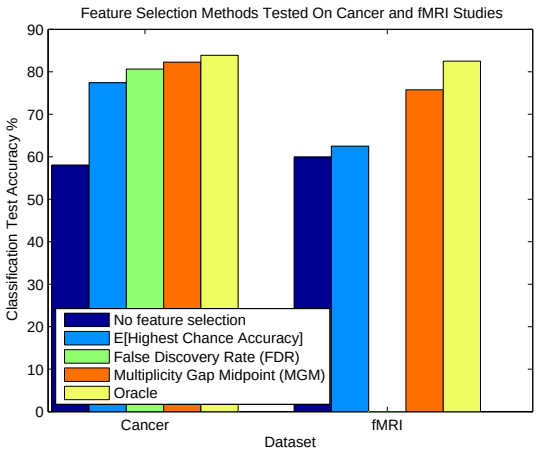

Figure 2. Accuracies for different feature selection methods for two classification tasks: Cancer (left) fMRI (right). The False Discovery Rate (FDR) method selected no features in the fMRI task.

Task 1: Cognitive state classification using functional magnetic resonance imaging (fMRI) In this task, we are given a time series of neural activity from thirteen human subjects. Each feature is the neuro-activation of a particular region of the brain at a given time. The goal is to distinguish between two cognitive states: reading a sentence, and viewing a picture (Mitchell et al., 2004). Each subject has ≈80,000 features and 40 examples.

Task 2: Colon cancer patient classification using microarray gene expression levels (Cancer) In this task, the goal is to predict whether a patient is diagnosed with colon cancer. The data are microarray gene expression levels from tissue samples (Alon et al., 1999). There are 2,000 features and 62 examples.

Testing Method In each experiment, we use a Gaussian Naive Bayes classifier and perform a leave-one-out-cross-validation. On each round, we leave out one example, and split the remaining examples into equal training and validation sets. We train using the first set, and measure classification accuracy on the validation set. We select the best performing features according to a specific criterion. After selecting features, we retrain by combining the validation and training sets. We then test the left out example. We repeat the process for each example.

We tested five different feature selection criteria:

1. **No feature selection** Uses all features.
2. **Highest Expected Chance Accuracy** Selects features that make fewer than $\mathbb{E}[X_{(1)}]$ mistakes.

3. **Binomial Hypothesis Test with False Discovery Rate correction** We select a feature if we reject the hypothesis that a classifier's true accuracy, trained on that feature, is 50%.[3] We use an $\alpha = 5\%$ level in the tests.
4. **Multiplicity Gap Midpoint (MGM) method** The method proposed in Section 5.1.
5. **Oracle Threshold** This is the threshold that would have led to the optimal testing accuracy.

5.3. Results and Discussion

In Figure 2, we see the classification results of five discriminative feature selection methods for both the colon cancer and fMRI datasets (for the fMRI dataset, we averaged the results of the 13 subjects together).

In both datasets, the threshold $\mathbb{E}[X_{(1)}]$ yields an improvement over no feature selection. But the assumptions made in calculating that threshold, namely that all features are independent and irrelevant, result in a very conservative threshold which admits few features.

The multiplicity gap midpoint (MGM) method relaxes these assumptions and performs significantly better. This method comes closest to the accuracy that could have been achieved had an oracle told us the optimal threshold to use[4].

As a state-of-the-art baseline, we tried a binomial hypothesis test with a false discovery rate correction. As is common in the statistical and scientific literature, we chose a significance level $\alpha = 0.05$. This method completely failed to select any features for the fMRI task, indicating that it is overly conservative for very high-dimensional problems. The method performed fairly well on the colon cancer dataset, but did so after selecting fewer than ten features.

It is worth noting that we could tune the α value of the false discovery rate test to admit more features and help performance. But the goal of the midpoint heuristic is to avoid this tuning (in fact, if we were to do tuning, it would make more sense to just tune the threshold for selecting features directly). Thus we feel the midpoint method provides a more appropriate *default threshold* than a specific value of α would in a classical test.

We chose the Gaussian Naive Bayes classifier because it is extremely fast to train and test making it very appropriate for use in a *wrapped feature selector*. This classifier is also robust to noise but is not entirely immune to overfitting. We found that adding additional features increased performance up to a point, but eventually noisy features overwhelmed the classifier, and performance degraded.

Figure 3 shows this effect for three fMRI subjects and the colon cancer dataset. The curves shows test accuracies at various feature selection thresholds. In each plot, the x-axis is the number of errors allowed, and the y-axis is the test accuracy of the resulting classifier. We mark the extremes of the multiplicity gap $\mathbb{E}[X_{(1)}]$ and $E[X]$ on each plot. On all thirteen subjects as well as the colon cancer dataset, the optimal (oracle chosen) threshold falls within this gap.

5.4. Future Work

The goal of this paper was to show how order statistics can be a useful tool for problems in machine learning. While our initial work focused on accuracy, we feel similar techniques can be applied to other measures such as information gain, entropy, and AUC.

Also, in our initial analysis we compute a significance threshold assuming that all features are independent. One natural extension of this work is to develop a method that adjusts for correlations between features.

6. Conclusion

We provided a theoretical analysis of the chance accuracy of large collections of classifiers. We showed that on problems with small numbers of examples and large numbers of features, we should expect some classifier to be highly accurate by random chance. We derived a theorem to directly calculate this accuracy.

We used this theorem to provide a principled feature selection criterion for sparse, high-dimensional problems. This criterion is theoretically well-motivated, simple to implement, and computationally inexpensive.

We demonstrated this method on microarray and fMRI datasets and showed that this method performs very close to the optimal oracle accuracy. We also showed that on the fMRI dataset this technique chooses relevant features while another state-of-the-art method, the False Discovery Rate (FDR), completely fails at standard significance levels.

Acknowledgments

We would like to offer our tremendous thanks to Haikady Nagaraja, Larry Wasserman, Tom Mitchell,

[3] This is appropriate since both datasets have nearly equal class priors.

[4] The oracle is determined by calculating the highest accuracy on a test set for every possible "number of errors" threshold on the validation set.

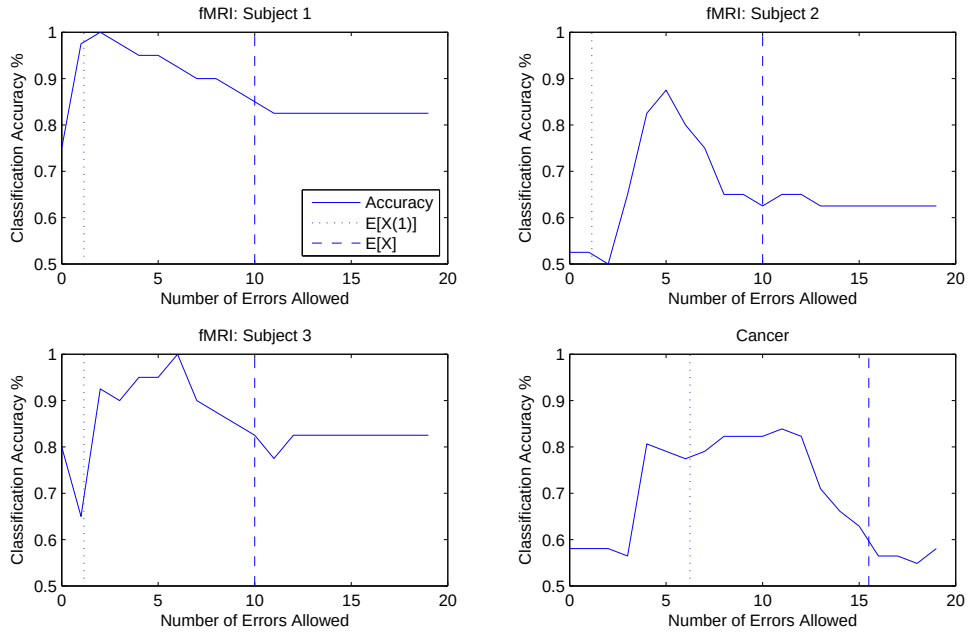

Figure 3. Test accuracies at various feature selection thresholds. In each plot, the x-axis is the number of errors allowed, and the y-axis is the test accuracy of the resulting classifier. We mark the extremes of the multiplicity gap $\mathbb{E}[X_{(1)}]$ and $E[X]$ with vertical lines on each plot.

and Geoff Gordon for their useful comments. We would also like to acknowledge the National Science Foundation, W.M Keck Foundation, and Yahoo! for their generous financial support.

Abstract

We show that linear value-function approximation is equivalent to a form of linear model approximation. We then derive a relationship between the model-approximation error and the Bellman error, and show how this relationship can guide feature selection for model improvement and/or value-function improvement. We also show how these results give insight into the behavior of existing feature-selection algorithms.

1. Introduction

Broadly speaking, there are two types of reinforcement-learning (RL) algorithms: model-free and model-based algorithms. Model-free approaches typically use samples to learn a value function, from which a policy is implicitly derived. In contrast, model-based approaches build a model of system behavior from samples, and the model is used to compute a value function or policy. Both approaches have advantages and disadvantages, and function approximation can be applied to either, to represent a value function or a model. Examples of function approximators include decision trees, neural networks, and linear functions.

The first contribution of this paper shows that, when linear value-function approximation is used for policy evaluation as in nominally model-free approaches such as linear TD learning (Sutton, 1988) or LSTD (Bradtke & Barto, 1996), the value function is *precisely* the same as the value function that results from an exact solution to a corresponding approximate, linear model, where the value function and linear model are defined over the same set of features.

This insight results in a novel view of the Bellman error and a deeper understanding of the problem of feature selection when linear function approximation is used. Specifically, we show that the Bellman error can be decomposed into two types of errors in the learned linear model: the reward error and the feature error. This decomposition gives insight into the behavior of existing approximation techniques, suggests new views of feature selection, and explains the behavior of existing feature-selection algorithms.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

2. Formal Framework and Notation

We are interested in both controlled and uncontrolled Markov processes with a set S of states s and, when applicable, a set A of actions a. Our main results and experiments consider the uncontrolled or policy-evaluation case, but many of the ideas can be applied to the controlled case, as is discussed in more detail in Section 3.2.

We refer to the uncontrolled case as a Markov reward process (MRP): $M = (S, P, R, \gamma)$, and the controlled case as a Markov decision process (MDP): $M = (S, A, P, R, \gamma)$. Given a state s_i, the probability of a transition to a state s_j given action a is given by P^a_{ij} and results in an expected reward of R^a_i. In the uncontrolled case, we use P_{ij} and R_i to stand for the transitions and rewards.

We are concerned with finding value functions V that map each state s_i to the expected total γ-discounted reward for the process. In particular, we would like to find the solution to the Bellman equation

$$V[s_i] = \max_a (R^a_i + \gamma \sum_j P^a_{ij} V[s_j])$$

in the controlled case (the "max" and a's are eliminated from the equation in the uncontrolled case).

For any matrix, A, we use A^T to indicate the transpose of A and $span(A)$ to indicate the column space of A.

2.1. Linear Value Functions

In cases where the value function cannot be represented exactly, it is common to use some form of parametric value-function approximation, such as a linear combination of features or basis functions:

$$\hat{V} = \sum_{i=1}^{k} w_i \phi_i,$$

where $\Phi = \{\phi_1, \ldots, \phi_k\}$ is a set of linearly independent[1] basis functions of the state, with $\phi_i(s)$ defined as the value of feature i in state s. The vector $\mathbf{w} = \{w_1, \ldots, w_k\}$ is a set of scalar weights. We can think of Φ as a design matrix with $\Phi[i,j] = \phi_j(s_i)$, that is, the basis functions span the columns of Φ and the states span the rows. Expressing the weights $\mathbf{w}$ as a column vector, we have $\hat{V} = \Phi\mathbf{w}$.

Methods for finding a reasonable $\mathbf{w}$ given Φ and a set of samples include linear TD (Sutton, 1988), LSTD (Bradtke & Barto, 1996) and LSPE (Yu & Bertsekas, 2006). If the model can be expressed as a factored MDP, then the weights can be found directly (Koller & Parr, 1999). We refer to this family of methods as *linear fixed-point* methods because they all solve for the fixed point

$$\hat{V} = \Phi\mathbf{w}_\Phi = \Pi_\sigma(R + \gamma P \Phi \mathbf{w}_\Phi), \tag{1}$$

where Π_σ is an operator that is the σ-weighted L_2 projection into $span(\Phi)$, where σ is a state weighting distribution, typically the stationary distribution of P. If $\Sigma = diag(\sigma)$, $\Pi_\sigma = \Phi(\Phi^T\Sigma\Phi)^{-1}\Phi^T\Sigma$. In some cases, an unweighted projection (uniform σ) or some other σ is used. Most of our results do not depend upon the projection weights, so we shall assume uniform σ unless otherwise stated. Solving for $\mathbf{w}_\Phi$ yields:

$$\begin{aligned} \mathbf{w}_\Phi &= (I - \gamma(\Phi^T\Phi)^{-1}\Phi^T P\Phi)^{-1}(\Phi^T\Phi)^{-1}\Phi^T R \quad (2)\\ &= (\Phi^T\Phi - \gamma\Phi^T P\Phi)^{-1}\Phi^T R. \quad (3)\end{aligned}$$

In this paper, we assume that P is known and that Φ can be constructed exactly, while in all but the factored model case, these would be sampled. This assumption allows us to characterize the representational power of the features as a separate issue from the variance introduced by sampling.

2.2. Linear Models

As in the case of linear value functions, we assume the existence of a set of linearly independent features $\phi_1 \ldots \phi_k$ for representing transition and reward models, with $\phi_i(s)$ defined as the value of feature i in state s. While value-function approximation typically uses features to predict values, we will consider the use of these features to predict *next* features. For feature vector $\Phi(s) = [\phi_1(s) \ldots \phi_k(s)]^T$, we define $\Phi(s'|s)$ as the random vector of next features:

$$\Phi(s'|s) \overset{s' \sim P(s'|s)}{=} [\phi_1(s'), \ldots, \phi_k(s')]^T,$$

our objective will be to produce a $k \times k$ matrix P_Φ that predicts expected next feature vectors,

$$P_\Phi{}^T \Phi(s) \approx E_{s' \sim P(s'|s)}\{\Phi(s'|s)\},$$

and minimizes the expected feature-prediction error:

$$P_\Phi = \arg\min_{P_k} \sum_s \| P_k^T \Phi(s) - E\{\Phi(s'|s)\} \|_2^2. \tag{4}$$

(For brevity, we shall henceforth leave $s' \sim P(s'|s)$ implicit). One way to solve the minimization problem in Eq. (4) is to compute the expected next feature explicitly as the $n \times k$ matrix $P\Phi$ and then find the least-squares solution to the over-constrained system $\Phi P_\Phi \approx P\Phi$, since the i^{th} row of ΦP_Φ is P_Φ's prediction of the next feature values for state i and the i^{th} row of $P\Phi$ is the expected value of these features. The least-squares solution is

$$P_\Phi = (\Phi^T\Phi)^{-1}\Phi^T P\Phi, \tag{5}$$

with approximate next feature values $\widehat{P\Phi} = \Phi P_\Phi$. To predict the reward model using the same features, we could perform a standard least-squares projection into $span(\Phi)$ to compute an approximate reward predictor:

$$r_\Phi = (\Phi^T\Phi)^{-1}\Phi^T R, \tag{6}$$

with corresponding approximate reward: $\hat{R} = \Phi r_\Phi$. As in the value-function approximation case, it is possible to do a weighted L_2 projection, a straightforward generalization that we omit for conciseness of presentation.

Classically, an advantage of learning a model and deriving values from the model (indirect learning) over using samples to estimate the values (direct learning) is that such a method can be very data efficient. On the other hand, learning an accurate model can require a great deal of experience. Surprisingly, we find that the two approaches are the same, at least in the linear approximation setting.

3. Linear Fixed-Point Solution = Linear-Model Solution

The notion that linear fixed-point methods are implicitly computing some sort of model has been recognized in varying degrees for several years. For example, Boyan (1999)

[1] Permitting linearly dependent basis functions would not change our results, but would complicate exposition since the resulting weight vectors would no longer be unique. In practice, one may use SVD to enforce the selection of a unique solution when features are linearly dependent.

considered the intermediate calculations performed by LSTD in some special cases, and interpreted parts of the LSTD algorithm as computing a compressed model. In this section, we show that the linear fixed-point solution for features Φ is *exactly* the solution to the linear model described by P_Φ and r_Φ. We first prove it for the uncontrolled case, and then generalize our result to the controlled case. Our results concern unweighted projections, but generalize readily to weighted projections.

3.1. The Uncontrolled Case

Recall that the approximate model transforms feature vectors to feature vectors, so any k-vector is a state in the approximate model. If $\mathbf{x}$ is such a state, then, in the approximate model, ${r_\Phi}^T\mathbf{x}$ is the reward for this state and ${P_\Phi}^T\mathbf{x}$ is the next state vector. The Bellman equation for state $\mathbf{x}$ is:

$$V[\mathbf{x}] = {r_\Phi}^T\mathbf{x} + \gamma V[{P_\Phi}^T\mathbf{x}] = \sum_{i=0}^{\infty} \gamma^i {r_\Phi}^T ({P_\Phi}^i)^T\mathbf{x}.$$

Expressed with respect to the original state space, the value function becomes

$$V = \Phi \sum_{i=0}^{\infty} \gamma^i {P_\Phi}^i r_\Phi,$$

which is a linear combination of the columns of Φ. Since $V = \Phi\mathbf{w}$ for some $\mathbf{w}$, the fixed-point equation becomes:

$$\begin{aligned} V &= \hat{R} + \gamma\widehat{P\Phi\mathbf{w}} && (7)\\ \Phi\mathbf{w} &= \Phi r_\Phi + \gamma\Phi P_\Phi\mathbf{w} && (8)\\ \mathbf{w} &= (I - \gamma P_\Phi)^{-1} r_\Phi. && (9) \end{aligned}$$

We call the solution to the system above the *linear model solution*. A solution will exist when P_Φ has a spectral radius less than $1/\gamma$. This condition is not guaranteed because P_Φ is not necessarily a stochastic matrix; it is simply a matrix that predicts expected next feature values. The cases where the spectral radius of P_Φ exceeds $1/\gamma$ correspond to the cases where the value function defined by P_Φ and r_Φ assigns unbounded value to some states.

Theorem 3.1 *For any MRP M and set of features Φ, the linear-model solution and the linear fixed-point solution are identical.*

Proof We begin with the expression for the linear-model solution from Eq. (9) and then proceed by substituting the definitions of P_Φ and r_Φ from Eq. (5) and Eq. (6), yielding:

$$\begin{aligned} \mathbf{w} &= (I - \gamma P_\Phi)^{-1} r_\Phi \\ &= (I - \gamma(\Phi^T\Phi)^{-1}\Phi^T P\Phi)^{-1}(\Phi^T\Phi)^{-1}\Phi^T R \\ &= \mathbf{w}_\Phi. \ \blacksquare \end{aligned}$$

This result demonstrates that for a given set of features Φ, there is no difference between using the exact model to find an *approximate* linear fixed-point value function in terms of Φ and first constructing an approximate linear model in terms of Φ and then solving for the *exact* value function of the approximate model using Eq. (9). Although the model-based view produces exactly the same value function as the value-function-based view, the model-based view can give a new perspective on error analysis and feature selection, as shown in later sections.

3.2. The Controlled Case: LSPI

For the controlled case, we denote a *policy* as $\pi : S \mapsto A$. Since rewards and transitions are action dependent, the value function is defined over state–action pairs and is called a Q-function: For a fixed policy π, Q^π is the unique fixed-point solution to the Bellman equation

$$Q^\pi[s_i, a] = R_i^a + \gamma \sum_j P_{ij}^a Q^\pi[s_j, \pi(s_j)].$$

As in Section 2.1, Q^π can be approximated by functions in $span(\Phi)$: $\hat{Q} = \sum_{i=1}^k w_i\phi_i$, but now the basis functions ϕ_i are defined over state–action pairs rather than states.

In the controlled case, the policy π can be refined iteratively, as in the Least-Squares Policy Iteration (LSPI) algorithm (Lagoudakis & Parr, 2003). Starting with an arbitrary policy π_1, LSPI performs two steps iteratively until certain termination conditions are satisfied. In iteration i, it first computes an approximate linear value function $\hat{Q}_i$ for the current policy π_i (the *policy-evaluation* step), and then computes a new policy π_{i+1} that is greedy with respect to $\hat{Q}_i$ (the *policy-improvement* step).

In the policy-evaluation step, an algorithm LSTDQ, which is the Q-version of the LSTD algorithm, is used to compute $\hat{Q}_i$. Since a Markov decision process controlled by a fixed policy is equivalent to an induced Markov reward process whose state space is $S \times A$, LSTDQ can be viewed as LSTD running over this induced MRP. Due to Theorem 3.1, LSTDQ effectively builds a least-squares linear model approximation and then finds the *exact* solution to this model. Therefore, the intermediate value functions $\hat{Q}_i$ found by LSPI are the exact value functions of the respective approximate linear models with the smallest (weighted) L_2 error.

4. Analysis of Error: Uncontrolled Case

Value-function-based methods often analyze the error of a value function $\hat{V}$ in terms of the one-step lookahead error, or *Bellman error*:

$$BE(\hat{V}) = R + \gamma P\hat{V} - \hat{V}.$$

In the context of linear value functions and linear models, we shall define the Bellman error for a set Φ of features as the error in the linear fixed-point value function for Φ:

$$BE(\Phi) = BE(\Phi \mathbf{w}_\Phi) = R + \gamma P \Phi \mathbf{w}_\Phi - \Phi \mathbf{w}_\Phi.$$

To understand the relationship between the error in the linear model and the Bellman error, we define two components of the model error, the *reward error*:

$$\Delta_R = R - \hat{R},$$

and the *per-feature error*:

$$\Delta_\Phi = P\Phi - \widehat{P\Phi}.$$

The per-feature error is the error in the prediction of the expected next feature values, so both terms can be thought of as the residual error of the linear model. The next theorem relates the Bellman error to these model errors.

Theorem 4.1 *For any MRP M and features Φ,*

$$BE(\Phi) = \Delta_R + \gamma \Delta_\Phi \mathbf{w}_\Phi. \tag{10}$$

Proof Using the definitions of $BE(\Phi)$, Δ_R, and Δ_Φ:

$$\begin{aligned} BE(\Phi) &= R + \gamma P \Phi \mathbf{w}_\Phi - \Phi \mathbf{w}_\Phi \\ &= (\Delta_R + \hat{R}) + \gamma(\Delta_\Phi + \widehat{P\Phi})\mathbf{w}_\Phi - \Phi \mathbf{w}_\Phi \\ &= (\Delta_R + \gamma \Delta_\Phi \mathbf{w}_\Phi) + \hat{R} + (\gamma \Phi P_\Phi - \Phi)\mathbf{w}_\Phi \\ &= (\Delta_R + \gamma \Delta_\Phi \mathbf{w}_\Phi) + \hat{R} - \Phi(I - \gamma P_\Phi)\mathbf{w}_\Phi \\ &= (\Delta_R + \gamma \Delta_\Phi \mathbf{w}_\Phi) + \hat{R} - \Phi r_\Phi \\ &= \Delta_R + \gamma \Delta_\Phi \mathbf{w}_\Phi. \end{aligned}$$

The final step follows from the definition of $\hat{R}$, and the penultimate step follows from Eq. (9) and Theorem 3.1. ∎

This decomposition of the Bellman error lets us think of the Bellman error as composed of two separate sources of error: reward error, and per-feature error. In the next section, we show that this view can give insight into the problem of feature selection, but we also caution that there can be interactions between Δ_R and Δ_Φ. For example, consider the basis composed of the single basis function $\Phi^* = [V^*]$. Clearly, $BE(\Phi^*) = 0$, but for any non-trivial problem and approximate model, Δ_R and Δ_Φ will be nonzero and will cancel each other out in Eq. (10).

A similar result may be possible for the controlled case, but there are some subtleties. For example, there is not a clean notion of a fixed point for the outer loop of the LSPI algorithm since the algorithm is not guaranteed to converge to a single policy or $\mathbf{w}$.

5. Feature Selection

We present several insights on the problem of feature selection that follow from the results presented above.

5.1. General Observations about Δ_R and Δ_Φ

The condition $\Delta_R = \Delta_\Phi = 0$ is sufficient (but not necessary) to achieve zero Bellman error and a perfect value function. Specifically, it requires that the features of the approximate model capture the structure of the reward function, and that the features of the approximate model are sufficient to predict expected next features. In the case where Φ is a set of indicator functions over disjoint partitions of S, these conditions are similar to those specified for model minimization (Dean & Givan, 1997) in MDPs.

Features that are insufficient to represent the immediate reward are likely to be problematic since any error in the prediction of the immediate reward based upon the features (Δ_R) can appear directly in the Bellman error through the first summand of Eq. (10). This finding is consistent with the observation of Petrik (2007) of the problems that arise when the reward is orthogonal to the features.

For $\Delta_\Phi = 0$, the Bellman error is determined entirely by Δ_R, with no dependence on γ. This observation has some interesting implications for feature selection and the analysis of the resulting approximate value function, topics we address further in Section 5.3.

5.2. Incremental Feature Generation

This section presents two existing methods for incrementally building a basis, the *Krylov basis*, and *Bellman Error Basis Functions* (BEBFs). We also propose a new method based upon the model error, Model Error Basis Functions (MEBFs), then show that all three methods are equivalent given the same initial conditions.

5.2.1. The Krylov Basis

The Krylov basis is defined in terms of powers of the transition matrix multiplied by R. We refer to the Krylov basis with k basis functions, starting from $\mathbf{X}$, as $Krylov_k(\mathbf{X})$, with $Krylov_k(\mathbf{X}) = \{P^{i-1}\mathbf{X} : 1 \leq i \leq k\}$. For an MRP, typically $\mathbf{X} = R$. The Krylov basis, and Krylov methods in general, are standard techniques for the iterative solution to systems of linear equations. Its relevance to feature selection for RL was demonstrated by Petrik (2007).

5.2.2. BEBFs

Many researchers have proposed using features based upon the residual error in the current feature set (Wu & Givan, 2004; Sanner & Boutilier, 2005; Keller et al., 2006). Parr et al. (2007) describe this family of techniques as Bellman Error Basis Functions (BEBFs), and analyze some of the properties of this approach. More formally, if $\Phi_k \mathbf{w}_{\Phi_k}$ is the current value function, BEBF adds $\phi_{k+1} = BE(\Phi_k)$ as the next basis function. We refer to the basis resulting from $k-1$ iterations of BEBF, starting from $\mathbf{X}$, as $BEBF_k(\mathbf{X})$.

Theorem 5.1 *(Petrik[2]) For any $k \geq 1$,*

$$span(Krylov_k(R)) = span(BEBF_k(R)).$$

Proof The proof is by induction on k. For the basis:

$$Krylov_1(R) = BEBF_1(R) = R.$$

For the inductive step, we assume equality up to k, so for both methods the value function can be expressed as:

$$\Phi_k \mathbf{w}_{\Phi_k} = \sum_{i=1}^{k} w_i P^{i-1} R.$$

Now, observe that:

$$BE(\Phi_k) = R + \gamma P(\sum_{i=1}^{k} w_i P^{i-1} R) - \sum_{i=1}^{k} w_i P^{i-1} R.$$

The only part of the above that is not already in the basis is the contribution from $P^{k+1}R$, which is precisely what is added in $Krylov_{k+1}(R)$. ∎

5.2.3. MEBFs

A natural generalization of BEBFs to the model-based view would be to add features that capture the residual error in the model. Starting from Φ_k, this technique (MEBF) adds Δ_R and Δ_Φ (or the linearly independent components thereof) to the basis at each iteration to create Φ_{k+1}. In contrast to BEBFs, this method can add a large number of basis functions at each iteration since Δ_Φ has as many columns as Φ. One might imagine that this process could result in an exponential growth in the number of basis functions. In fact, however, the number of new basis functions added at each iteration will not grow since each new set of basis functions that is added will drive the error in the previous basis functions to 0.

We refer to the basis resulting from $k-1$ iterations of MEBF, starting from $\mathbf{X}$, as $MEBF_k(\mathbf{X})$. For an initial basis of Φ, the MEBF basis expansion is guaranteed to contain the BEBF basis expansion.

Theorem 5.2 $span(BEBF_2(\Phi)) \subseteq span(MEBF_2(\Phi))$.

Proof Follows immediately from Eq. (10). ∎

Theorem 5.3 *For $k \geq 1$:*

$$span(Krylov_k(R)) = span(MEBF_k(R)).$$

Proof The proof is by induction on k. For the basis:

$$Krylov_1(R) = MEBF_1(R) = R.$$

For the inductive step, we assume equality up to k and consider the behavior of MEBF. For $k \geq 1$, $\Delta_R = 0$, since R is the first basis function added. The basis Φ_k is equivalent to a collection of basis functions of the form $\phi_i = P^{i-1}R$ for $1 \leq i \leq k$. As a result, $P\phi_i$ is already in the basis for all $1 \leq i < k$. Thus, the only nonzero column of Δ_Φ will correspond to feature ϕ_k and will be $P^k R - P_\Phi P^{k-1} R$. Since $P_\Phi P^{k-1} R$ is necessarily in $span(\Phi_k)$, the only new contribution to the basis made by MEBF will be from $P^k R$, which is precisely what is added by $Krylov_{k+1}(R)$. ∎

These results show that, starting from R, all three methods will produce the same basis. An advantage of BEBF is that it will produce orthogonal basis vectors. An advantage of MEBF is that it can add multiple new basis vectors at each iteration if it is initialized with a set of basis functions.

5.3. Invariant Subspaces of P

The form of the Bellman error in Eq. (10) suggests that features for which $\Delta_\Phi = 0$ are particularly interesting. If a dictionary of such features were readily available, then the feature-selection problem would reduce to the problem of predicting the immediate reward using this dictionary.

The condition $\Delta_\Phi = 0$ means that, collectively, the features are a basis for a perfect linear predictor of their *own* next, expected values. More formally, features Φ are *subspace invariant* with respect to P if $P\Phi$ is in $span(\Phi)$, which means that there exists a Λ such that $P\Phi = \Phi\Lambda$.

At first, it may seem like subspace invariance is an extraordinary requirement that could hold only for a complete basis for P. It turns out, however, that there are many ways to describe invariant subspaces of P. Any set of eigenvectors of P forms an invariant subspace. For eigenvectors $\mathcal{X}_1 \ldots \mathcal{X}_k$ with eigenvalues $\lambda_1 \ldots \lambda_k$, $\Lambda = \text{diag}(\lambda_1 \ldots \lambda_k)$. The set of generalized eigenvectors corresponding to a particular eigenvalue λ of P is subspace invariant with respect to P. For an eigenvalue λ with multiplicity i, there will be i generalized eigenvectors, $\mathcal{X}_1 \ldots \mathcal{X}_i$ satisfying $(P - \lambda I)\mathcal{X}_j = \mathcal{X}_{j-1}$ for $1 \leq j \leq i$ and $(P - \lambda I)^j \mathcal{X}_j = 0$ for $0 \leq j \leq i$. More generally, if Φ^1 and Φ^2 are subspace invariant with respect to P, then so is their union. Finally, the Schur decomposition of a matrix P provides a set of nested invariant subspaces of P.

In fairness, we point out that these methods all require knowledge of P and superlinear computation time in the dimension of P. We defer discussion of the practicality of implementing these methods to Section 6 and Section 7.

Theorem 5.4 *For any MRP M and subspace invariant feature set Φ, $\Delta_\Phi = 0$.*

Proof First, we observe that P_Φ has a particularly simple

[2] M. Petrik, personal communication, 2007.

form as a consequence of subspace invariance:

$$P_\Phi = (\Phi^T\Phi)^{-1}\Phi^T P\Phi = (\Phi^T\Phi)^{-1}\Phi^T\Phi\Lambda = \Lambda.$$

Substituting into the definition of Δ_Φ:

$$\Delta_\Phi = P\Phi - \widehat{P\Phi} = P\Phi - \Phi P_\Phi = \Phi\Lambda - \Phi\Lambda = 0. \ \blacksquare$$

Subspace invariant features have additional intriguing properties. The resulting value function always exists and can be interpreted as the result of using the true transition model with the approximate reward function $\hat{R}$.

Theorem 5.5 *For any MRP M and subspace invariant feature set Φ, $\mathbf{w}_\Phi$ always exists and*

$$\Phi\mathbf{w}_\Phi = (I - \gamma P)^{-1}\hat{R}.$$

Proof Starting with the form of $\mathbf{w}_\Phi$ from Eq. (7) and the fact that $\Delta_\Phi = 0$:

$$\begin{aligned} \Phi\mathbf{w}_\Phi &= \hat{R} + \gamma\widehat{P\Phi}\mathbf{w}_\Phi \\ &= \hat{R} + \gamma P\Phi\mathbf{w}_\Phi \\ \Phi\mathbf{w}_\Phi - \gamma P\Phi\mathbf{w}_\Phi &= \hat{R} \\ \Phi\mathbf{w}_\Phi &= (I - \gamma P)^{-1}\hat{R}. \end{aligned}$$

To confirm that such a $\mathbf{w}_\Phi$ actually exists, we note that $\hat{R} \in span(\Phi)$ by construction, and that $(I - \gamma P)^{-1}$ must exist for the actual P and $0 \leq \gamma < 1$, allowing us to rewrite:

$$\Phi\mathbf{w}_\Phi = \sum_{i=0}^{\infty} \gamma^i P^i \hat{R},$$

which remains in $span(\Phi)$ because of Φ's subspace invariance with respect to P. $\blacksquare$

Our analysis has some similarities with that of Petrik (2007). Petrik considered the eigenvalue decomposition of P as a basis and considered the error in the projection of V^* into this basis. Petrik also suggested the use of the Jordan form, which would provide generalized eigenvectors for matrices that are not diagonalizable. Our analysis focuses on the Bellman error of the linear fixed-point solution. Insights from the model-based view of linear approximation architectures allow us to decompose the error into distinct components corresponding to the reward and transition models, making the role of invariant subspaces particularly salient.

6. Experimental Results

We present policy-evaluation results on three different problems. Our objective is to demonstrate how our theoretical results can inform the feature-selection process and explain the behavior of known feature-selection algorithms. We consider 4 algorithms:

PVF: This is the proto-value function (PVF) framework described by Mahadevan and Maggioni (2007). PVFs use eigenvalues of the Laplacian derived from an empirically constructed adjacency matrix (from random walk trajectories), enumerated in increasing order of eigenvalue. We reproduced their method as closely as possible, including adding links to the adjacency matrix for all policies, not just the policy under evaluation. Curiously, removing the off-policy links seemed to produce worse performance. We avoided using samples to eliminate the confounding (for our purposes) issue of variance between experiments. We used the combinatorial Laplacian for the 50-state and blackjack problems, but used the normalized Laplacian in the two-room problem to match Mahadevan and Maggioni (2007).

PVF-MP: This algorithm selects basis functions from the set of PVFs, but selects them incrementally based upon the Bellman error. Specifically, basis function $k+1$ is the PVF that has highest dot product with the Bellman error resulting from the previous k basis functions. It can be interpreted as a form of matching pursuits (Mallat & Zhang, 1993) on the Bellman error with a dictionary of PVFs.

Eig-MP: This algorithm is similar to PVF-MP, but selects from a dictionary of the eigenvectors of P. Both Eig-MP and PVF-MP are similar in spirit to Petrik's WL algorithm.

BEBF: This is the BEBF algorithm starting with $\Phi_0 = R$, as described in Section 5.2.

Our experiments performed unweighted L_2 projection and report unweighted L_2 norm error. We also considered L_∞ error and L_2 projections weighted by stationary distributions, but the results were not qualitatively different. We report the Bellman error, the reward error, and the *feature error*, which is the contribution of the per-feature errors to the Bellman error: $\gamma\Delta_\Phi\mathbf{w}_\Phi$. These metrics are presented as a function of the number of basis functions.

6.1. 50-state Chain

We applied all 4 algorithms to the 50-state chain problem from Lagoudakis and Parr (2003), with the results shown in Figure 1(a–c). As demanded by theory, Eig-MP has 0 feature error, which means that the entirety of the Bellman error is expressed in Δ_R. BEBFs represent the other extreme since $\Delta_R = 0$ after the first basis function is added and the entirety of the Bellman error is expressed through Δ_Φ. For this problem, PVFs appear to be approximately subspace invariant, resulting in low Δ_Φ. However, both Eig-MP and the PVF methods do poorly because the reward is not easily expressed as linear combination of a small number of PVFs. PVF-MP does better than plain PVFs because it is actively trying to reduce the error, while plain PVFs choose basis functions in an order that ignores the reward.

6.2. Two-room Problem

We tried all four algorithms on an optimal policy for the two-room navigation problem from Mahadevan and Maggioni (2007). The transition matrix for this problem is not diagonalizable and typical methods for extracting generalized eigenvectors proved unreliable, so we do not show results for the Eig-MP method. Figure 1(d–f) shows the breakdown of error for the remaining algorithms. In this case, the Laplacian approach produces features that behave less like an invariant subspace, resulting in high Δ_R and Δ_Φ. However, there is some cancellation between them.

6.3. Blackjack

We tested a version of the bottomless-deck blackjack problem from Sutton and Barto (1998), evaluating the policy they propose. For the model described in the book, all methods except BEBF performed extremely poorly. To make the problem more amenable to eigenvector-based methods, we implemented an ergodic version that resets to an initial distribution over hands with a value of 12 or larger and used a discount of 0.999. The breakdown of error for the different algorithms is shown in Figure 1(g–i), where we again omit Eig-MP. As expected, BEBFs exhibit $\Delta_R = 0$, and drive the Bellman error down fairly rapidly. PVFs exhibit some interesting behaviors: When the PVFs are enumerated in order of increasing eigenvalue, they form an invariant subspace. As a result, the feature error for PVFs hugs the abscissa in Figure 1(i). However, this ordering completely fails to match R until the very last eigenvectors are added, resulting in very poor performance overall. In contrast, PVF-MP adds basis eigenvectors in an order that does not result in subspace invariant features sets, but that does match R earlier, resulting in a more consistent reduction of error.

7. Discussion and Future Work

A significant finding in our work is the close relationship between value-function approximation and model-based learning. Our experimental results illustrate the relationship between the power of the features to represent an approximate model and the Bellman error.

While features that represent feature transitions accurately have highly desirable properties, both components of the model, the reward function and the transition function, should be respected by the features. Both a strength and weakness of the BEBF/MEBF/Krylov methods is their connection to specific policies and reward structures. Our results are consonant with those of Petrik (2007), which showed good performance for the Krylov basis and some surprisingly weak performance for eigenvector-based methods despite their appealing properties.

To focus on the expressive power of the features, our results in this paper do not directly consider sampled data, the regime in which linear fixed-point methods are most often employed. Some initial results on the effects of noise in feature generation for BEBF/MEBF/Krylov methods can be found in Parr et al. (2007), however further analysis would still be helpful. For eigenvector-based methods, there are some questions about the cost of estimating eigenvectors of P, or an approximation to P via the Laplacian. Computing eigenvectors can be computationally intensive and, for general P, prone to numerical instabilities.

An important direction for future work is seeking a deeper understanding of the interaction between feature-selection and policy-improvement algorithms such as LSPI.

8. Conclusion

This paper demonstrated a fundamental equivalence between linear value-function approximation and linear model approximation for RL. This equivalence led to a novel view of the Bellman error, which then gave insight into the problem of feature selection. These insights were used to explain the behavior of existing feature-selection algorithms on some sample problems. While this research has not, yet, led to a novel algorithmic approach, we believe that it helps address fundamental questions of representation and feature selection encountered by anyone wishing to solve real RL problems.

Acknowledgment

We thank Carlo Tomasi and Xiaobai Sun for helpful discussions, Sridhar Mahadevan and Jeff Johns for pointing out some discrepancies between our interpretation of the two-room problem in an earlier version of this paper and the version in Mahadevan and Maggioni (2007), and Marek Petrik for Theorem 5.1. Abstract

In the absence of explicit queries, an alternative is to try to infer users' interests from implicit feedback signals, such as clickstreams or eye tracking. The interests, formulated as an implicit query, can then be used in further searches. We formulate this task as a probabilistic model, which can be interpreted as a kind of transfer or meta-learning. The probabilistic model is demonstrated to outperform an earlier kernel-based method in a small-scale information retrieval task.

1. Introduction

The classic problem in information retrieval (IR) is to rank a set of documents according to the user's current interest, with the documents most relevant for the user ranked among the first. The same theme recurs currently in other applications of machine learning such as recommender systems. Current IR systems rely mostly on explicit, typed queries to perform the ranking.

The main problem in this traditional IR scenario is that it is difficult even for experienced users to formulate good textual queries (Turpin & Scholer, 2006), and therefore user's interest needs to be inferred partly from other sources. A straightforward way is to collect explicit feedback, that is, the user labels some of the documents relevant or irrelevant for her interests. Giving explicit feedback is however laborious. It would be ideal if the IR system would be able to unobtrusively collect and use *implicit feedback* to infer the interest of the user while she works and use this information to improve the quality of the search results. We call this task *proactive information retrieval*.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Several forms of implicit feedback, such as clickstream data, time spent during reading, and amount of scrolling and exit behaviour, have been used with some success (Kelly & Teevan, 2003; Claypool et al., 2001; Fox et al., 2005; Joachims et al., 2005; Joachims & Radlinski, 2007). While these sources of feedback are often readily available, they offer only limited information of users' interests.

Gaze patterns are a promising source of information about the attention of the user, and hence of implicit feedback. They have been used for information retrieval in two papers (Puolamäki et al., 2005; Hardoon et al., 2007). In the latter, eye tracking-based feedback improved information retrieval performance in an experiment where no explicit queries were available, and everything was inferred from the eye movements and the texts. The setup was slightly different from standard IR. The users saw sets of ten simplified (Wikipedia) documents, about half of which were relevant to a topic given to them beforehand, while the remaining documents were of other randomly selected topics. Based on the gaze pattern, an implicit query was constructed and used to rank unseen documents. The results were significantly better than random rankings.

We extend these results in two ways. First, we will use the eye tracking-based feedback in a more realistic IR scenario. Instead of randomly sampled documents, the user is shown a ranked list of top-5 results, and the task of the system is to improve the ranking of the yet unseen documents. Second, we will improve on the methodology. In (Hardoon et al., 2007) we introduced a two-stage prediction algorithm ("SVM model" in the following), where the latter stage was an SVM which classified new documents into relevant and irrelevant, given a parameter vector that consists of a weight for each word. The parameter vector was inferred with a regressor which had been trained to predict the weight of a word based on the eye movement pattern on the

word. The problem with this method is that learning of the regressor requires a ground truth which is tricky. In the earlier paper we used the parameter vector of an SVM taught to classify the relevant and irrelevant documents in the off-line learning stage, based on their textual content. This is intuitively a sensible strategy, and the experimental results validated it, but the choice is unlikely to be optimal.

In this paper, we introduce a probabilistic model for inferring relevance of the documents. Incorporating both of the two stages, inference of the relevance of a new document and inference of the implicit query, into a single generative model solves rigorously the problem of getting the ground truth and the learning procedure will be optimal for the task, given our modeling assumptions. The method indeed outperforms the earlier one (Hardoon et al., 2007).

Learning of the probabilistic model is related to transfer learning and meta-learning. The implicit query is expressed in the model as latent variables shared within each search task. The central task is to learn an implicit query for a topic unseen in the original training phase, which translates to transfer learning. The eye movements from which the implicit query is inferred can be considered as meta-data for the documents.

We test the method in an experimental scenario designed to closely resemble a real information retrieval setup. The user makes a query within a restricted Wikipedia corpus located in our customized Wikipedia server. A search engine then ranks the top-10 documents for this query, and the first five are shown sequentially to the user using a web browser. The browser has been modified to record and transmit the eye movement measurements to the Wikipedia server. We rank the remaining 5 documents by our eye movement-based model and aggregate the new and the original ranking to produce an ordering for the remaining 5 documents. Average precision in the re-ranked 5 documents was used as the goodness criterion.

Our method, once trained, consists only of a linear discriminator applied to term-specific gaze and term features. Therefore, the method can be applied efficiently in linear time whenever the eye tracking data is available.

2. The Information Retrieval Task

The usual approach in IR is to rank the documents based on their match to a textual query (Baeza-Yates & Ribeiro-Neto, 1999). In our setup the user types in a textual query that reflects her interest but is typically an incomplete description. Then the search engine shows her the top-ranked documents. The eye movements of the user are measured while she reads the documents presented sequentially in the ranked order. Our objective is to use the gaze patterns to improve the ranking of the yet unseen documents. These documents are consequently shown to the user in an order modified using the implicit query inferred from the gaze patterns. In doing so the relevant documents are hopefully shown to the user earlier, that is, the average precision of the search result is improved.

2.1. Okapi BM25 Ranking Function

A widely used ranking function is given by Okapi BM25 (Robertson & Walker, 1994; Robertson & Zaragoza, 2007), which is also used as a baseline method throughout this paper. Okapi BM25 ranks the documents given a textual query q that is a set of terms. Our approach is independent of the actual ranking function, however; indeed, in this work, we could replace Okapi BM25 with any information retrieval system that outputs a ranking of documents for a given query.

Consider a document collection C where each document $d = \{tf_t\}_{t \in V}$ in the collection is a vector of term frequencies, where tf_t is the frequency of term t in the document and V is the vocabulary. For ad hoc retrieval the BM25 weighting function can be expressed as

$$w_t(d, C) = \frac{(1 + k_1) tf_t}{k_1 \left((1 - b) + b \frac{dl}{avdl}\right) + tf_t} \log \frac{|C| - df_t + \frac{1}{2}}{df_t + \frac{1}{2}}, \quad (1)$$

where df_t is the document frequency of term t, dl is the document length and $avdl$ is the average document length across the collection. The k_1 and b are free parameters which we for the purposes of this paper fix to $k_1 = 1.2$ and $b = 0.75$, as suggested by Robertson and Walker (1999). The documents are ranked according to the sum of the weights of the terms in query q:

$$W(d, q, C) = \sum_{t \in q} w_t(d, C). \quad (2)$$

2.2. Metasearch

We have at our disposal a separate and independent ranking system, described in detail in Section 3, that ranks the yet unseen documents based on the gaze patterns of the users. In effect, we have two rankings: the ranking derived from the textual query and given by the Okapi BM25 ranking function described in Section 2.1, and the ranking derived from the gaze patterns.

The problem of combining multiple search engine rankings into one is known as *metasearch* and it has been studied extensively during the past years (see, for example, Cohen et al., 1998; Aslam & Montague, 2001). Because in this work we aim for simplicity and robustness, we use a straightforward linear combination of rankings. Another reason for this choice is that we want our approach to work also with a "black box" search engine which only gives us a ranking of the documents, without any probability of relevance associated with the documents.

In more detail, let $r_{BM25}(d)$ and $r_{EYE}(d)$ be the ranks of the document d given by the Okapi BM25 ranking function and the eye movement model, respectively. We re-rank the yet unseen documents using $score(d)$ defined by

$$score(d) = \gamma r_{BM25}(d) + (1-\gamma) r_{EYE}(d), \quad (3)$$

with the document having the smallest $score(d)$ ranked first. Here γ is a constant between zero and one.

3. Learning to Learn: A Probabilistic Model

In this section we introduce a probabilistic model that can be used to infer the ranking of yet unseen documents for a new and unknown query, given how the user has viewed a set of documents. In practice, the viewed documents are the highest-ranked documents for a given unknown query, and the inferred ranking is used to modify the order in which the further documents are presented.

3.1. Probabilistic Model

The available data is a collection of documents, encoded as TFIDF vectors $\mathbf{d}$, where the component corresponding to term t is

$$\mathbf{d}_t = tf_t \log \frac{|C|}{df_t}.$$

For the viewed documents we additionally have eye movement features. The feature vector $\mathbf{e}_{it}$ contains feature values for term t in document i. There are two types of features: eye movement features that are computed from the eye movement pattern over the term, and textual features that depend only on the term and its location in the document. The features are described in Section 4.3.

In the model, the relevancy r of a document is assumed to depend on the TFIDF vector $\mathbf{d}$ of the document and a search task specific *query vector* $\mathbf{w}$. Our main assumption is that the importance of a certain term for a search query depends only on the way the term is viewed, not on the meaning of the term. This allows us to learn global parameters α and $\boldsymbol{\beta}$, which are common for all search tasks, for the mapping from the features $\mathbf{e}$ to the term's weights w_t. The model is illustrated in Figure 1.

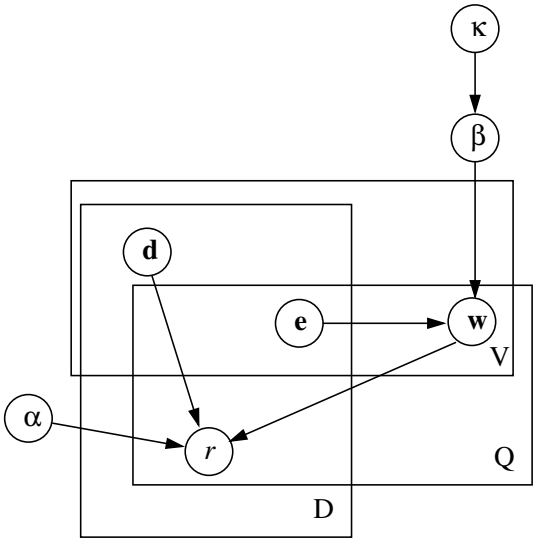

Figure 1. Graphical representation for the generative process for learning to learn. The plates are repeated the number of times shown in their bottom right corner; V is the number of terms in the vocabulary, Q of search tasks, and D of documents in the collection. The $\mathbf{d}$ is the TFIDF representation of the document and r is the 0–1 relevance of a document in a given search task. The $\mathbf{e}$ are the term-specific eye movement and text features and $\mathbf{w}$ is the query inferred from the eye movement features. The α and $\boldsymbol{\beta}$ are parameters shared by all search tasks, and κ is a prior parameter.

The query vector $\mathbf{w}$ of a search task is a vector in $\mathbb{R}^{|V|}$, where $|V|$ is the number of terms in the vocabulary. The entries in the query vector can be interpreted as the relative importance of the terms for the query. We assume that the entries in the query vector are normally distributed, with the mean depending on the eye movement features during the search task. We further assume that the mapping from the eye movements to the query weights is universal in the sense that the parameters of the mapping depend neither on the search task nor on the specific term.

The query weight w_{qt} for term t in the search task q depends on the viewed documents (in our experiments top-k with $k = 5$) in the search task, denoted by D_q, and on all term features in the search task, denoted collectively by $\mathbf{E}^q$. We assume that the dependency is

linear,

$$p(w_{qt}|\mathbf{E}^q, \boldsymbol{\beta}, \boldsymbol{\beta}') = N\left(\frac{1}{|D_q|}\sum_{i\in D_q}\left(\boldsymbol{\beta}^T\mathbf{e}_{it}I_{it} + \boldsymbol{\beta}'^T\mathbf{e}_{it}(1-I_{it})\right), \sigma^2\right), \quad (4)$$

where the indicator variable $I_{it} = 1$ if term t is viewed in document i, and 0 otherwise. If a term appears in the document but is not viewed only the textual features have non-zero values. If a word t does not appear in document i, the term's features are set to zero: $\mathbf{e}_{it} = \mathbf{0}$. The two regression coefficient vectors $\boldsymbol{\beta}$ and $\boldsymbol{\beta}'$, for viewed and unviewed terms, respectively, are common for all tasks. For notational simplicity we denote both of these parameters by $\boldsymbol{\beta}$ in the following.

For the probability of relevance r of a document in a search task q we assume the functional form of logistic regression. The probability is assumed to be a sigmoidal function of the dot product of the document TFIDF vector $\mathbf{d}$ and the query vector $\mathbf{w}_q$,

$$p(r|\mathbf{d}, \mathbf{w}_q, \alpha) = \frac{1}{1 + e^{-(\alpha + \mathbf{d}^T\mathbf{w}_q)}}. \quad (5)$$

The parameter α is common for all tasks.

We assume availability of a collection of background tasks for learning. Each background task is a search session where we know the relevances of the displayed documents, and have observed users' eye movements. The background tasks are used to learn the shared parameters.

The hyperparameters of the model, α and $\boldsymbol{\beta}$ on which the transfer learning is based, are estimated by maximizing the posterior from which all other parameters have been marginalized out. The logarithm of the marginalized posterior to be maximized is

$$\begin{aligned} L &= \sum_{i\in D_{BG}} \log p(r_i|\mathbf{d}_i, \alpha, \boldsymbol{\beta}) + \log p(\boldsymbol{\beta}|\kappa) \\ &= \sum_{i\in D_{BG}} \log \int p(r_i|\mathbf{d}_i, \mathbf{w}_{q(i)}, \alpha) p(\mathbf{w}_{q(i)}|\mathbf{E}^{q(i)}, \boldsymbol{\beta}) d\mathbf{w}_{q(i)} \\ &\quad + \log p(\boldsymbol{\beta}|\kappa) \\ &\approx \sum_{i\in D_{BG}} \log p(r_i|\mathbf{d}_i, \hat{\mathbf{w}}(q(i), \boldsymbol{\beta}), \alpha) + \log p(\boldsymbol{\beta}|\kappa), \end{aligned}$$

where $q(i)$ is the index of the background task during which document i was shown, D_{BG} is the set of all top-k documents in background tasks, and $\log p(\boldsymbol{\beta}|\kappa) = -\kappa/2\boldsymbol{\beta}^T\boldsymbol{\beta}$ is a Gaussian prior for $\boldsymbol{\beta}$. We assume a uniform prior for α. In the last step, the integral is approximated for computational reasons by a point estimate evaluated at the mode $\hat{\mathbf{w}}$ of $p(\mathbf{w}_{q(i)}|\mathbf{E}^{q(i)}, \boldsymbol{\beta})$; the entries of the mode are

$$\begin{aligned} \hat{w}_t(q, \boldsymbol{\beta}) &= \arg\max_{w_{qt}} p(w_{qt}|\mathbf{E}^q, \boldsymbol{\beta}) \\ &= \frac{1}{|D_q|}\sum_{i\in D_q}\left(\boldsymbol{\beta}^T\mathbf{e}_{it}I_{it} + \boldsymbol{\beta}'^T\mathbf{e}_{it}(1-I_{it})\right). \quad (6) \end{aligned}$$

Here $|D_q| = k$ is the number of viewed documents (top-k documents) in the search task q.

The learned values of the hyperparameters α and $\boldsymbol{\beta}$ are used to transfer knowledge from the old tasks to a new one. For the new task, we observe only eye movements on a small number of documents; we do not know the relevances of the documents as in the learning phase. The best prediction of relevance would result by integrating over the potential query vectors, but for computational reasons we again estimate the integral by the mode of $p(\mathbf{w}_{q(i)}|\mathbf{E}^{q(i)}, \boldsymbol{\beta})$. The mode can be interpreted as the estimated query vector $\mathbf{w}_{new}$, estimated using the equation (6), where the sum now is over the documents in the new task.

The ultimate goal is to find documents which are relevant to the new query. We rank the test set of unseen documents according to the probabilities (5) computed using $\mathbf{w}_{new}$.

3.2. SVM Model

The probabilistic model was motivated by the model (denoted by "SVM model") of Hardoon et al. (2007); we compared our model with the linear variant of the SVM model that performed almost as well as the best one in the original paper.

The main difference between our probabilistic model and the SVM model is that we have a full generative framework for all observations. A useful consequence of this is that we have a principled way for generating the search task specific implicit query $\mathbf{w}$ from the term-specific eye movements patterns. In the SVM model this step was somewhat ad hoc; the ground truth was obtained by classifying relevant vs. irrelevant documents in the training data. The regressor then tried to predict the SVM discriminator weights from eye tracking data. There is no guarantee that the discriminator weights used by the SVM are optimal, or even always good, targets taking into account uncertainties stemming from the noisy eye movements.

Note that in this paper we used fairly simple computational approximations for generating the task-specific implicit queries $\mathbf{w}$. The fact that the results are still good gives the model further support; if necessary,

more accurate approximations can be developed later.

3.3. Connection to Transfer Learning and Meta-Learning

In our problem we need to learn to learn an implicit query from the text of the document and gaze pattern. This needs to be done for search topics unseen in the training phase. Each search topic has a hidden representation that we have to learn, namely the query vector $\mathbf{w}$. We have additionally introduced hyperparameters, namely the α and $\boldsymbol{\beta}$, that are shared across all search tasks. The shared parameters contain information that is needed to learn the search task-specific query vector.

Our modeling assumption is that there exists information in the gaze pattern that is independent of the actual semantic content of the words and of the specific query. We encode independence of the specific query by introducing the parameters α and $\boldsymbol{\beta}$ that are shared across the search tasks. Independence of the semantic content is achieved by constructing the model so that the query vector $\mathbf{w}$ depends only on text and eye movement features associated with a specific term, but not on the semantic content of the terms. In other words, the model is invariant with respect to any permutation of term labels.

The learning process, described in Section 3.1, can be interpreted to have two phases: in the first phase the parameters α and $\boldsymbol{\beta}$ that are shared across all search tasks are learned using several background search tasks. In the second "on-line" phase a search task-specific query vector $\mathbf{w}$ (for a previously unseen search task) is estimated using the shared parameters.

Our problem is related to transfer learning and meta-learning (Thrun, 1996; Baxter, 2004; Caruana, 1997; Ando & Zhang, 2005; Thrun, 1998; Pratt & Thrun, 1997; Vilalta & Drissi, 2002; Giraud-Carrier et al., 2004). Transfer learning and meta learning utilize data from other "similar" learning tasks and from multiple applications of the learning system. For example, learning to recognize objects in cartoons might help to recognize objects in photographs (Elidan et al., 2006); or in our case, learning to infer query vectors in search tasks helps in learning a query vector in a yet unseen search task. We can think that in our case the inductive bias extracted is parametrized by α and $\boldsymbol{\beta}$ and fixed when these parameters are learned. When we observe a new search task we can then use the information coded in α and $\boldsymbol{\beta}$ to learn the task-specific query vector $\mathbf{w}$ that can finally be used to predict the relevance of a given document.

4. Experiments

We conducted small scale eye tracking experiments to validate the proposed model. The experiments were designed to simulate the common case where some keywords are available but they are not a sufficient description of the interests.

4.1. Search Tasks

We constructed 13 search tasks for text documents (see Table 1). The search tasks were chosen prior to doing any experiments. The criteria for selecting the search tasks were that there should be several relevant documents for each task and, furthermore, that the original query should also suggest irrelevant documents. That is, there should be irrelevant documents which are ranked quite high. This is why the search terms were purposefully ambiguous.

For example, in search task number 3 the task was to find information about "ancient Rome." The user would be instructed to find documents that would tell about ancient Rome. The textual search query, forced by us, was "Rome." As a result, the search results included articles also, for example, of modern Rome. Our purpose was to see whether the gaze pattern could be used to infer a new query. Intuitively, the query vector $\mathbf{w}$ inferred from the eye movements could include with positive weight terms related to ancient Rome, such as "ancient", "Caesar" and "Carthage"; and possibly with negative weight terms related to the modern times, such as "airport" or "president".

The document corpus consisted of articles downloaded from Wikipedia. Only the lead section of the documents before the first section header was shown to the user and used in the experiments. For each search task, we selected 10 documents having the highest BM25 score.

4.2. Experimental Procedure

There were three participants in the experiments, one female and two males. The test subjects were voluntary under and post-graduate researchers (the authors were not included).

The participants were asked to search for documents of a given topic using a web search engine. They were advised to act as if they were collecting the relevant documents of the topic for later reading, that is, they were supposed to stop reading the document once they had determined whether the document was relevant. Each task was started by clicking a search button which submitted the pre-entered search term to a custom server.

Table 1. The search tasks and the given search terms.

Task number	Desired topic	Search term
1	American football	football
2	Alternative medicine	medicine
3	Ancient Rome	Rome
4	Adhesive tape	tape
5	Environmental conservation	conservation
6	Seal (marine mammal)	seal
7	Extra-solar planets	planets
8	Visual nervous system	vision
9	Internet forums	forum
10	Marketing strategies	strategies
11	National libraries	libraries
12	British Royal Navy	navy
13	Space shuttles	shuttle

Our search engine did not return a list of the most relevant documents as search engines usually do. Instead, it returned the most relevant document directly. In the bottom of each document there were two links which were used for marking the document as either relevant or not relevant. Clicking one of these links retrieved the next document. All other links were removed from the documents. The search engine returned the documents in the order determined by the BM25 algorithm. Each search session included 10 documents. After finishing one session the test subject was automatically given a topic and search terms for the next task.

The relevance judgements given by the users were used as ground truth during the training phase of the model. In testing phase they were used to validate the results.

During the search tasks the users' eye movements were recorded with a Tobii 1750 eye tracker. Tobii tracks gaze location by measuring the reflection pattern on the cornea of eye. It does not require wearing a helmet or a headrest. The users were sitting 60 cm away from a 17 inch computer screen. The system was calibrated once in the beginning of the experiment.

4.3. Term Features

The eye tracker and the browser recorded the sequence of fixations; it was then transmitted to the Wikipedia document server when the user clicked any link. A part of the gaze trajectory was considered a fixation if the gaze stayed inside a 30 pixel square (about 0.6 visual angle) for more than 100 ms. Fixations that appeared outside the bounding boxes of vocabulary words were ignored. The vocabulary consisted of stemmed words, with stop words removed. The size of the vocabulary was 3030 words.

For each term t, we extracted 19 eye movement features and 3 text features, denoted collectively by $\mathbf{e}_t$. We used the same eye movement features, such as number of fixations, absolute, relative and mean fixation durations, used by Hardoon et al. (2007) as well. The 3 text features were independent of the actual search task; they are the number of characters in the word, the relative position of the word in the document, and the inverse document frequency of the word.

4.4. Combination of Textual and Eye Movement Based Searches

We show that a simple combination of our eye movement-based ranking and a ranking by a state-of-the-art textual IR algorithm has higher precision than the textual search alone. For the textual search we use BM25, a well-known bag-of-words ranking function.

We measured the eye movements while the users were reading top-5 documents as returned by BM25. The documents below the rank 5 were used for testing. We ranked the test documents with our method thus getting a second ranking in addition to the original BM25 ranking. We combined the two rankings by reordering the documents according to the weighted average (3).

To compare the original BM25 ranking and the combined ranking, we compare their average precision, a common measure for evaluating search results. It is computed as the average of the precisions at positive rankings: $\frac{1}{R}\sum_{i=1}^{R}\frac{i}{r_i}$, where R is the total number of relevant documents, and the r_i are the rankings of the positive documents such that $r_i < r_{i+1}$. The best possible average precision is one, which corresponds to all relevant documents being ranked in the first positions.

We learn the query vector for each search task by leaving the data for that task out and using the remaining tasks as background tasks in the first phase of the training, as was discussed in Section 3.1. In the "online" phase we use the top-5 documents from the left-out task to infer the query vector.

We combine BM25 and the probabilistic model by using equation (3). For that purpose we need to decide a value for the weighting factor γ. We compare the mean average precision of the plain BM25 and the combination of BM25 and the proposed probabilistic model for documents that are ranked 6–10 in each background task for several discrete values of γ, and for each task select the γ value that has the best mean improvement in average precision. We use the average of these task-specific best values of γ in order to obtain a common value of $\gamma = 0.2$, which is then the value used in all of the experiments. The value $\kappa = 1$ for the prior pa-

rameter is selected in an analogous fashion at the same time.

The results are shown in Table 2. On the test set, in 9 search tasks out of 13 the mean average precision of the combined ranking across test subjects outperformed the baseline BM25 ranking. The difference in average precision is statistically significant ($p = 0.047$, one-tailed Wilcoxon Signed Rank Test).

The worst performance is shown by task 6 in which the only relevant document in ranks 6–10 (according to the users' relevance judgement) was moved from being 6th to 10th, thus reducing the average precision for documents in ranks 6–10 from unity of the BM25 baseline down to 0.29. In all the other tasks the performance either improved clearly, or for some degraded slightly.

In order to examine the relative contributions of the eye movement and textual features we compared two probabilistic models, one using just the text features (of all words, irrespective of whether they were looked at or not) and one using all the features. The mean average precision of the latter was 6.3 percentage units higher but for this amount of data the difference was not statistically significant ($p = 0.22$).

4.5. Comparison to the SVM Model

We compared the performance of the combination of BM25 and the probabilistic model to an analogous combination of BM25 and the SVM (of Section 3.2). The SVM model is trained using the eye movements on the training documents, as described in (Hardoon et al., 2007), and the resulting ranking is combined to the BM25 ranking identically as was done above for the probabilistic model.

The mean average precision of the combination of BM25 and the SVM is worse than the average precision of BM25 for all values of the weighting parameter γ. The bad performance of the SVM model here is probably due to the fact that the ground truth for the query vectors, estimated with SVM from the very small data sets, is likely to be very noisy. It is also possible that the probabilistic model is otherwise better suited for the relatively small training set sizes.

5. Discussion

We introduced a generative model of how the relevance of documents is related to the viewing patterns of people during a search task. The model is trained in two phases. In the first phase, the hyperparameters that are independent of the search topic are learned. In the second "on-line" phase, the learned parameters are used to infer an implicit query from the gaze patterns during a new search session.

The system is realistically applicable; we have indeed implemented it using a standard web browser that has been modified to record and transmit the information about the gaze patterns to the web server. The document corpus used in the experiments consisted of abstracts of Wikipedia articles.

Our results imply that the performance of the method correlates with the search task; in particular, there are some tasks for which the methods seems to perform quite badly although on average it clearly improves the results. It needs to be investigated more carefully later, which kinds of search tasks the eye movements are helpful in, and whether different types of models are useful for different kinds of tasks.

Abstract

Compressive sensing (CS) is an emerging £eld that, under appropriate conditions, can signi£cantly reduce the number of measurements required for a given signal. In many applications, one is interested in multiple signals that may be measured in multiple CS-type measurements, where here each signal corresponds to a sensing "task". In this paper we propose a novel multi-task compressive sensing framework based on a Bayesian formalism, where a Dirichlet process (DP) prior is employed, yielding a principled means of simultaneously inferring the appropriate sharing mechanisms as well as CS inversion for each task. A variational Bayesian (VB) inference algorithm is employed to estimate the full posterior on the model parameters.

1. Introduction

Over the last two decades researchers have considered sparse signal representations in terms of orthonormal basis functions (*e.g.*, the wavelet transform). For example, consider an m-dimensional real-valued signal $\boldsymbol{u}$ and assume an $m \quad m$ orthonormal basis matrix $\boldsymbol{\Psi}$; we may then express $\boldsymbol{u} = \boldsymbol{\Psi}\boldsymbol{\theta}$, where $\boldsymbol{\theta}$ is an m-dimensional column vector of weighting coef£cients. For most natural signals there exists an orthonormal basis $\boldsymbol{\Psi}$ such that $\boldsymbol{\theta}$ is sparse. Consider now an approximation to $\boldsymbol{u}$, $\hat{\boldsymbol{u}} = \boldsymbol{\Psi}\hat{\boldsymbol{\theta}}$, where $\hat{\boldsymbol{\theta}}$ approximates $\boldsymbol{\theta}$ by retaining the largest N coef£cients and setting the remaining $m \quad N$ coef£cients to zero; due to the aforementioned sparseness properties, $||\boldsymbol{u} \quad \hat{\boldsymbol{u}}||^2$ is typically very small even for $N \ll m$. Conventional techniques require one to measure the m-dimensional signal $\boldsymbol{u}$ but £nally discard $m \quad N$ coef£cients (Charilaos, 1999). This sample-then-compress framework is often wasteful since the signal acquisition is potentially expensive, and only a small amount of data N is eventually required for the accurate approximation $\hat{\boldsymbol{u}}$. One may therefore consider the following fundamental question: Is it possible to directly measure the informative part of the signal? Recent research in the £eld of compressive sensing shows that this is indeed possible (Candes, 2006)(Donoho, 2006).

Exploiting the same sparseness properties of $\boldsymbol{u}$ employed in transform coding ($\boldsymbol{u} = \boldsymbol{\Psi}\boldsymbol{\theta}$ with $\boldsymbol{\theta}$ sparse), in compressive sensing one measures $\boldsymbol{v} = \boldsymbol{\Phi}\boldsymbol{\theta}$, where $\boldsymbol{v}$ is an n-dimensional vector with $n < m$, and $\boldsymbol{\Phi}$ is the $n \quad m$ sensing matrix. There are several ways in which $\boldsymbol{\Phi}$ may be constituted, with the reader referred to (Donoho, 2006) for details. In most cases $\boldsymbol{\Phi}$ is represented as $\boldsymbol{\Phi} = \mathbf{T}\boldsymbol{\Psi}$, where $\mathbf{T}$ is an $n \quad m$ matrix with components constituted randomly (Tsaig & Donoho, 2006); hence, the CS measurements correspond to projections of $\boldsymbol{u}$ with the rows of $\mathbf{T}$: $\boldsymbol{v} = \mathbf{T}\boldsymbol{u} = \mathbf{T}\boldsymbol{\Psi}\boldsymbol{\theta} = \boldsymbol{\Phi}\boldsymbol{\theta}$, which is an underdetermined problem. Assuming the signal $\boldsymbol{u}$ is N-sparse in $\boldsymbol{\Psi}$, implying that the coef£cients $\boldsymbol{\theta}$ only have N nonzero values (Candes, 2006) (Donoho, 2006), Candès, Romberg and Tao in (Candes et al., 2006) show that, with overwhelming probability, $\boldsymbol{\theta}$ (and hence $\boldsymbol{u}$) is recovered via

$$\min ||\boldsymbol{\theta}||_{l_1}, \quad \text{s.t.}, \quad \boldsymbol{v} = \boldsymbol{\Phi}\boldsymbol{\theta}, \tag{1}$$

if the number of CS measurements $n > C \ N \ \log m$ (C is a small constant); if N is small (*i.e.*, if u is highly compressible in the basis $\boldsymbol{\Psi}$) then $n \ll m$. In practice the signal $\boldsymbol{u}$ is not exactly sparse, but a large number of coef£cients in the basis $\boldsymbol{\Psi}$ may be discarded with minimal error in reconstructing $\boldsymbol{u}$; in this practical case the CS framework has also been shown to operate effectively.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

The problem in (1) may be solved by linear programming (S. Chen & Saunders, 1999) and greedy algorithms (Tropp & Gilbert, 2005) (Donoho et al., 2006). A Bayesian compressive sensing (BCS) methodology is proposed in (Ji et al., 2007b), by posing the CS inversion problem as a linear-regression problem with a sparseness prior on the regression weights $\boldsymbol{\theta}$. One advantage of BCS is that this framework may be extended to multi-task compressive sensing (Ji et al., 2007a), in which each CS measurement $\boldsymbol{v}_i = \boldsymbol{\Phi}_i \boldsymbol{\theta}_i$ represents a sensing "task" and the objective is to jointly invert for all $\{\boldsymbol{\theta}_i\}_{i=1,M}$, through an appropriate sharing of information between the M data collections. In multi-task CS, one may potentially reduce the number of measurements required for each task by exploiting the statistical relationships among the tasks, for example, "Distributed Compressed Sensing" (DCS) (Baron et al., 2005), an empirical Bayesian strategy "Simultaneous Sparse Approximation" in (Wipf & Rao, 2007), and a hierarchical Bayesian model for multi-task CS (Ji et al., 2007a). However, these multi-task algorithms assume all tasks are appropriate for sharing, which may not be true in many practical applications. In this paper we introduce a Dirichlet process (DP) prior (West et al., 1994) to the hierarchical BCS model, which can simultaneously perform the inversion of the underlying signals *and* infer the appropriate sharing/clustering structure across the M tasks.

As detailed below, an important property of DP for the work presented here is that it provides a tool for semi-parametric clustering (*i.e.*, the number of clusters need not be set in advance). The DP-based hierarchical model is employed to realize the desired property of simultaneously clustering and CS inversion of the M measurements $\{\boldsymbol{v}_i\}_{i=1,M}$. A variational Bayes (Blei & Jordan, 2004) inference algorithm is considered, yielding a full posterior over the model parameters $\boldsymbol{\theta}_i$.

2. Multi-Task CS Modeling with DP Priors

2.1. Multi-Task CS Formulation for Global Sharing

Let $\boldsymbol{v}_i$ represent the CS measurements associated with task i, and assume a total of M tasks. The i-th CS measurement may be represented as

$$\boldsymbol{v}_i = \boldsymbol{\Phi}_i \boldsymbol{\theta}_i + \boldsymbol{\epsilon}_i, \tag{2}$$

where the CS measurements $\boldsymbol{v}_i$ are characterized by an n_i-dimensional real vector, the sensing matrix $\boldsymbol{\Phi}_i$ corresponding to task i is of size $n_i \quad m$, and $\boldsymbol{\theta}_i$ is the set of (sparse) transform coef£cients associated with task i. The j^{th} coef£cient of $\boldsymbol{\theta}_i$ is denoted $_{i,j}$. The residual error vector $\boldsymbol{\epsilon}_i \in \mathbb{R}^{n_i}$ is modeled as n_i *i.i.d.* draws from a zero-mean Gaussian distribution with an unknown precision $_0$ (variance $1/\ _0$); the residual corresponds to the error imposed by setting the small transform coef£cients exactly to zero when performing the CS inversion.

We impose a hierarchical sparseness prior on the parameters $\boldsymbol{\theta}_i$, the lower level of which is

$$p(\boldsymbol{\theta}_i|\boldsymbol{\alpha}_i) = \prod_{j=1}^{m} \mathcal{N}(\ _{i,j}|0,\ \ ^{-1}_{i,j}), \tag{3}$$

where $_{i,j}$ is the j^{th} component of the vector $\boldsymbol{\alpha}_i$. To impose sparseness, on a layer above a Gamma hyperprior is employed independently on the precisions $_{i,j}$. The likelihood function for the parameters $\boldsymbol{\theta}_i$ and $_0$, given the CS measurements $\boldsymbol{v}_i$, may be expressed as

$$p(\boldsymbol{v}_i|\boldsymbol{\theta}_i,\ \ _0) = (\frac{2}{_0})^{-\frac{n_i}{2}} \exp(\ \ \frac{_0}{2}\|\boldsymbol{v}_i \quad \boldsymbol{\Phi}_i\boldsymbol{\theta}_i\|_2^2). \tag{4}$$

Concerning the aforementioned hyperprior, for the multi-task CS model proposed in (Ji et al., 2007a), the parameters $\boldsymbol{\alpha}_i = \boldsymbol{\alpha}$, for $i = 1, \quad , M$, and $\boldsymbol{\alpha} \quad \prod_{j=1}^{m} Ga(c,d)$. In this framework the CS data from all M tasks are used to jointly infer the hyper-parameters $\boldsymbol{\alpha}$ (global processing). However, the assumption in such a setting is that it is appropriate to employ all of the M tasks jointly to infer the hyper-parameters. One may envision problems for which the M tasks may be clustered into several sets of tasks (with the union of these sets constituting the M tasks), and data sharing may only be appropriate within each cluster. Through use of the Dirichlet process (DP) (Escobar & West, 1995) employed as the prior over $\boldsymbol{\alpha}_i$, we simultaneously cluster the multi-task CS data, and within each cluster the CS inversion is performed jointly. Consequently, we no longer need assume that all CS data from the M tasks are appropriate for sharing.

2.2. Dirichlet Process for Clustered Sharing

The Dirichlet process, denoted as $DP(\lambda, G_0)$, is a measure on measures, and is parameterized by a positive scaling parameter λ and the base distribution G_0. Assume we have $\{\boldsymbol{\alpha}_i\}_{i=1,M}$ and each $\boldsymbol{\alpha}_i$ is drawn identically from G, and G itself is a random measure drawn from a Dirichlet process,

$$\begin{aligned} \boldsymbol{\alpha}_i|G \quad &^{iid} \quad G, \quad i = 1, \quad , M, \\ G \quad &\quad DP(\lambda, G_0), \end{aligned} \tag{5}$$

where G_0 is a non-atomic base measure.

Sethuraman (Sethuraman, 1994) provides an explicit characterization of G in terms of a stick-breaking construction. Consider two in£nite collections of independent random variables $_k$ and $\boldsymbol{\alpha}_k^*$, $k = 1, 2, \quad , \infty$, where the $_k$ are drawn *i.i.d.* from a Beta distribution, denoted $Beta(1, \lambda)$, and the $\boldsymbol{\alpha}_k^*$ are drawn *i.i.d.* from the base distribution G_0.

The stick-breaking representation of G is then de£ned as

$$G = \sum_{k=1}^{\infty} w_k \delta_{\boldsymbol{\alpha}_k^*}, \quad \text{with} \tag{6}$$

$$w_k = {}_k \prod_{i=1}^{k-1} (1 \quad {}_i), \tag{7}$$

where ${}_k|\lambda \overset{iid}{} Beta(1,\lambda)$ and $\boldsymbol{\alpha}_k^*|G_0 \overset{iid}{} G_0$. This representation makes explicit that the random measure G is discrete with probability one and the support of G consists of an in£nite set of atoms located at $\boldsymbol{\alpha}_k^*$, drawn independently from G_0. The mixing weights w_k for atom $\boldsymbol{\alpha}_k^*$ are given by successively breaking a unit length "stick" into an in£nite number of pieces, with $0 \le w_k \le 1$ and $\sum_{k=1}^{\infty} w_k = 1$.

2.3. Multi-Task CS with DP Priors

We employ a DP prior with stick-breaking representation for $\boldsymbol{\alpha}_i$ in the model in (3), which assumes that $\boldsymbol{\alpha}_i|G \quad G$ and $G = \sum_{k=1}^{\infty} w_k \delta_{\boldsymbol{\alpha}_k^*}$. The base distribution G_0 corresponds to the sparseness promoting representation discussed in Sec 2.1. To facilitate posterior computation we introduce an indicator variable z_i with $z_i = k$ indicating $\boldsymbol{\alpha}_i = \boldsymbol{\alpha}_k^*$. Therefore the DP multi-task CS model is expressed as

$$\begin{aligned}
\boldsymbol{v}_i|\boldsymbol{\theta}_i, \ {}_0 \quad & \mathcal{N}(\boldsymbol{\Phi}_i\boldsymbol{\theta}_i, \ {}_0^{-1} I), \\
{}_{i,j}|z_i, \{\boldsymbol{\alpha}_k^*\}_{k=1,K} \quad & \mathcal{N}(0, \ {}_{z_i,j}^{*\,-1}), \\
z_i|\{w_k\}_{k=1,K} \quad & \overset{iid}{} \ Multinomial(\{w_k\}_{k=1,K}), \\
w_k \quad = \quad & {}_k \prod_{l=1}^{k-1} (1 \quad {}_l), \\
{}_k \quad & \overset{iid}{} \ Beta(1,\lambda), \\
\lambda|e,f \quad & Ga(e,f), \\
\boldsymbol{\alpha}_k^*|c,d \quad & \overset{iid}{} \ \prod_{j=1}^{m} Ga(c,d), \\
{}_0 \quad & Ga(a,b),
\end{aligned} \tag{8}$$

where $i = 1, \quad , M$, $j = 1, \quad , m$, $k = 1, \quad , K$, $1 \le K \le \infty$, and ${}_{i,j}$ is the j-th element of $\boldsymbol{\alpha}_i$. For convenience, we denote the model in (8) as DP-MT CS. In practice K is chosen as a relatively large integer (*e.g.*, $K = M$ if M is relatively large) which yields a negligible difference compared to the true DP (Ishwaran & James, 2001), while making the computation practical.

The choice of G_0 here is consistent with the sparseness-promoting hierarchical prior discussed in Section II-A. Consider task i and assume $\boldsymbol{\alpha}_i$ takes value $\boldsymbol{\alpha}_k^*$; the prior distribution over $\boldsymbol{\theta}_i$ is then

$$p(\boldsymbol{\theta}_i|c,d) = \prod_{j=1}^{m} \int \mathcal{N}(\ {}_{i,j}|0, \ {}_{k,j}^{*\,-1}) Ga(\ {}_{k,j}^{*}|c,d) d \ {}_{k,j}^{*}. \tag{9}$$

Equation (9) is a type of automatic relevance determination (ARD) prior which enforces the sparsity over $\boldsymbol{\theta}_i$ (Tipping, 2001). We usually set c and d very close to zero (*e.g.*, 10^{-4}) to make a broad prior over $\boldsymbol{\alpha}_k^*$, which allows the posteriors on many of the elements of $\boldsymbol{\alpha}_k^*$ to concentrate at very large values, consequently the posteriors on the associated elements of $\boldsymbol{\theta}_i$ concentrate at zero, and therefore the sparseness of $\boldsymbol{\theta}_i$ is achieved (MacKay, 1994) (Neal, 1996). Since these posteriors have "heavy tails" compared to a Gaussian distribution, they allow for more robust shrinkage and borrowing of information. Similarly, hyper-parameters a, b, e, and f are all set to a small value to have a non-informative prior over ${}_0$ and λ respectively.

3. Variational Bayesian Inference

One may perform inference via MCMC (Gilks et al., 1996), however this requires vast computational resources and MCMC convergence is often dif£cult to diagnose (Gilks et al., 1996). Variational Bayes inference is therefore introduced as a relatively ef£cient method for approximating the posterior. From Bayes' rule, we have

$$p(\mathbf{H}|\mathbf{V},\Upsilon) = \frac{p(\mathbf{V}|\mathbf{H})p(\mathbf{H}|\Upsilon)}{\int p(\mathbf{V}|\mathbf{H})p(\mathbf{H}|\Upsilon)d\mathbf{H}}, \tag{10}$$

where $\mathbf{V} = \{\boldsymbol{v}_i\}_{i=1,M}$ are CS measurements from M CS tasks, $\mathbf{H} = \{ \ {}_0, \lambda, \boldsymbol{\pi}, \{z_i\}_{i=1,M}, \{\boldsymbol{\theta}_i\}_{i=1,M}, \{\boldsymbol{\alpha}_k^*\}_{k=1,K}\}$ are hidden variables (with $\boldsymbol{\pi} = \{ \ {}_k\}_{k=1,K}$) and $\Upsilon = \{a,b,c,d,e,f\}$ are known hyper-parameters. The integration in the denominator of (10), called the *marginal likelihood*, or *"evidence"* (Beal, 2003), is generally intractable to compute analytically. Instead of directly estimating $p(\mathbf{H}|\mathbf{V},\Upsilon)$, variational methods seek a distribution $q(\mathbf{H})$ to approximate the true posterior distribution $p(\mathbf{H}|\mathbf{V},\Upsilon)$. Consider the log marginal likelihood

$$\log p(\mathbf{V}|\Upsilon) = \mathcal{F}(q(\mathbf{H})) + \mathcal{D}_{KL}(q(\mathbf{H})||p(\mathbf{H}|\mathbf{V},\Upsilon)), \tag{11}$$

where

$$\mathcal{F}(q(\mathbf{H})) = \int q(\mathbf{H}) \log \frac{p(\mathbf{V}|\mathbf{H}|,\Upsilon)p(\mathbf{H},\Upsilon)}{q(\mathbf{H})} d\mathbf{H}, \tag{12}$$

and $\mathcal{D}_{KL}(q(\mathbf{H})||p(\mathbf{H}|\mathbf{V},\Upsilon))$ is the KL divergence between $q(\mathbf{H})$ and $p(\mathbf{H}|\mathbf{V},\Upsilon)$. The approximation of $p(\mathbf{H}|\mathbf{V},\Upsilon)$ using $q(\mathbf{H})$ can be achieved by maximizing $\mathcal{F}(q(\mathbf{H}))$, which forms a strict lower bound on $\log p(\mathbf{V}|\Upsilon)$. In this way estimation of $q(\mathbf{H})$ may be made computationally tractable. In particular, for computational convenience,

$q(\mathbf{H})$ is expressed in a factorized form, with the same functional form as the priors $p(\mathbf{H}|\Upsilon)$. For the model in (8), we assume

$$q(\mathbf{H}) = q(\ \ _0)q(\lambda)q(\boldsymbol{\pi})\prod_{i=1}^{M} q(z_i)\prod_{i=1}^{M} q(\boldsymbol{\theta}_i)\prod_{k=1}^{K} q(\boldsymbol{\alpha}_k^*), \tag{13}$$

where $q(\ \ _0)$ $Ga(\tilde{a},\tilde{b})$, $q(\lambda)$ $Ga(\tilde{e},\tilde{f})$, $q(\boldsymbol{\pi})$ $\prod_{k=1}^{K-1} Beta(\ _{1k},\ _{2k})$, $q(z_i)$ $Multinomial(\boldsymbol{w})$, $q(\boldsymbol{\theta}_i)$ $\mathcal{N}(\ _i,\boldsymbol{\Gamma}_i)$, $q(\boldsymbol{\alpha}_k^*)$ $\prod_{j=1}^{m} Ga(\ ^*_{k,j}|\tilde{c}_{k,j},\tilde{d}_{k,j})$, with $\boldsymbol{w} = \{w_k\}_{k=1,K}$.

By substituting (13) and (8) into (12), the lower bound $\mathcal{F}(q)$ is readily obtained. The optimization of the lower bound $\mathcal{F}(q)$ is realized by taking functional derivatives with respect to each of the $q(\ )$ distributions while £xing the other q distributions, and setting $\partial\mathcal{F}(q)/\partial q(\ ) = 0$ to £nd the distribution $q(\ )$ that increases $\mathcal{F}$ (Beal, 2003). The update equations for the variational posteriors are summarized in the Appendix. The convergence of the algorithm is monitored by the increase of the lower bound $\mathcal{F}$. One practical issue of the variational Bayesian inference is that the VB algorithm converges to a local maximum of the lower bound of the marginal log-likelihood since the true posterior usually is multi-modal. Therefore the average of multiple runs of the algorithm from different starting points may avoid this issue and yield better performance.

4. Experimental Results

4.1. Synthetic data

In the £rst set of examples we consider synthesized data to examine the sharing mechanisms associated with the DP-MT CS inversion. In the £rst example we generate data with 10 underlying clusters. Figure 1 shows ten "templates", each corresponding to a 256-length signal, with 30 non-zero components (the values of those non-zero components are randomly drawn from $\mathcal{N}(0,1)$). The non-zero locations are chosen randomly for each template such that the correlation between these sparse templates is zero. For each template, £ve sparse signals (each with 256 samples) are generated by randomly selecting three non-zero elements from the associated template and setting the coef£cients to zero, and three zero-amplitude points in the template are randomly now set to be non-zero (each of these three non-zero values again drawn from $\mathcal{N}(0,1)$). In this manner the sparseness properties of the £ve signals generated from a given template are highly related, and the ten clusters of sparse signals have distinct sparseness properties. For each sparse signal a set of CS random projections are performed, with the components of each projection vector drawn randomly from $\mathcal{N}(0,1)$(Donoho, 2006). The reconstruction error is de£ned as $||\hat{\boldsymbol{u}} \quad \boldsymbol{u}||_2/||\boldsymbol{u}||_2$, where $\hat{\boldsymbol{u}}$ is the recovered signal and $\boldsymbol{u}$ is the original one.

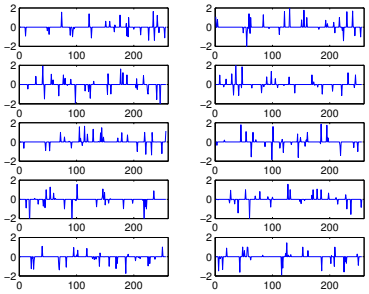

Figure 1. Ten template signals for 10-cluster case.

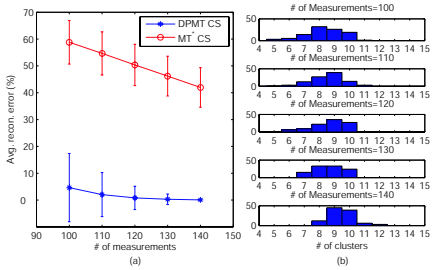

Figure 2. Multi-task CS inversion error (%) for DP-MT and MT CS for the ten-cluster case. (a) Reconstruction errors, (b) histograms of the number of clusters yielded by DP-MT.

Figure 2 shows the reconstruction errors of the CS inversion by DP-MT CS as well as the global-sharing MT CS discussed in Sec 2.1 (denoted as MT* CS for simplicity), as a function of the number of CS measurements. Both CS algorithms are based on the VB DP-MT algorithm described in Sec 3, however for MT*, we set $\kappa_{i,1} = 1$, and $\kappa_{i,k} = 0$ for $k > 1$ for all tasks and £x the values of $\kappa_{i,k}$ in each iteration without update. The experiment was run 100 times (with 100 different random generations of random projection as well as initial membership), and the error bars in Figure 2 represent the standard deviation about the mean. From Figure 2 the advantage of the DP-based formulation is evident. In Figure 2 we also present histograms for the number of different clusters inferred by the DP-MT CS. It is clear from Figure 2 that the algorithm tends to infer about 10 clusters, but there is some variation, with the variation in the number of clusters increasing with decreasing number of CS measurements.

To further examine the impact of the number of underlying clusters, we now consider examples for which the data are generated for 5, 3, 2 and 1 underlying. For each of templates, £ve sparse signals are generated randomly, in the manner discussed above for the ten-cluster case. In Figures 3-6 are shown results in the form considered in Figure 2, for the case of 5, 3, 2 and 1 underlying clusters for data generation. One notes the following phenomenon: As the number of underlying clusters diminishes, the difference between DP-MT and MT* CS algorithms diminishes, with almost identical performance witnessed for the case

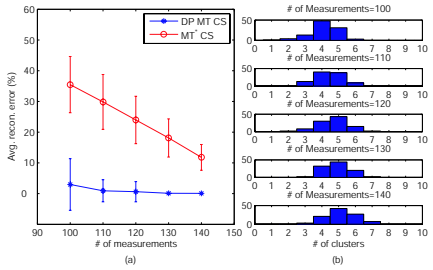

Figure 3. Multi-task CS inversion error (%) for DP-MT and MT CS for the £ve-cluster case. (a) Reconstruction errors, (b) histograms of the number of clusters yielded by DP-MT.

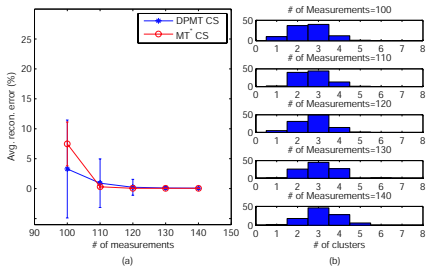

Figure 4. Multi-task CS inversion error (%) for DP-MT and MT CS for the three-cluster case. (a) Reconstruction errors, (b) histograms of the number of clusters yielded by DP-MT.

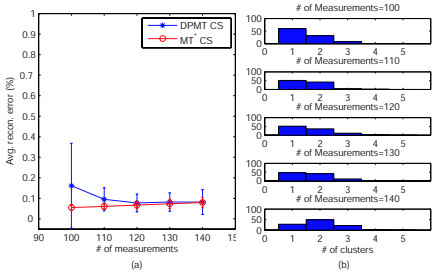

Figure 5. Multi-task CS inversion error (%) for DP-MT and MT CS for the two-cluster case. (a) Reconstruction errors, (b) histograms of the number of clusters yielded by DP-MT.

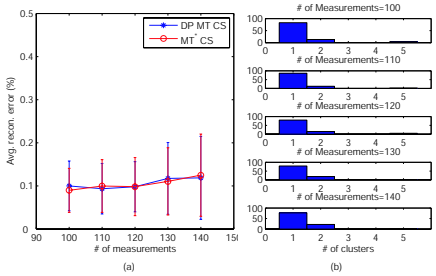

Figure 6. Multi-task CS inversion error (%) for DP-MT and MT CS for the one-cluster case. (a) Reconstruction errors, (b) histograms of the number of clusters yielded by DP-MT.

of three and two clusters; this phenomenon is particularly evident as the number of CS measurements increases. As an aside, we also note that the DP-based inference of the number of underlying clusters adapts well to the underlying data generation.

We now provide an explanation for the relationships between the DP-MT and MT* CS algorithms. For two sparse signals like those in Figure 1, they have distinct non-zero coef£cients and therefore one would typically infer that they have dissimilar sparseness properties. However, they share many zero-amplitude coef£cients. If we consider M sparse signals, and if *all* of the M signals share the same large set of zero-amplitude coef£cients, then they are appropriate for sharing even if the associated (small number of) non-zero coef£cients are entirely distinct. For the 10-cluster case, because of the large number of clusters, the templates do not cumulatively share the same set of zero-amplitude coef£cients; in this case global sharing for CS inversion is inappropriate, and the same is true for the 5-cluster case. However, for the 3 and 2 cluster cases, the templates share a signi£cant number of zero-amplitude coef£cients, and therefore global sharing is appropriate. This underscores that global sharing across M tasks is appropriate when there is substantial sharing of zero-amplitude coef£cients, even when all of the non-zero-amplitude coef£cients are distinct. However, one typically does not know *a priori* if global sharing is appropriate (as it was *not* in Figures 2 and 3), and therefore the DP-based formulation offers generally high-quality results when global sharing is appropriate *and* when it is not.

We consider the sharing mechanisms manifested for two examples from the three-cluster case considered in Figure 4. The truncation level K can be set either to a large number or be estimated in principle by increase the number of sticks included until the log-marginal likelihood (the lower bound) in the VB algorithm starts to decrease. In this example we choose the number of sticks in the DP formulation to $K = 8$ which corresponds to the upper bound of the log-marginal likelihood, and we show the stick (cluster) with which each of the 15 tasks were grouped at the end of the inference process. These examples were selected because they both yielded roughly the same average CS inversion accuracy across the 15 CS inversions (0.40% and 0.38% error), but these two runs yield distinct clusterings. This example emphasizes that because the underlying signals are very sparse and they have signi£cant overlap in the set of zero-amplitude coef£cients, the particular clustering manifested by the DP formulation is not particularly important for the £nal CS-inversion quality.

4.2. Real images

In the following examples, applied to imagery, we perform comparisons between DP-MT, MT*, and also a single-task Bayesian CS (ST), in which the CS inversion is performed independently on each of the tasks. ST CS is realized with

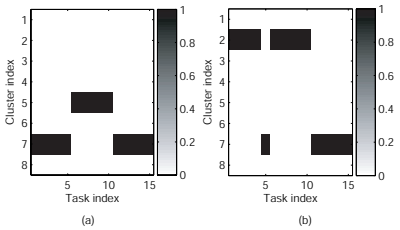

Figure 7. 2 example runs of the DP-MT CS clustering for the 3-cluster case (100 CS measurements). The grey scale denotes the probability that a given task is associated with a particular cluster. (a) Reconstruction error was 0.40%, (b) reconstruction error of 0.38%.

the same algorithm as DP-MT and MT*, but set $\kappa_{i,1} = 1$, and $\kappa_{i,k} = 0$ for $k > 1$, and consider only one CS task at a time ($M = 1$)..

We conduct two examples on CS reconstruction of typical imagery from "natural" scenes. All the images in these examples are of size $256 \quad 256$ and are highly compressible in a wavelet basis. We choose the "Daubechies 8" wavelet as our orthonormal basis, and the sensing matrix $\boldsymbol{\Phi}$ is constructed in the same manner as in Sec 4.1. In this experiment we adopt a hybrid CS scheme, in which using CS we measure only £ne-scale wavelet coef£cients, while retaining all coarse-scale coef£cients (no compression in the coarse scale) (Tsaig & Donoho, 2006). We also assume all the wavelet coef£cients at the £nest scale are zero and only consider (estimate) the other 4096 coef£cients. In both examples, the coarsest scale is $j_0 = 3$, and the £nest scale is $j_1 = 6$. We use the mean of the posterior over $\boldsymbol{\theta}$ to perform the image reconstruction. The reconstruction error is de£ned as $||\hat{\boldsymbol{u}} \quad \boldsymbol{u}||_2/||\boldsymbol{u}||_2$, where $\hat{\boldsymbol{u}}$ is the reconstructed image and $\boldsymbol{u}$ is the original one.

In the £rst example, we choose 12 images from three different scenes. To reconstruct the image, we perform an inverse wavelet transform on the CS-estimated coef£cients. In Figure 8 (a) we show the reconstructed images with all 4096 measurements using linear reconstruction ($\boldsymbol{\theta} = \boldsymbol{\Phi}^T \boldsymbol{v}$), which is the best possible performance. Figure 8 (b)-(d) represent the reconstructed images by the DP-MT, MT*, and the ST algorithms, respectively, with the number of CS measurements $n = 1764$ (1700 measurements in the £ne scales and 64 in the coarse scale) for each task. The reconstruction errors for these four methods are compared in Table 1. We notice that the DP-MT algorithm reduces the reconstruction error compared to the ST method, which indicates that the multi-task CS inversion shares information among tasks and therefore requires less measurements than the single task learning does to achieve the same performance. In addition to the CS inversion, the DP-MT also yield task clustering, with this inferred simultaneously with the CS inversion; while this clustering is not the £nal product of interest, it is informative, with results shown in Figures 9. Note that the algorithms infer three clusters, each corresponding to a particular class of imagery. By contrast the MT* algorithm imposes complete sharing among all tasks, and the results in Table I indicate that this undermines performance.

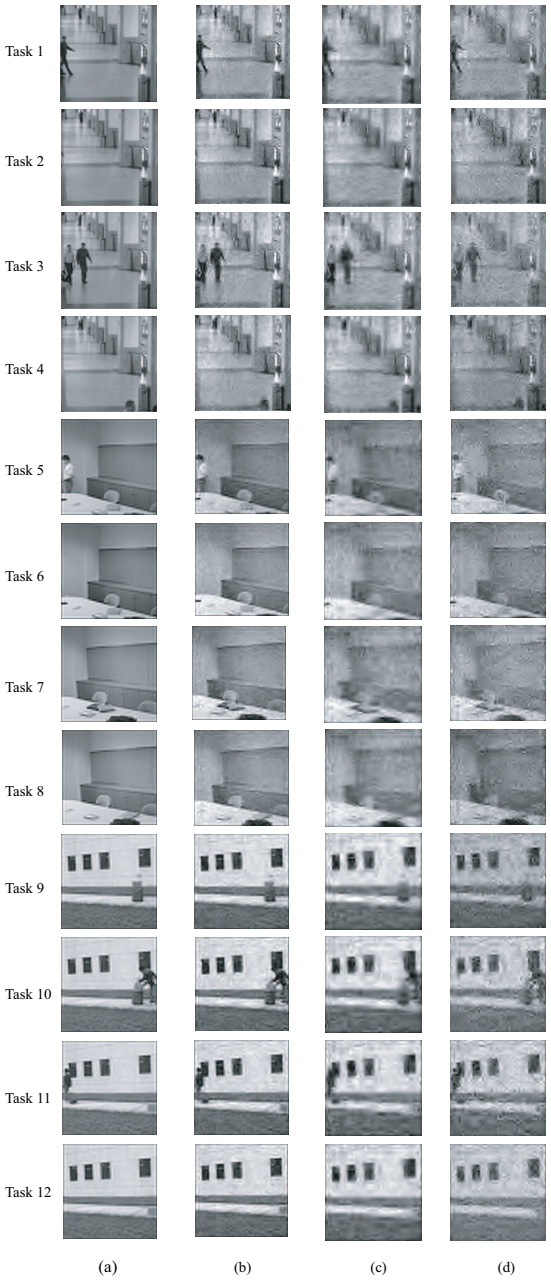

Figure 8. CS recon., (a) Linear, (b) DP-MT, (c) MT , (d) ST

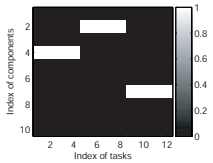

Figure 9. Sharing mechanism for 12 tasks in Figure 8 yielded by DP-MT CS.

Table 1. Reconstruction error (%) for the example in 8.

	Task 1	Task 2	Task 3	Task 4	Task 5	Task 6	Task 7	Task 8	Task 9	Task 10	Task 11	Task 12
DP-MT	8.79	7.89	9.69	8.04	14.33	13.22	15.18	14.54	15.51	16.71	16.11	15.19
MT*	10.19	9.14	11.49	9.18	16.94	15.59	17.46	16.50	18.62	19.82	19.34	18.03
ST	10.28	10.37	12.81	10.28	18.37	16.18	18.65	17.67	20.77	22.24	21.19	19.59
Linear	6.66	6.20	7.08	6.14	12.41	11.70	12.43	11.99	13.83	14.41	14.10	13.53

In the second example we consider 11 images from three scenes. The reconstructed images are shown in Figure 10 by the linear reconstruction, DP-MT, MT* and ST algorithms; the reconstruction errors are listed in Table 2 for all four methods. As expected, the multi-task CS inversion algorithm yields smaller reconstruction error than the single task algorithm. The clustering result is shown in Figure 11, in which images 1-4 and 9-11 are clustered together by DP-MT. However, recall the simple example considered in Figure 7. The DP-based algorithm seeks to share the underlying sparseness of the images, even though the images themselves may appear distinct. In fact, the results in Figure 11 motivated the simple example considered in Figure 7.

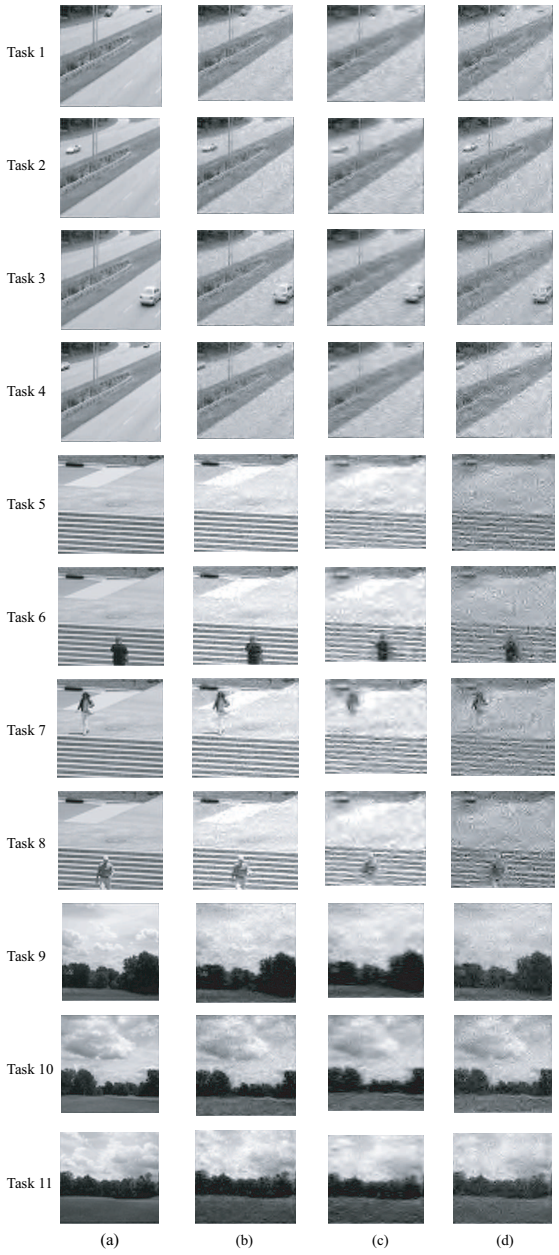

Figure 10. CS recon. (a) Linear, (b) DP-MT, (c) MT , (d) ST

5. Conclusions

Hierarchical Dirichlet process (DP) priors are considered for the imposition of sparseness on the transform coef£cients in the context of inverting multiple CS measurements. An independent zero-mean Gaussian prior is placed on each transform coef£cient of each CS task and the task-dependent precision parameters are assumed drawn from a distribution G, where G is drawn from a Dirichlet process (DP); the base distribution of the DP is a product of Gamma distributions. The DP framework imposes the belief that many of the tasks may share underlying sparseness properties, and the objective is to cluster the CS measurements, where each cluster constitutes a particular form of sparseness. The DP formulation is non-parametric, in the sense that the number of clusters is not set *a priori* and is inferred from the data. A computationally ef£cient variational Bayesian inference has been considered on all model parameters. For all examples considered, the DP-MT CS inversion performed at least as well as ST CS inversion and CS inversion based on global sharing. Especially when global sharing was inappropriate, the DP-based inversion is signi£cantly better.

In future research, we may consider correlation between spatially and spectrally adjacent transformation coef£cients and remove the assumption of exchangeability employed within the DP, which in practice may not be true.

Appendix: Update Equations in VB DP MT

The updated hyperparameters for all $q(\ )$ in Sec 3 are

- $\tilde{a} = a + \frac{1}{2}\sum_{i=1}^{M} n_i$ and $\tilde{b} = b + \frac{1}{2}\sum_{i=1}^{M}\left[tr(\mathbf{\Phi}_i\mathbf{\Gamma}_i^{-1}\mathbf{\Phi}_i^T)+(\mathbf{\Phi}_i\boldsymbol{\mu}_i \quad \boldsymbol{v}_i)^T(\mathbf{\Phi}_i\boldsymbol{\mu}_i \quad \boldsymbol{v}_i)\right]$.

- $\tilde{e} = e+K \quad 1$ and $\tilde{f} = f \quad \sum_{k=1}^{K-1}\left[\psi(\ _{2k}) \quad \psi(\ _{1k}+\ _{2k})\right]$, where $\psi(x) = \frac{\partial}{\partial x}\log\mathbf{\Gamma}(x)$.

Estimating Labels from Label Proportions

Abstract

Consider the following problem: given sets of unlabeled observations, each set with known label proportions, predict the labels of another set of observations, also with known label proportions. This problem appears in areas like e-commerce, spam filtering and improper content detection. We present consistent estimators which can reconstruct the correct labels with high probability in a uniform convergence sense. Experiments show that our method works well in practice.

1 Introduction

Assume that a web services company wants to increase its profit in sales. Obviously sending out discount coupons will increase sales, but sending coupons to customers who would have purchased the goods anyway decreases the margins. Alternatively, failing to send coupons to customers who would only buy in case of a discount reduces overall sales. We would like to identify the class of would-be customers who are most likely to change their purchase decision when receiving a coupon. The problem is that there is no direct access to a sample of would-be customers. Typically only a sample of people who buy regardless of coupons (those who bought when there was no discount) and a mixed sample (those who bought when there was discount) are available. The mixing proportions can be reliably estimated using random assignment to control and treatment groups. How can we use this information to determine the would-be customers?

Likewise, consider the problem of spam filtering. Datasets of spam are likely to contain almost pure spam (this is achieved e.g. by listing e-mails as spam bait), while user's inboxes typically contain a mix of spam and non-spam. We would like to use the inbox data to improve estimation of spam. In many cases it is possible to estimate the *proportions* of spam and non-spam in a user's inbox much more cheaply than the actual labels. We would like to use this information to categorize e-mails into spam and non-spam.

Similarly, consider the problem of filtering images with "improper content". Datasets of such images are readily accessible thanks to user feedback, and it is reasonable to assume that this labeling is highly reliable. However the rest of images on the web (those not labeled) is a far larger dataset, albeit without labels (after all, this is what we would like to estimate the labels for). That said, it is considerably cheaper to obtain a good estimate of the *proportions* of proper and improper content in addition to having one dataset of images being of likely improper content. We would like to obtain a classifier based on this information.

In this paper we present a method to estimate labels *directly* in such situations, assuming that only label proportions be known. In the above examples, this would be helpful in identifying potential customers, spam e-mails and improper images. We prove bounds indicating that the estimates obtained are close to those from a fully labeled scenario. The formal setting though is more general than the above examples might suggest: we do not require *any* label to be known, only their proportions within each of the involved datasets. Also we are not restricted to the binary case but instead can deal with large numbers of classes.

Problem Formulation Assume that we have n sets of observations $X_i = \{x_1^i, \ldots, x_{m_i}^i\}$ of respective sample sizes m_i (our calibration set) as well as a set $X = \{x_1, \ldots, x_m\}$ (our test set). Moreover, assume that we know the fractions π_{iy} of patterns of labels $y \in \mathcal{Y}$ ($|\mathcal{Y}| \leq n$) contained in each set X_i and assume that we also know the marginal probability $p(y)$ of the

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Table 1. Notation Conventions

X_i	i^{th} set of observations: $X_i = \{x_1^i, \ldots, x_{m_i}^i\}$
m_i	number of observations in X_i
X	test set of observations: $X = \{x_1, \ldots, x_m\}$
Y	test set of labels: $Y = \{y_1, \ldots, y_m\}$
m	number of observations in the test set X
π_{iy}	proportion of label y in set i
$\phi(x, y)$	map from (x, y) to a Hilbert Space

Table 2. Major quantities of interest in the paper

Numbers on the left represent the order in which the corresponding quantity is computed in the algorithm (letters denote the variant of the algorithm: 'a' for general feature map $\phi(x, y)$ and 'b' for factorizing feature map $\phi(x, y) = \psi(x) \otimes \varphi(y)$). Lowercase subscripts refer to model expectations, uppercase subscripts are sample averages.

Expectations with respect to the model:

$$\begin{aligned} \mu_{xy} &:= \mathbf{E}_{(x,y)\sim p(x,y)}[\phi(x, y)] \\ \mu_x^{\text{class}}[y, y'] &:= \mathbf{E}_{(x)\sim p(x|y)}[\phi(x, y')] \\ \mu_x^{\text{set}}[i, y'] &:= \mathbf{E}_{(x)\sim p(x|i)}[\phi(x, y')] \\ \mu_x^{\text{class}}[y] &:= \mathbf{E}_{(x)\sim p(x|y)}[\psi(x)] \\ \mu_x^{\text{set}}[i] &:= \mathbf{E}_{(x)\sim p(x|i)}[\psi(x)] \end{aligned}$$

Expectations with respect to data:

$$\begin{aligned} \mu_{XY} &:= \tfrac{1}{m} \textstyle\sum_{i=1}^m \phi(x_i, y_i) \\ \text{(1a)}\quad \mu_X^{\text{set}}[i, y'] &:= \tfrac{1}{m_i} \textstyle\sum_{x\in X_i} \phi(x, y') \text{ (\textbf{known})} \\ \text{(1b)}\quad \mu_X^{\text{set}}[i] &:= \tfrac{1}{m_i} \textstyle\sum_{x\in X_i} \psi(x) \text{ (\textbf{known})} \end{aligned}$$

Estimates:

$$\begin{aligned} \text{(2)}\quad \hat{\mu}_x^{\text{class}} &= (\pi^\top \pi)^{-1} \pi^\top \mu_X^{\text{set}} \\ \text{(3a)}\quad \hat{\mu}_{XY} &= \textstyle\sum_{y\in\mathcal{Y}} p(y) \hat{\mu}_x^{\text{class}}[y, y] \\ \text{(3b)}\quad \hat{\mu}_{XY} &= \textstyle\sum_{y\in\mathcal{Y}} p(y) \varphi(y) \otimes \hat{\mu}_x^{\text{class}}[y] \\ \text{(4)}\quad \hat{\theta}^* &\text{ solution of (5) for } \mu_{XY} = \hat{\mu}_{XY}. \end{aligned}$$

test set X.[1] It is our goal to design algorithms which are able to obtain conditional class probability estimates $p(y|x)$ solely based on this information. As an illustration, take the spam filtering example. We have $X_1 =$ "mail in spam box" (only spam) and $X_2 =$ "mail in inbox" (spam mixed with non-spam). The test set X then may be X_2 itself, for example. The goal is to find $p(\text{spam}|\text{mail})$ in X_2. Note that (for general π_{iy}) this is more difficult than transduction, where we have at least one dataset with actual labels plus an unlabeled test set where we might have an estimate as to what the relative fractions of class labels might be.

2 Mean Operators

Our idea relies on uniform convergence properties of the expectation operator and of corresponding risk functionals (Altun & Smola, 2006). In doing so, we are able to design estimators with the same performance guarantees in terms of uniform convergence as those with full access to the label information.

[1]Label dictionaries $\mathcal{Y}_i$ do not need to be the same across all sets i: define $\mathcal{Y} := \cup_i \mathcal{Y}_i$ and allow for $\pi_{iy} = 0$ as needed.

2.1 Exponential Families

Denote by $\mathcal{X}$ the space of observations and let $\mathcal{Y}$ be the space of labels. Moreover, let $\phi(x, y) : \mathcal{X} \times \mathcal{Y} \to \mathcal{H}$ be a feature map into a Reproducing Kernel Hilbert Space (RKHS) $\mathcal{H}$ with kernel $k((x, y), (x', y'))$. In this case we may state conditional exponential models via

$$p(y|x, \theta) = \exp\left(\langle \phi(x, y), \theta \rangle - g(\theta|x)\right) \text{ with} \tag{1}$$

$$g(\theta|x) = \log \sum_{y\in\mathcal{Y}} \exp \langle \phi(x, y), \theta \rangle , \tag{2}$$

where the normalization g is called the log-partition function. For $\{(x_i, y_i)\}$ drawn iid from a distribution $p(x, y)$ on $\mathcal{X} \times \mathcal{Y}$ the conditional log-likelihood is

$$\begin{aligned} \log p(Y|X, \theta) &= \sum_{i=1}^m \left[\langle \phi(x_i, y_i), \theta \rangle - g(\theta|x_i)\right] \\ &= m \langle \mu_{XY}, \theta \rangle - \sum_{i=1}^m g(\theta|x_i) \end{aligned} \tag{3}$$

where μ_{XY} is defined as in Table 2. In order to avoid overfitting one commonly maximizes the log-likelihood penalized by a prior $p(\theta)$. This means that we need to solve the following optimization problem

$$\theta^* := \operatorname*{argmin}_\theta \left[-\log p(Y|X, \theta) p(\theta)\right]. \tag{4}$$

For instance, for a Gaussian prior on θ, i.e. for $-\log p(\theta) = \lambda \|\theta\|^2 + \text{const.}$ we have

$$\theta^* = \operatorname*{argmin}_\theta \left[\sum_{i=1}^m g(\theta|x_i) - m \langle \mu_{XY}, \theta \rangle + \lambda \|\theta\|^2\right]. \tag{5}$$

The problem is that in our setting we do not know the labels y_i, so the sufficient statistics μ_{XY} cannot be computed exactly. The only place where the labels enter the estimation process is via the mean μ_{XY}. Our strategy is to exploit the fact that this quantity, however, is statistically well behaved and converges under relatively mild technical conditions at rate $O(m^{-\frac{1}{2}})$ to its expected value (see Theorem 2)

$$\mu_{xy} := \mathbf{E}_{(x,y)\sim p(x,y)}[\phi(x, y)]. \tag{6}$$

Our goal therefore will be to estimate μ_{xy} and use it as a proxy for μ_{XY}, and only then solve (5) with the estimated $\hat{\mu}_{XY}$ instead of μ_{XY}. We will discuss explicit convergence guarantees in Section 3 after describing how to compute the mean operator in detail.

2.2 Estimating the Mean Operator

In order to obtain θ^* we would need μ_{XY}, which is impossible to compute exactly, since we do not have

Y. However, we know that μ_{XY} and μ_{xy} are close. Hence, if we are able to approximate μ_{xy} this, in turn, will be a good estimate for μ_{XY}.

Our quest is therefore as follows: express μ_{xy} as a linear combination over expectations with respect to the distributions on the datasets $X_1, \ldots, X_n$ (where $n \geq |\mathcal{Y}|$). Secondly, show that the expectations of the distributions having generated the sets X_i ($\mu_x^{\text{set}}[i, y']$, see Table 2) can be approximated by empirical means ($\mu_X^{\text{set}}[i, y']$, also see Table 2). Finally, we need to combine both steps to provide guarantees for μ_{XY}.

It will turn out that in certain cases some of the algebra can be sidestepped, in particular whenever we may be able to identify several sets with each other (e.g. the test set X is one of the training datasets X_i) or whenever $\phi(x, y)$ factorizes into $\psi(x) \otimes \varphi(y)$.

Mean Operator: Since μ_{xy} is a linear operator mapping $p(x, y)$ into a Hilbert Space we may expand μ_{xy}

$$\mu_{xy} = \sum_{y \in \mathcal{Y}} p(y) \mathbf{E}_{x \sim p(x|y)}[\phi(x, y)] = \sum_{y \in \mathcal{Y}} p(y) \mu_x^{\text{class}}[y, y]$$

where the shorthand $\mu_x^{\text{class}}[y, y]$ is defined in Table 2. This means that if we were able to compute $\mu_x^{\text{class}}[y, y]$ we would be able to "reassemble" μ_{xy} from its individual components. We now show that $\mu_x^{\text{class}}[y, y]$ can be estimated directly.

Key to our assumptions is that $p(x|y, i) = p(x|y)$. In other words, we assume that the *conditional* distribution of x is independent of the index i, as long as we know the label y. This yields the following:

$$p(x|i) = \sum_y p(x|y) \pi_{iy}. \tag{7}$$

This allows us define the following means

$$\mu_x^{\text{set}}[i, y'] := \mathbf{E}_{x \sim p(x|i)}[\phi(x, y')] \overset{(7)}{=} \sum_y \pi_{iy} \mu_x^{\text{class}}[y, y'].$$

Note that in order to compute $\mu_x^{\text{set}}[i, y']$ we do *not* need any label information with respect to $p(x|i)$. However, since we have at least $|\mathcal{Y}|$ of those equations and we assumed that π has full rank, they allow us to solve a linear system of equations and compute $\mu_x^{\text{class}}[y, y]$ from $\mu_x^{\text{set}}[i, y']$ for all i. That is, we may use

$$\mu_x^{\text{set}} = \pi \mu_x^{\text{class}} \text{ and hence } \mu_x^{\text{class}} = (\pi^\top \pi)^{-1} \pi^\top \mu_x^{\text{set}} \tag{8}$$

to compute $\mu_x^{\text{class}}[y, y]$ for all $y \in \mathcal{Y}$. Whenever $\pi \in \mathbb{R}^{n \times n}$ is invertible (8) reduces to $\mu_x^{\text{class}} = \pi^{-1} \mu_x^{\text{set}}$. With some slight abuse of notation we have μ_x^{class} and μ_x^{set} represent the *matrices* of terms $\mu_x^{\text{class}}[y, y']$ and $\mu_x^{\text{set}}[i, y']$ respectively.

Algorithm 1

Input datasets X, $\{X_i\}$, probabilities π_{iy} and $p(y)$
for $i = 1$ **to** n **and** $y' \in \mathcal{Y}$ **do**
  Compute empirical means $\mu_X^{\text{set}}[i, y']$
end for
Compute $\hat{\mu}_x^{\text{class}} = (\pi^\top \pi)^{-1} \pi^\top \mu_X^{\text{set}}$
Compute $\hat{\mu}_{XY} = \sum_{y \in \mathcal{Y}} p(y) \hat{\mu}_x^{\text{class}}[y, y]$
Solve the minimization problem

$$\hat{\theta}^* = \operatorname*{argmin}_\theta \left[\sum_{i=1}^m g(\theta | x_i) - m \left\langle \hat{\mu}_{XY}, \theta \right\rangle + \lambda \|\theta\|^2 \right]$$

Return $\hat{\theta}^*$.

Obviously we cannot compute $\mu_x^{\text{set}}[i, y']$ explicitly, since we only have *samples* from $p(x|i)$. However the same convergence results governing the convergence of μ_{XY} to μ_{xy} also hold for the convergence of $\mu_X^{\text{set}}[i, y']$ to $\mu_x^{\text{set}}[i, y']$. Hence we may use the empirical average $\mu_X^{\text{set}}[i, y']$ as the estimate for $\mu_x^{\text{set}}[i, y']$ and from that find an estimate for μ_{XY} (see Algorithm 1).

2.3 Special Cases

In some cases the calculations described in Algorithm 1 can be carried out more efficiently.

Minimal number of sets, i.e. $|\mathcal{Y}| = n$: Provided that π has full rank, $(\pi^\top \pi)^{-1} \pi^\top = \pi^{-1}$. This means that the inverse can be computed more directly.

Testing on one of the calibration sets, i.e. $X = X_i$: This means that X is one of the training sets. We only need one less set of observations. This is particularly useful for factorizing feature maps.

Special feature map $\phi(x, y) = \psi(x) \otimes \varphi(y)$: In this case the calculations of $\hat{\mu}_x^{\text{class}}[y, y']$ and $\mu_X^{\text{set}}[i, y']$ are greatly simplified, since we may pull the dependency on y out of the expectations. Defining $\mu_x^{\text{class}}[y]$, $\mu_x^{\text{set}}[i]$, and $\mu_X^{\text{set}}[i]$ as in Table 2 allows us to simplify

$$\hat{\mu}_{XY} = \sum_{y \in \mathcal{Y}} p(y) \varphi(y) \otimes \hat{\mu}_x^{\text{class}}[y] \tag{9}$$

$$\text{where } \hat{\mu}_x^{\text{class}} = (\pi^\top \pi)^{-1} \pi^\top \mu_X^{\text{set}}. \tag{10}$$

A significant advantage of (10) is that we only need to perform $O(n)$ averaging operations rather than $O(n \cdot |\mathcal{Y}|)$. Obviously the cost of computing $(\pi^\top \pi)^{-1} \pi^\top$ remains unchanged but the latter is negligible in comparison to the operations in Hilbert Space.

Binary classification: One may show that the feature map $\phi(x, y)$ takes on a particularly appealing form of $\phi(x, y) = y \psi(x)$ where $y \in \{\pm 1\}$. This follows since we can always re-calibrate $\langle \phi(x, y), \theta \rangle$ by an offset in-

dependent of y such that $\phi(x,1)+\phi(x,-1)=0$.

If we moreover assume that X_1 only contains class 1 and $X_2 = X$ contains a mixture of classes with labels 1 and -1 with proportions $p(1) =: \rho$ and $p(-1) = 1-\rho$ respectively, we obtain the mixing matrix

$$\pi = \begin{bmatrix} 1 & 0 \\ \rho & 1-\rho \end{bmatrix} \Rightarrow \pi^{-1} = \begin{bmatrix} 1 & 0 \\ \frac{-\rho}{1-\rho} & \frac{1}{1-\rho} \end{bmatrix}$$

Plugging this into (10) and the result in (9) yields

$$\begin{aligned}\hat{\mu}_{XY} &= \rho\mu_X^{\text{set}}[1] - (1-\rho)\left[\tfrac{-\rho}{1-\rho}\mu_X^{\text{set}}[1] + \tfrac{1}{1-\rho}\mu_X^{\text{set}}[2]\right] \\ &= 2\rho\mu_X^{\text{set}}[1] - \mu_X^{\text{set}}[2]. \end{aligned} \tag{11}$$

Consequently taking a simple weighted difference between the averages on two sets, e.g. one set containing spam whereas the other one containing an unlabeled mix of spam and non-spam allows one to obtain the sufficient statistics needed for estimation.

3 Convergence Bounds

The obvious question is how well $\hat{\mu}_{XY}$ manages to approximate μ_{XY} and secondly, how badly any error in estimating μ_{XY} would affect the overall quality of the solution. We approach this problem as follows: first we state the uniform convergence properties of μ_{XY} and similar empirical operators relative to μ_{xy}. Secondly, we apply those bounds to the cases discussed above, and thirdly, we show that the approximate minimizer of the log-posterior has a bounded deviation from what we would have obtained by knowing μ_{XY} exactly.

3.1 Uniform Convergence for Mean Operators

In order to introduce the key result we need to introduce Rademacher averages:

Definition 1 (Rademacher Averages) *Let $\mathcal{X}$ be a domain and p a distribution on $\mathcal{X}$ and assume that $X := \{x_1, \dots, x_m\}$ is drawn iid from p. Moreover, let $\mathcal{F}$ be a class of functions $\mathcal{X} \to \mathbb{R}$. Furthermore denote by σ_i Rademacher random variables, i.e. $\{\pm 1\}$ valued with zero mean. The Rademacher average is*

$$R_m(\mathcal{F}, p) := \mathbf{E}_X \mathbf{E}_\sigma \left[\sup_{f \in \mathcal{F}} \left| \frac{1}{m} \sum_{i=1}^{m} \sigma_i f(x_i) \right| \right]. \tag{12}$$

This quantity measures the flexibility of the function class $\mathcal{F}$ — in our case linear functions in $\phi(x,y)$.

Theorem 2 (Convergence of Empirical Means) *Denote by $\phi : \mathcal{X} \to \mathcal{B}$ a map into a Banach space $\mathcal{B}$, denote by $\mathcal{B}^*$ its dual space and let $\mathcal{F}$ the class of linear functions on $\mathcal{B}$ with bounded $\mathcal{B}^*$ norm by 1. Let $R > 0$ such that for all $f \in \mathcal{F}$ we have $|f(x)| \le R$. Moreover, assume that X is an m-sample drawn from p on $\mathcal{X}$. For $\bar{\epsilon} > 0$ we have that with probability at least $1 - \exp(-\bar{\epsilon}^2 m / 2R^2)$ the following holds:*

$$\|\mu_X - \mu_x\|_{\mathcal{B}} \le 2R_m(\mathcal{F}, p) + \bar{\epsilon} \tag{13}$$

For $k \ge 0$ we only have a failure probability of $1 - \exp(-\bar{\epsilon}^2 m / R^2)$.

Theorem 3 (Bartlett & Mendelson (2002)) *Whenever $\mathcal{B}$ is a Reproducing Kernel Hilbert Space with kernel $k(x,x')$ the Rademacher average can be bounded from above by $R_m(\mathcal{F}) \le m^{-\frac{1}{2}} \left[\mathbf{E}_x[k(x,x)]\right]^{\frac{1}{2}}$*

Our approximation error can be bounded as follows. From the triangle inequality we have:

$$\|\hat{\mu}_{XY} - \mu_{XY}\| \le \|\hat{\mu}_{XY} - \mu_{xy}\| + \|\mu_{xy} - \mu_{XY}\|.$$

For the second term we may employ Theorem 2 directly. To bound the first term note that by linearity

$$\epsilon := \hat{\mu}_{XY} - \mu_{xy} = \sum_y p(y) \left[(\pi^\top \pi)^{-1} \pi^\top \hat{\epsilon}\right]_{y,y} \tag{14}$$

where we define the matrix of coefficients

$$\hat{\epsilon}[i, y'] := \mu_x^{\text{set}}[i, y'] - \mu_X^{\text{set}}[i, y']. \tag{15}$$

Now note that all $\hat{\epsilon}[i, y']$ also satisfy the conditions of Theorem 2 since the sets X_i are drawn iid from the distributions $p(x|i)$ respectively. We may bound each term individually in this fashion and subsequently apply the union bound to ensure that all $n \cdot |\mathcal{Y}|$ components satisfy the constraints. Hence each of the terms needs to satisfy the constraint with probability $1 - \delta/(n|\mathcal{Y}|)$ to obtain an overall bound with probability $1-\delta$. To obtain bounds we would need to bound the linear operator mapping $\hat{\epsilon}$ into ϵ.

3.2 Special Cases

A closed form solution in the general case is not particularly useful. However, we give an explicit analysis for two special cases: firstly the situation where $\phi(x,y) = \psi(x) \otimes \varphi(y)$ and secondly, the binary classification setting where $\phi(x,y) = y\psi(x)$ and $X_i = X$, where much tighter bounds are available.

Special feature map We only need to deal with n rather than with $n \times |\mathcal{Y}|$ empirical estimates, i.e. $\mu_X^{\text{set}}[i]$ vs. $\mu_X^{\text{set}}[i, y']$. Hence (14) and (15) specialize to

$$\epsilon = \sum_y p(y) \sum_{i=1}^{n} \varphi(y) \otimes \left[(\pi^\top \pi)^{-1} \pi^\top\right]_{yi} \hat{\epsilon}[i] \tag{16}$$

$$\hat{\epsilon}[i] := \mu_x^{\text{set}}[i] - \mu_X^{\text{set}}[i]. \tag{17}$$

Assume that with high probability each $\hat{\epsilon}[i]$ satisfies $\|\hat{\epsilon}[i]\| \leq c_i$ (we will deal with the explicit constants c_i later). Moreover, assume for simplicity that $|\mathcal{Y}| = n$ and that π has full rank (otherwise we need to follow through on our expansion using $(\pi^\top\pi)^{-1}\pi^\top$ instead of π^{-1}). This implies that

$$\begin{aligned}\|\epsilon\|^2 &= \sum_{i,j} \langle \hat{\epsilon}[i], \hat{\epsilon}[j] \rangle \times \\ &\quad \sum_{y,y'} p(y)p(y')k(y,y') \left[\pi^{-1}\right]_{yi} \left[\pi^{-1}\right]_{y'j} \\ &\leq \sum_{i,j} c_i c_j \left| \left[\pi^{-1}\right]^\top K^{y,p} \pi^{-1} \right|_{ij} \end{aligned} \tag{18}$$

where $K^{y,p}_{y,y'} = k(y,y')p(y)p(y')$. Combining several bounds we have the following theorem:

Theorem 4 *Assume that we have n sets of observations X_i of size m_i, each of which drawn from distributions with probabilities π_{iy} of observing data with label y. Moreover, assume that $k((x,y),(x',y')) = k(x,x')k(y,y') \geq 0$ where $k(x,x) \leq 1$ and $k(y,y) \leq 1$. Finally, assume that $m = |X|$. In this case the mean operator μ_{XY} can be estimated by $\hat{\mu}_{XY}$ with probability at least $1-\delta$ with precision*

$$\begin{aligned}&\|\mu_{XY} - \hat{\mu}_{XY}\| \leq \left[2 + \sqrt{\log((n+1)/\delta)}\right] \times \\ &\left[m^{-\frac{1}{2}} + \left[\sum_{i,j} m_i^{-\frac{1}{2}} m_j^{-\frac{1}{2}} \left| \left[\pi^{-1}\right]^\top K^{y,p} \pi^{-1} \right|_{ij}\right]^{\frac{1}{2}}\right]\end{aligned}$$

Proof We begin our argument by noting that both for $\phi(x,y)$ and for $\psi(x)$ the corresponding Rademacher averages R_m for functions of RKHS norm bounded by 1 is bounded by $m^{-\frac{1}{2}}$. This is a consequence of all kernels being bounded by 1 in Theorem 3 and $k \geq 0$.

Next note that in Theorem 2 we may set $R = 1$, since for $\|f\| \leq 1$ and $k((x,y),(x,y)) \leq 1$ and $k(x,x) \leq 1$ it follows from the Cauchy Schwartz inequality that $|f(x)| \leq 1$. Solving $\delta \leq \exp -m\epsilon^2$ for ϵ yields $\epsilon \leq m^{-\frac{1}{2}}\left[2 + \sqrt{\log(1/\delta)}\right]$.

Finally, note that we have $n+1$ deviations which we need to bound: one between μ_{XY} and μ_{xy}, and n for each of the $\epsilon[i]$ respectively. Dividing the failure probability δ into $n+1$ cases yields bounds of the form $m^{-\frac{1}{2}}\left[2 + \sqrt{\log((n+1)/\delta)}\right]$ and $m_i^{-\frac{1}{2}}\left[2 + \sqrt{\log((n+1)/\delta)}\right]$ respectively. Plugging all error terms into (18) and summing over terms yields the claim and substituting this back into the triangle inequality proves the claim. ■

Binary Classification Next we consider the special case of binary classification where $X_2 = X$. Using (11) we see that the corresponding estimator is given by

$$\hat{\mu}_{XY} = 2\rho\mu_X^{\text{set}}[1] - \mu_X^{\text{set}}[2]. \tag{19}$$

Since $\hat{\mu}_{XY}$ shares a significant fraction of terms with μ_{XY} we are able to obtain tighter bounds as follows:

Theorem 5 *With probability $1-\delta$ (for $1 > \delta > 0$) the following bound holds:*

$$\|\hat{\mu}_{XY} - \mu_{XY}\| \leq 2\rho\left[2 + \sqrt{\log(2/\delta)}\right]\left[m_1^{-\frac{1}{2}} + m_+^{-\frac{1}{2}}\right]$$

m_+ is the number of observations with $y = 1$ in X_2.

Proof Denote by $\mu[X_+]$ and $\mu[X_-]$ the averages over the subsets of X_2 with positive and negative labels respectively. By construction we have that

$$\begin{aligned}\mu_{XY} &= \rho\mu[X_+] - (1-\rho)\mu[X_-] \\ \hat{\mu}_{XY} &= 2\rho\mu_X^{\text{set}}[1] - \rho\mu[X_+] - (1-\rho)\mu[X_-]\end{aligned}$$

Taking the difference yields $2\rho\left[\mu_X^{\text{set}}[1] - \mu[X_+]\right]$. To prove the claim note that we may use Theorem 2 both for $\left\|\mu_X^{\text{set}}[1] - \mathbf{E}_{x\sim p(x|y=1)}[\psi(x)]\right\|$ and for $\left\|\mu[X_+] - \mathbf{E}_{x\sim p(x|y=1)}[\psi(x)]\right\|$. Taking the union bound and summing over terms proves the claim. ■

The bounds we provided show that $\hat{\mu}_{XY}$ converges at the same rate to μ_{xy} as μ_{XY} does, assuming that the sizes of the sets X_i increase at the same rate as X.

3.3 Stability Bounds

To complete our reasoning we need to show that those bounds translate in guarantees in terms of the minimizer of the log-posterior. In other words, estimates using the correct mean μ_{XY} vs. its estimate $\hat{\mu}_{XY}$ do not differ by a significant amount. For this purpose we make use of (Altun & Smola, 2006, Lemma 17).

Lemma 6 *Denote by f a convex function on $\mathcal{H}$ and let $\mu, \hat{\mu} \in \mathcal{H}$. Moreover let $\lambda > 0$. Finally denote by $\theta^*, \in \mathcal{H}$ the minimizer of*

$$L(\theta, \mu) := f(\theta) - \langle \mu, \theta \rangle + \lambda \|\theta\|^2 \tag{20}$$

with respect to θ and $\hat{\theta}^*$ the minimizer of $L(\hat{\theta}, \hat{\mu})$ respectively. In this case the following inequality holds:

$$\left\|\theta^* - \hat{\theta}^*\right\| \leq \lambda^{-1} \|\mu - \hat{\mu}\|. \tag{21}$$

This means that a good estimate for μ immediately translates into a good estimate for the minimizer of the approximate log-posterior. This leads to the following bound on the risk minimizer.

Corollary 7 *The deviation between θ^*, as defined in (4) and $\hat{\theta}^*$, the minimizer of the approximate log-posterior using $\hat{\mu}_{XY}$ rather than μ_{XY}, is bounded by $O(m^{-\frac{1}{2}} + \sum_i m_i^{-\frac{1}{2}})$.*

Finally, we may use (Altun & Smola, 2006, Theorem 16) to obtain bounds on the quality of $\hat{\theta}^*$ when considering how well it minimizes the *true* negative log-posterior. Using the bound

$$L(\hat{\theta}^*, \mu) - L(\theta^*, \mu) \leq \left\|\hat{\theta}^* - \theta^*\right\| \|\hat{\mu} - \mu\| \tag{22}$$

yields the following bound for the log-posterior:

Corollary 8 *The minimizer $\hat{\theta}^*$ of the approximate log-posterior using $\hat{\mu}_{XY}$ rather than μ_{XY} incurs a penalty of at most $\lambda^{-1} \|\hat{\mu}_{XY} - \mu_{XY}\|^2$.*

4 Extensions

Note that our analysis so far focused on a specific setting, namely maximum-a-posteriori analysis in exponential families. While this is a common and popular setting, the derivations are by no means restricted to this. We have the entire class of (conditional) models described by Altun & Smola (2006); Dudík & Schapire (2006) at our disposition. They are characterized via

$$\underset{p}{\text{minimize}} -H(p) \text{ subject to } \|\mathbf{E}_{z\sim p}[\phi(z)] - \mu\| \leq \epsilon$$

Here p is a distribution, H is an entropy-like quantity defined on the space of distributions, and $\phi(z)$ is some evaluation map into a Banach space. This means that the optimization problem can be viewed as an approximate maximum entropy estimation problem, where we do not enforce exact moment matching of μ but rather allow ϵ slack. In both Altun & Smola (2006) and Dudík & Schapire (2006) the emphasis lay on *unconditional* density models: the dual of the above optimization problem. In particular, it follows that for H being the Shannon-Boltzmann entropy, the dual optimization problem is the maximum a posteriori estimation problem, which is what we are solving here.

In the conditional case, p denotes the collection of probabilities $p(y|x_i)$ and the operator $\mathbf{E}_{z\sim p}[\phi(z)] = \frac{1}{m}\sum_{i=1}^m \mathbf{E}_{y|p(y|x_i)}[\phi(x_i, y)]$ is the conditional expectation operator on the set of observations. Finally, $\mu = \frac{1}{m}\sum_{i=1}^m \phi(x_i, y_i)$, that is, it describes the empirical observations. We have two design parameters:

Function Space: Depending on which Banach Space norm we may choose to measure the deviation between μ and its expectation with respect to p in terms of e.g. the ℓ_2 norm, the ℓ_1 norm or the ℓ_∞ norm. The latter would lead to sparse coding and convex combinations.

Entropy and Regularity: Depending on the choice of entropy and divergence functionals we obtain a range of diverse estimators. For instance, if we were to choose the *unnormalized* entropy instead of the entropy, we would obtain AdaBoost style problems. We may also use Csiszar and Bregmann divergences.

The key point is that our reasoning of estimating μ_{XY} based on an aggregate of samples with unknown labels but known label proportions is still applicable. This means that it should be possible to design boosting algorithms and sparse coding methods which could operate on similarly restricted sets of observations.

5 Related Work and Alternatives

Transduction Gärtner et al. (2006) and Mann & McCallum (2007) performed transduction by enforcing a proportionality constraint on the unlabeled data via a Gaussian Process model. At first glance these methods might seem applicable for our problem but as stated in Section 1, they do require that we have at least some labeled instances of *all classes* at our disposition which need to be drawn in an unbiased fashion. This is clearly not the case in our setting.

Self consistent proportions Kück & de Freitas (2005) introduced a more informative variant of the binary multiple-instance learning, in which groups of instances are given along with estimates of the fraction of positively-labeled instances per group. This is then used to design a hierarchical probabilistic model which will generate consistent fractions. The optimization is solved via a MCMC sampler. While only described for a binary problem it could be easily extended to multi-class settings. Chen et al. (2006) and Musicant et al. (2007) use a similar approach with similar drawbacks, since we typically only have as many sets as classes.

Conditional Probabilities A seemingly valid alternative approach is to try building a classifier for $p(i|x)$ and subsequently recalibrating the probabilities to obtain $p(y|x)$. At first sight this may appear promising since this method is easily applicable in conjunction with most discriminative methods. The idea would be to reconstruct $p(y|x)$ by

$$p(y|x) = \sum_i \pi_{iy} p(i|x). \tag{23}$$

However, this is not a useful estimator in our setting for a simple reason: it assumes the conditional independence $y \perp\!\!\!\perp x \mid i$, which obviously does not hold.

A simple example illustrates the problem. Assume that $\mathcal{X}, \mathcal{Y} = \{1, 2\}$ and that $p(y = 1|x = 1) = p(y = 2|x = 2) = 1$. In other words, the estimation problem

is solvable since the classes are well separated. Moreover, assume that π is given by

$$\pi = \begin{bmatrix} 0.5 - \epsilon & 0.5 + \epsilon \\ 0.5 & 0.5 \end{bmatrix} \text{ for } 0 < \epsilon \ll 1.$$

Here, $p(i|x)$ is useless for estimating $p(y|x)$, since we will only exceed random guessing by at most ϵ.

Reduction to Binary For binary classification and real-valued classification scores we may resort to yet another fairly straightforward method: build a classifier which is able to distinguish between the sets X_1 and X_2 and subsequently threshold labels such that the appropriate fraction of observations in X_1 and X_2 respectively has its proper labels. Unfortunately, multi-class variants of this reduction are nontrivial and experiments show that even for the binary case this method is inferior to our approach.

Density Estimation Finally, one way of obtaining the probabilities $p(x, y|i)$ is to perform density estimation for each set of observations X_i. Subsequently we may use

$$p(x|y) = \sum_i \left[\pi^{-1}\right]_{yi} p(x, y|i) \tag{24}$$

to re-calibrate the probability estimates. Bayes' theorem is finally invoked to compute posterior probabilities. This tends to fail for high-dimensional data due to the curse of dimensionality in density estimation.

6 Experiments

Datasets: We use binary and three-class classification datasets from the UCI repository[2] and the LibSVM site.[3] If separate training and test sets are available, we merge them before performing nested 10-fold cross-validation. Since we need to generate as many splits as classes, we limit ourselves to three classes.

For the binary datasets we use half of the data for X_1 and the rest for X_2. We also remove all instances of class 2 from X_1. That is, the conditional class probabilities in X_2 match those from the repository, whereas in X_1 their counterparts are deleted.

For three-class datasets we investigate two different partitions. In scenario A we use class 1 exclusively in X_1, class 2 exclusively in X_2, and a mix of all three classes weighted by $(0.5 \cdot p(1), 0.7 \cdot p(2), 0.8 \cdot p(3))$ to generate X_3. In scenario B we use the following splits

$$\begin{bmatrix} c_1 \cdot 0.4 \cdot p(1) & c_1 \cdot 0.15 \cdot p(2) & c_1 \cdot 0.14 \cdot p(3) \\ c_2 \cdot 0.1 \cdot p(1) & c_2 \cdot 0.15 \cdot p(2) & c_2 \cdot 0.06 \cdot p(3) \\ c_3 \cdot 0.5 \cdot p(1) & c_3 \cdot 0.7 \cdot p(2) & c_3 \cdot 0.8 \cdot p(3) \end{bmatrix}$$

Here the constants c_1, c_2 and c_3 are chosen such that the probabilities are properly normalized. As before, X_3 contains half of the data.

Model Selection: As stated, we carry out a *nested* 10-fold cross-validation procedure: 10-fold cross-validation to assess the performance of the estimators; within each fold, 10-fold cross-validation is performed to find a suitable value for the parameters.

For supervised classification, i.e. discriminative sorting, such a procedure is quite straightforward because we can directly optimize for classification error. For kernel density estimation (KDE), we use the log-likelihood as our criterion.

Due to the high number of hyper-parameters (at least 8) in MCMC, it is difficult to perform *nested* 10-fold cross-validation. Instead, we choose the *best* parameters from a simple 10-fold crossvalidation run. In other words, we are giving the MCMC method an unfair advantage over our approach by reporting the best performance during the model selection procedure.

Finally, for the re-calibrated sufficient statistics $\hat{\mu}_{XY}$ we use the estimate of the log-likelihood on the validation set as the criterion for cross-validation, since no other quantity, such as classification errors is readily available for estimation.

Algorithms: For discriminative sorting we use an SVM with a Gaussian RBF kernel whose width is set to the median distance between observations (Schölkopf, 1997); the regularization parameter is chosen by cross-validation. The same strategy applies for our algorithm. For KDE, we use Gaussian kernels with diagonal densities. Cross-validation is performed over the kernel width. For MCMC, 10^3 samples are generated after a burn in period of 10^3 steps (Kück & de Freitas (2005)).

Optimization: Bundle methods (Smola et al., 2007; Teo et al. , 2007) are used to solve the optimization problem in Algorithm 1.

Results: The experimental results are summarized in Table 3. Our method outperforms KDE and discriminative sorting. In terms of computation, our approach is somewhat more efficient, since it only needs to deal with a smaller sample size (only X rather than the union of all X_i). The training time for our method is less than 2 minutes for all cases, whereas MCMC on average takes 15 minutes and maybe even much longer

[2] http://archive.ics.uci.edu/ml/

[3] http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/

when the number of active kernels and/or observations are high. However, for large number of partitions n, the MCMC procedure might potentially have an edge over our method as we do not take full advantage of this setting. However, this can be achieved easily by optimizing the condition number of the pseudoinverse of the redundant system of linear equations.

Our method also performs well on multiclass datasets. As described in Section 3.2, the quality of our minimizer of the log-posterior depends on the mixing matrix and this is noticeable in the reduction of performance for the dense mixing matrix (scenario B) in comparison to the better conditioned sparse mixing matrix (scenario A). In other words, for ill conditioned π even our method has its limits, simply due to numerical considerations of effective sample size.

7 Conclusion

We have showed a rather surprising result, namely that it is possible to consistently reconstruct the labels of a dataset if we can only obtain information about the proportions of occurrence of each class (in at least as many data aggregates as there are classes). In particular, we prove that up to constants, our algorithm enjoys the same rates of convergence afforded to methods which have full access to all label information.

This has a range of potential applications in e-commerce, spam filtering and improper content detection. It also suggests that techniques used to anonymize observations, e.g. demographic data, may not be really safe. Experiments show our algorithm is fast and outperforms competitive methods.

Abstract

Algorithms for learning to rank Web documents usually assume a document's relevance is independent of other documents. This leads to learned ranking functions that produce rankings with redundant results. In contrast, user studies have shown that diversity at high ranks is often preferred. We present two online learning algorithms that directly learn a diverse ranking of documents based on users' clicking behavior. We show that these algorithms minimize abandonment, or alternatively, maximize the probability that a relevant document is found in the top k positions of a ranking. Moreover, one of our algorithms asymptotically achieves optimal worst-case performance even if users' interests change.

1. Introduction

Web search has become an essential component of the Internet infrastructure, and has hence attracted significant interest from the machine learning community (e.g. Herbrich et al., 2000; Burges et al., 2005; Radlinski & Joachims, 2005; Chu & Ghahramani, 2005; Metzler & Croft, 2005; Yue et al., 2007; Taylor et al., 2008). The conventional approach to this learning-to-rank problem has been to assume the availability of manually labeled training data. Usually, this data consists of a set of documents judged as relevant or not to specific queries, or of pairwise judgments comparing the relative relevance of pairs of documents. These judgments are used to optimize a ranking function offline, to a standard information retrieval metric, then deploying the learned function in a live search engine.

We propose a new learning to rank problem formulation that differs in three fundamental ways. First, unlike most previous methods, we learn from usage data rather than manually labeled relevance judgments. Usage data is available in much larger quantities and at much lower cost. Moreover, unlike manual judgments, which need to be constantly updated to stay relevant, usage data naturally reflects current users' needs and the documents currently available. Although some researchers have transformed usage data into relevance judgments, or used it to generate features (e.g. Joachims, 2002; Radlinski & Joachims, 2005; Agichtein et al., 2006), we go one step further by directly optimizing a usage-based metric.

Second, we propose an online learning approach for learning from usage data. As training data is being collected, it immediately impacts the rankings shown. This means the learning problem we address is regret minimization, where the goal is to minimize the total number of poor rankings displayed over *all* time. In particular, in this setting there is a natural tradeoff between exploration and exploitation: It may be valuable in the long run to present some rankings with unknown documents, to allow training data about these documents to be collected. In contrast, in the short run exploitation is typically optimal. With only few exceptions (e.g. Radlinski & Joachims, 2007), previous work does not consider such an online approach.

Third and most importantly, except for (Chen & Karger, 2006), previous algorithms for learning to rank have considered the relevance of each document independently of other documents. This is reflected in the performance measures typically optimized, such as Precision, Recall, Mean Average Precision (MAP) (Baeza-Yates & Ribeiro-Neto, 1999) and Normalized Discounted Cumulative Gain (NDCG) (Burges et al., 2006). In fact, recent work has shown that these measures do not necessarily correlate with user satisfaction (Turpin & Scholer, 2006). Additionally, it intuitively stands to reason that presenting many slight variations of the same relevant document in web search results may increase the MAP or NDCG score, yet would be suboptimal for users. Moreover, web queries often have different meanings for different users (a canonical example is the query *jaguar*) suggesting that a ranking with diverse documents may be preferable.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

We will show how clickthrough data can be used to learn rankings maximizing the probability that any new user will find at least one relevant document high in the ranking.

2. Related Work

The standard approach for learning to rank uses training data, in the form of judgments assessing the relevance of individual documents to a query, to learn parameters θ for a scoring function $f(q, d_i, \theta)$. Given a new query q, this function computes $f(q, d_i, \theta)$ for each document d_i *independently* and ranks documents by decreasing score (e.g. Herbrich et al., 2000; Joachims, 2002; Burges et al., 2005; Chu & Ghahramani, 2005). This also applies to recent algorithms that learn θ to maximize nonlinear performance measures such as MAP (Metzler & Croft, 2005; Yue et al., 2007) and NDCG (Burges et al., 2006; Taylor et al., 2008).

The theoretical model that justifies ranking documents in this way is the probabilistic ranking principle (Robertson, 1977). It suggests that documents should be ranked by their probablility of relevance to the query. However, the optimality of such a ranking relies on the assumption that there are no statistical dependencies between the probabilities of relevance among documents – an assumption that is clearly violated in practice. For example, if one document about jaguar cars is not relevant to a user who issues the query *jaguar*, other car pages become less likely to be relevant. Furthermore, empirical studies have shown that given a fixed query, the same document can have different relevance to different users (Teevan et al., 2007). This undermines the assumption that each document has a single relevance score that can be provided as training data to the learning algorithm. Finally, as users are usually satisfied with finding a small number of, or even just one, relevant document, the usefulness and relevance of a document does depend on other documents ranked higher.

As a result, most search engines today attempt to eliminate redundant results and produce *diverse* rankings that include documents that are potentially relevant to the query for different reasons. However, learning optimally diverse rankings using expert judgments would require document relevance to be measured for different possible meanings of a query. While the TREC interactive track[1] provides some documents labeled in this way for a small number of queries, such document collections are even more difficult to create than standard expert labeled collections.

[1] http://trec.nist.gov/data/t11_interactive/t11i.html

Several non-learning algorithms for obtaining a diverse ranking of documents from a non-diverse ranking have been proposed. One common one is Maximal Marginal Relevance (MMR) (Carbonell & Goldstein, 1998). Given a similarity (relevance) measure between documents and queries $sim_1(d, q)$ and a similarity measure between pairs of documents $sim_2(d_i, d_j)$, MMR iteratively selects documents by repeatedly finding $d_i = \text{argmax}_{d \in \mathcal{D}} \lambda sim_1(d, q) - (1 - \lambda) \max_{d_j \in S} sim_2(d, d_j)$ where S is the set of documents already selected and λ is a tuning parameter. In this way MMR selects the most relevant documents that are also different from any documents already selected.

Critically, MMR requires that the relevance function $sim_1(d, q)$, and the similarity function $sim_2(d_i, d_j)$ is known. It is usual to obtain sim_1 and sim_2 using algorithms such as those discussed above. The goal of MMR is to rerank an already learned ranking (that of ranking documents by decreasing sim_1 score) to improve diversity. All previous approaches of which we are aware that optimize diversity similarly require a relevance function to be learned prior to performing a diversification step (Zhu et al., 2007; Zhang et al., 2005; Zhai et al., 2003), with the exception of Chen and Karger (2006). Rather, they require that a model for estimating the probability a document is relevant, given a query and other non-relevant documents, is available. In contrast, we directly learn a diverse ranking of documents using users' clicking behavior.

3. Problem Formalization

We address the problem of learning an optimally diversified ranking of documents $\mathcal{D} = \{d_1, \ldots, d_n\}$ for one fixed query. Suppose we have a population of users, where each user u_i considers some subset of documents $A_i \subset \mathcal{D}$ as relevant to the query, and the remainder of the documents as non-relevant. Intuitively, users with different interpretations for the query would have different relevant sets, while users with similar interpretations would have similar relevant sets.

At time t, we interact with user u_t with relevant set A_t. We present an ordered set of k documents, $B_t = (b_1(t), \ldots, b_k(t))$. The user considers the results in order, and clicks on up to one document. The probability of user u_t clicking on document d_i (conditional on the user not clicking on a document presented earlier in the ranking) is assumed to be $p_{ti} \in [0, 1]$. We refer to the vector of probabilities $(p_{ti})_{i \in \mathcal{D}}$ as the *type* of user u_t. In the simplest case, we could take $p_{ti} = 1$ if $d_i \in A_t$ and 0 otherwise, in which case the user clicks on the first relevant document or does not click if no documents in B_t are relevant. However, in reality clicks tend to be noisy although more relevant docu-

Algorithm 1 Ranked Explore and Commit

input: Documents $(d_1, .., d_n)$, parameters ϵ, δ, k.

      display $\{b_1, \ldots, b_k\}$ to user; record clicks
      if user clicked on b_i **then** $p_j \leftarrow p_j + 1$
    end for
  end for
  $j^* \leftarrow \text{argmax}_j\, p_j$ *Commit to best document at this rank*
  $b_i \leftarrow d_{j^*}$
end for

ments are more likely to be clicked on. In our analysis, we will take $p_{ti} \in [0, 1]$.

We get payoff 1 if the user clicks, 0 if not. The goal is to maximize the total payoff, summing over all time. This payoff represents the number of users who clicked on any result, which can be interpreted as the user finding at least one potentially relevant document (so long as p_{ti} is higher when $d_i \in A_t$ than when $d_i \notin A_t$).

The event that a user does not click is called *abandonment* since the user abandoned the search results. Abandonment is an important measure of user satisfaction because it indicates that users were presented with search results of no potential interest.

4. Learning Algorithms

We now present two algorithms that directly minimize the abandonment rate. At a high level, both algorithms learn a marginal utility for each document at each rank, displaying documents to maximize the probability that a new user of the search system would find at least one relevant document within the top k positions. The algorithms differ in their assumptions.

4.1. Ranked Explore and Commit

The first algorithm we present is a simple greedy strategy that assumes that user interests and documents do not change over time. As we will see, after T time steps this algorithm achieves a payoff of at least $(1-1/e-\epsilon)OPT - O(k^3 n/\epsilon^2 \ln(k/\delta))$ with probability at least $1-\delta$. OPT denotes the maximal payoff that could be obtained if the click probabilities p_{ti} were known ahead of time for all users and documents, and $(1-1/e)OPT$ is the best obtainable polynomial time approximation, as will be explained in Section 5.1.

As described in Algorithm 1, Ranked Explore and Commit (REC) iteratively selects documents for each rank. At each rank position i, every document d_j is presented a fixed number x times, and the number of clicks it receives during these presentations is recorded. After nx presentations, the algorithm permanently assigns the document that received the most clicks to the current rank, and moves on to the next rank.

Algorithm 2 Ranked Bandits Algorithm

initialize $\mathsf{MAB}_1(n), \ldots, \mathsf{MAB}_k(n)$ *Initialize MABs*

      $f_{it} = 1$
    else
      $f_{it} = 0$
    end if
    update $(\mathsf{MAB}_i, arm = \hat{b}_i(t), reward = f_{it})$
  end for
end for

4.2. Ranked Bandits Algorithm

Ranked Explore and Commit is purely greedy, meaning that after each document is selected, this decision is never revisited. In particular, this means that if user interests or documents change, REC can perform arbitrarily poorly. In contrast, the Ranked Bandits Algorithm (RBA) achieves a combined payoff of $(1-1/e)OPT - O(k\sqrt{Tn \log n})$ after T time steps even if documents and user interests change over time.

This algorithm leverages standard theoretical results for multi-armed bandits. Multi-armed bandits (MAB) are modeled on casino slot machines (sometimes called one-armed bandits). The goal of standard MAB algorithms is to select the optimal sequence of slot machines to play to maximize the expected total reward collected. For further details, refer to (Auer et al., 2002a). The ranked bandits algorithm runs an MAB instance MAB_i for *each rank* i. Each of the k copies of the multi-armed bandit algorithm maintains a value (or index) for every document. When selecting the ranking to display to users, the algorithm MAB_1 is responsible for choosing which document is shown at rank 1. Next, the algorithm MAB_2 determines which

document is shown at rank 2, unless the same document was selected at the highest rank. In that case, the second document is picked arbitrarily. This process is repeated to select all top k documents.

Next, after a user considers up to the top k documents in order and clicks on one or none, we need to update the indices. If the user clicks on a document actually selected by an MAB instance, the reward for the arm corresponding to that document for the multi-armed bandit at that rank is 1. The reward for the arms corresponding to all other selected documents is 0. In particular, note that the RBA treats the bandits corresponding to each rank independently. Precise pseudocode for the algorithm is presented in Algorithm 2. A generalization of this algorithm, in an abstract setting without the application to Information Retrieval, was discovered independently by Streeter and Golovin (2007).

The actual MAB algorithm used for each MAB_i instance is not critical, and in fact any algorithm for the non-stochastic multi-armed bandit problem will suffice. Our theoretical analysis only requires that:

- The algorithm has a set S of n strategies.
- In each period t a payoff function $f_t : S \to [0, 1]$ is defined. This function is not revealed to the algorithm, and may depend on the algorithm's choices before time t.
- In each period the algorithm chooses a (random) element $y_t \in S$ based on the feedback revealed in prior periods.
- The feedback revealed in period t is $f_t(y_t)$.
- The expected payoffs of the chosen strategies satisfy:
$$\sum_{t=1}^{T} \mathbf{E}[f_t(y_t)] \;\geq\; \max_{y \in S} \sum_{t=1}^{T} \mathbf{E}[f_t(y)] \;-\; R(T)$$
where $R(T)$ is an explicit function in $o(T)$ which depends on the particular multi-armed bandit algorithm chosen, and the expectation is over any randomness in the algorithm. We will use the **Exp3** algorithm in our analysis, where $R(T) = O\left(\sqrt{Tn \log n}\right)$ (Auer et al., 2002b).

We will also later see that although these conditions are needed to bound worst-case performance, better practical performance may be obtained at the expense of worst-case performance if they are relaxed.

5. Theoretical Analysis

We now present a theoretical analysis of the algorithms presented in Section 4. First however, we discuss the offline version of this optimization problem.

5.1. The Offline Optimization Problem

The problem of choosing the optimum set of k documents for a given user population is NP-hard, even if all the information about the user population (i.e. the set of relevant documents for each user) is given offline and we restrict ourselves to $p_{ij} \in \{0, 1\}$. This is because selecting the optimal set of documents is equivalent to the maximum coverage problem: Given a positive integer k and a collection of subsets $S_1, S_2, \ldots, S_n$ of an m-element set, find k of the subsets whose union has the largest possible cardinality.

The standard greedy algorithm for the maximum coverage problem, translated to our setting, iteratively chooses the document that is relevant to the most users for whom a relevant document has not yet been selected. This algorithm is a $(1 - 1/e)$-approximation algorithm for this maximization problem (Nemhauser et al., 1978). The $(1 - 1/e)$ factor is optimal and no better worst-case approximation ratio is achievable in polynomial time unless $NP \subseteq DTIME\left(n^{\log \log n}\right)$ (Khuller et al., 1997).

5.2. Analysis of Ranked Bandits Algorithm

We start by analyzing the Ranked Bandits Algorithm. This algorithm works by simulating the offline greedy algorithm, using a separate instance of the multi-armed bandit algorithm for each step of the greedy algorithm. Except for the sublinear regret term, the combined payoff is as high as possible without violating the hardness-of-approximation result stated in the preceding paragraph.

To analyze the RBA, we first restrict ourselves to users who click on any given document with probability either 0 or 1. We refer to this restricted type of user as a *deterministic user*; we will relax the requirement later. Additionally, this analysis applies to a worst case (and hence fixed) sequence of users.

Further, it is useful to introduce some notation. For a set A and a sequence $B = (b_1, b_2, \ldots, b_k)$, let

$$G_i(A, B) = \begin{cases} 1 & \text{if } A \text{ intersects } \{b_1, \ldots, b_i\} \\ 0 & \text{otherwise} \end{cases}$$

$$g_i(A, B) = G_i(A, B) - G_{i-1}(A, B)$$

Recalling that A_t is the set of documents relevant to user u_t, we see that $G_k(A_t, B)$ is the payoff of presenting B to the user u_t. Let

$$B^* = \operatorname*{argmax}_B \sum_{t=1}^{T} G_k(A_t, B),$$

$$OPT = \sum_{t=1}^{T} G_k(A_t, B^*).$$

Recall that $(\hat{b}_1(t), \ldots, \hat{b}_k(t))$ is the sequence of documents chosen by the algorithms $\mathsf{MAB}_1, \ldots, \mathsf{MAB}_k$ at time t, and that $(b_1(t), \ldots, b_k(t))$ is the sequence of documents presented to the user. Define the feedback function f_{it} for algorithm MAB_i at time t, as follows:

$$f_{it}(b) = \begin{cases} 1 & \text{if } G_{i-1}(A_t, B_t) = 0 \text{ and } b \in A_t \\ 0 & \text{otherwise} \end{cases}.$$

Note that the value of f_{it} defined in the pseudocode for the Ranked Bandits Algorithms is equal to $f_{it}(\hat{b}_i(t))$.

Lemma 1. *For all i,*

$$\begin{aligned} &\mathbf{E}\left[\sum_{t=1}^{T} g_i(A_t, B_t)\right] \\ &\geq \frac{1}{k}\mathbf{E}\left[\sum_{t=1}^{T} (G_k(A_t, B^*) - G_{i-1}(A_t, B_t))\right] - R(T) \\ &= \frac{1}{k}OPT - \frac{1}{k}\mathbf{E}\left[\sum_{t=1}^{T} G_{i-1}(A_t, B_t)\right] - R(T). \end{aligned}$$

Proof. First, note that

$$g_i(A_t, B_t) \geq f_{it}(\hat{b}_i(t)). \tag{1}$$

This is trivially true when $f_{it}(\hat{b}_i(t)) = 0$. When $f_{it}(\hat{b}_i(t)) = 1$, $G_{i-1}(A_t, B_t) = 0$ and $\hat{b}_i(t) \in A_t$. This implies that $b_i(t) = \hat{b}_i(t)$ and that $g_i(A_t, B_t) = 1$.

Now using the regret bound for MAB_i we obtain

$$\begin{aligned} \sum_{t=1}^{T} \mathbf{E}[f_{it}(\hat{b}_i(t))] &\geq \max_b \sum_{t=1}^{T} \mathbf{E}[f_{it}(b)] - R(T) \\ &\geq \frac{1}{k}\mathbf{E}\left[\sum_{b \in B^*} \sum_{t=1}^{T} f_{it}(b)\right] - R(T). \end{aligned} \tag{2}$$

To complete the proof of the lemma, we will prove that

$$\sum_{b \in B^*} f_{it}(b) \geq G_k(A_t, B^*) - G_{i-1}(A_t, B_t). \tag{3}$$

The lemma follows immediately by combining (1)-(3). Observe that the left side of (3) is a non-negative integer, while the right side takes one of the values $\{-1, 0, 1\}$. Thus, to prove (3) it suffices to show that the left side is greater than or equal to 1 whenever the right side is equal to 1. The right side equals 1 only when $G_{i-1}(A_t, B_t) = 0$ and A_t intersects B^*. In this case it is clear that there exists at least one $b \in B^*$ such that $f_{it}(b) = 1$, hence the left side is greater than or equal to 1. □

Theorem 1. *The algorithm's combined payoff after T rounds satisfies:*

$$\mathbf{E}\left[\sum_{t=1}^{T} G_k(A_t, B_t)\right] \geq \left(1 - \frac{1}{e}\right) OPT - kR(T). \tag{4}$$

Proof. We will prove, by induction on i, that

$$OPT - \mathbf{E}\left[\sum_{t=1}^{T} G_i(A_t, B_t)\right] \leq \left(1 - \frac{1}{k}\right)^i OPT + iR(T). \tag{5}$$

The theorem follows by taking $i = k$ and using the inequality $\left(1 - \frac{1}{k}\right)^k < \frac{1}{e}$.

In the base case $i = 0$, inequality (5) is trivial. For the induction step, let

$$Z_i = OPT - \mathbf{E}\left[\sum_{t=1}^{T} G_i(A_t, B_t)\right].$$

We have

$$Z_i = Z_{i-1} - \mathbf{E}\left[\sum_{t=1}^{T} g_i(A_t, B_t)\right], \tag{6}$$

and Lemma 1 says that

$$\mathbf{E}\left[\sum_{t=1}^{T} g_i(A_t, B_t)\right] \geq \frac{1}{k} Z_{i-1} - R(T). \tag{7}$$

Combining (6) with (7), we obtain

$$Z_i \leq \left(1 - \frac{1}{k}\right) Z_{i-1} + R(T).$$

Combining this with the induction hypothesis proves (5). □

The general case, in which user u_i's type vector $(p_{ij})_{j \in \mathcal{D}}$ is an arbitrary element of $[0, 1]^{\mathcal{D}}$, can be reduced via a simple transformation to the case of deterministic users analyzed above. We replace user u_i with a *random* deterministic user $\hat{u}_i$ whose type vector $\hat{p}_i \in \{0, 1\}^{\mathcal{D}}$ is sampled using the following rule: the random variable $\hat{p}_{ij}$ has distribution

$$\hat{p}_{ij} = \begin{cases} 1 & \text{with probability } p_{ij} \\ 0 & \text{with probability } 1 - p_{ij}, \end{cases}$$

and these random variables are mutually independent. Note that the clicking behavior of user u_i when presented with a ranking B is *identical* to the clicking behavior observed when a random user type $\hat{u}_i$ is sampled from the above distribution, and the ranking B is presented to this random user. Thus, if we apply the specified transformation to users $u_1, u_2, \ldots, u_T$, obtaining a random sequence $\hat{u}_1, \hat{u}_2, \ldots, \hat{u}_T$ of deterministic users, this transformation changes neither the algorithm's expected payoff nor that of the optimum ranking B^*. Thus, Theorem 1 for general users can be deduced by applying the same theorem to the random sequence $\hat{u}_1, \ldots, \hat{u}_T$ and taking the expectation of the left and right sides of (4) over the random choices involved in sampling $\hat{u}_1, \ldots, \hat{u}_T$.

Note also that B^* is defined as the optimal *subset* of k documents, and OPT is the payoff of presenting B^*, without specifying the order in which documents are presented. However, the Ranked Bandits Algorithm learns an order for the documents in addition to identifying a set of documents. In particular, given $k' < k$, RBA(k') would receive exactly the same feedback as the first k' instances of MAB_i receive when running RBA(k). Hence any k' sized prefix of the learned ranking also has the same performance bound with respect the appropriate smaller set B'^*.

Finally, it is worth noting that this analysis *cannot* be trivially extended to non-binary payoffs, for example when learning a ranking of web advertisements. In particular, the greedy algorithm on which RBA is based in the non-binary payoff case can obtain a payoff that is a factor of $k - \varepsilon$ below optimal, for any $\varepsilon > 0$.

5.3. Analysis of Ranked Explore and Commit

The analysis of the Ranked Explore and Commit (REC) algorithm is analogous to that of the Ranked Bandits algorithm, except that the equivalents of Lemma 1 and Theorem 1 are only true with high probability after $t_0 = nxk$ time steps of exploration have occurred. Let B denote the ranking selected by REC.

Lemma 2. *Let $x = 2k^2/\epsilon^2 \log(2k/\delta)$. Assume A_t is drawn i.i.d. from a fixed distribution of user types. For any i, with probability $1 - \delta/k$,*

$$\mathbf{E}\left[\sum_{t=t_0}^{T} g_i(A_t, B)\right] \geq \frac{1}{k}\mathbf{E}\left[\sum_{t=t_0}^{T} (G_k(A_t, B^*) - G_{i-1}(A_t, B))\right] - \frac{\epsilon}{k}T.$$

Proof Outline. First note that in this setting, B^* and OPT are defined in expectation over the A_t drawn. For any document, by Hoeffding's inequality, with probability $1 - \delta/2k$ the true payoff of that document explored at rank i is within $\epsilon/2k$ of the observed mean payoff. Hence the document selected at rank i is within ϵ/k of the payoff of the best document available at rank i. Now, the same proof as for Lemma 1 applies, although with a different regret $R(T)$. □

Theorem 2. *With probability $(1 - \delta)$, the algorithm's combined payoff after T rounds satisfies:*

$$\mathbf{E}\left[\sum_{t=1}^{T} G_k(A_t, B)\right] \geq \left(1 - \frac{1}{e}\right) OPT - \epsilon T - nkx \quad (8)$$

Proof Outline. Applying Lemma 2 for all $i \in \{1, .., k\}$, with probability $(1 - k\delta/k) = (1 - \delta)$ the conclusion of the Lemma holds for all i.

Next, an analogous proof as for Theorem 1 applies, except replacing $R(T)$ with $\frac{\epsilon}{k}T$ and noting that the regret during the nkx exploration steps is at most 1 for every time step. □

It is interesting to note that, in contrast to the Ranked Bandits Algorithm, this algorithm can be adapted to the case where clicked documents provide real valued payoffs. The only modification necessary is that documents should always be presented by decreasing payoff value. However, we do not address this extension further due to space constraints.

6. Evaluation

In this section, we evaluate the Ranked Bandits and Ranked Explore and Commit algorithms, as well as two variants of RBA, with simulations using a user and document model.

We chose a model that produces a user population and document distribution designed to be realistic yet allow us to evaluate the performance of the presented algorithms under different levels of noise in user clicking behavior. Our model first assigns each of 20 users to topics of interest using a Chinese Restaurant Process (Aldous, 1985) with parameter $\theta = 3$. This led to a mean of 6.5 unique topics, with topic popularity decaying according to a power law. Taking a collection of 50 documents, we then randomly assigned as many documents to each topic as there were users assigned to the topic, leading to topics with more users having more relevant documents. We set each document assigned to a topic as relevant to all users assigned to that topic, and all other documents as non relevant. The probabilities of a user clicking on relevant and non-relevant documents were set to constants p_R and p_{NR} respectively.

We tested by drawing one user uniformly from the user population at each time step, and presented this user with the ranking selected by each algorithm, using $k = 5$. We report the average number of time steps where the user clicked on a result, and the average number of time steps where at least one of the presented documents was relevant to the user. All numbers we report are averages over 1,000 algorithm runs.

6.1. Performance Without Click Noise

We start by evaluating how well the REC and RBA algorithms maximize the clickthrough rate in the simplest case when $p_R = 1$ and $p_{NR} = 0$. We also compare their performance to the clickthrough rate that the same users would generate if presented with a static system that orders documents by decreasing true prob-

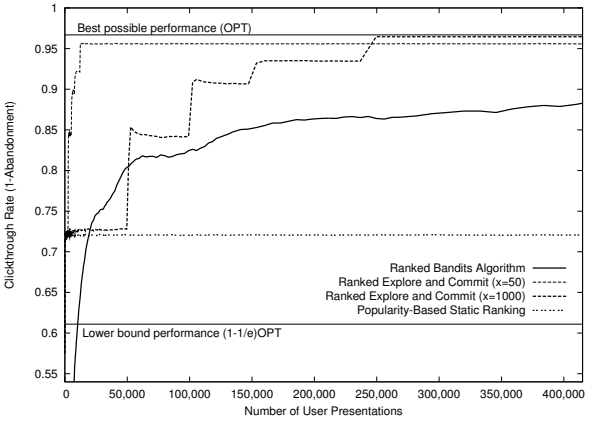

Figure 1. Clickthrough rate of the learned ranking as a function of the number of times the ranking was presented to users.

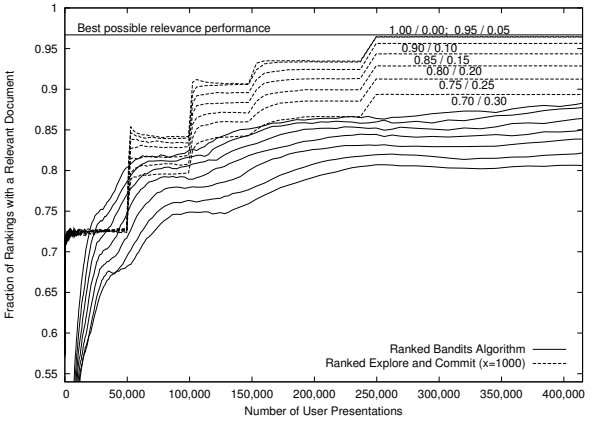

Figure 2. Effect of noise in clicking behavior on the quality of the learned ranking.

ability of relevance to the users assuming document relevances are independent. Figure 1 shows that both REC and RBA perform well above the static baseline and well above the performance guarantee provided by the theoretical results. This is not surprising, as the $(1 - 1/e)OPT$ bound is a worst-case bound. In fact, we see that REC with $x = 1000$ nearly matches the performance of the best possible ranking after finishing its initial exploration phase. We also see that the exploration parameter of REC plays a significant role in the performance, with lower exploration leading to faster convergence but slightly lower final performance. Note that despite REC performing best here, the ranking learned by REC is fixed after the exploration steps have been performed. If user interests and documents change over time, the performance of REC could fall arbitrarily. In contrast, RBA is guaranteed to remain near or above the $(1 - 1/e)OPT$ bound.

6.2. Effect of Click Noise

In Figure 1, the clickthrough rate and fraction of users who found a relevant document in the top k positions is identical (since users click if and only if they are presented with a relevant document). In contrast, Figure 2 shows how the fraction of users who find a relevant document decays as the probability of a user clicking becomes noisier. The figure presents the performance lines for REC and RBA across a range of click probabilities, from $(p_R = 1, p_{NR} = 0)$ to $(p_R = 0.7, p_{NR} = 0.3)$. We see that both algorithms decay gracefully: as the clicks become noisier noisy, the fraction of users presented with a relevant documents decays slowly.

6.3. Optimizing Practical Effectiveness

Despite the theoretical results shown earlier, it would be surprising if an algorithm designed for the worst case had best average case performance. Figure 3 shows the clickthrough rate (which the algorithms optimize), and fraction of users who find relevant documents (which is of more interest to information retrieval practitioners), for variants building on the insights of the ranked bandits idea. Specifically, two variants of RBA that have the best performance we could obtain in our simulation are shown. We found that using a UCB1-based multi-armed bandit algorithm (Auer et al., 2002a) in place of EXP3 improves the performance of RBA substantially when user interests are static. Note however, that UCB1 does not satisfy the constraints presented in Section 4.2 because it assumes rewards are identically distributed over time, an assumption violated in our setting when changes in the documents presented above rank i alter the reward distribution at rank i. Nevertheless, we see that this modification substantially improves the performance of RBA. We expect such an algorithm to perform best when few documents are prone to radical shifts in popularity.

7. Conclusions and Extensions

We have presented a new formulation of the learning to rank problem that explicitly takes into account the relevance of different documents being interdependent. We presented, analyzed and evaluated two algorithms and two variants for this learning setting. We have shown that the learning problem can be solved in a theoretically sound manner, and that our algorithms can be expected to perform reasonably in practice.

We plan to extend this work by addressing the non-binary document relevance settings, and perform empirical evaluations using real users and real documents. Furthermore, we plan to investigate how prior knowledge can be incorporated into the algorithms to improve speed of convergence. Finally, we plan to inves-

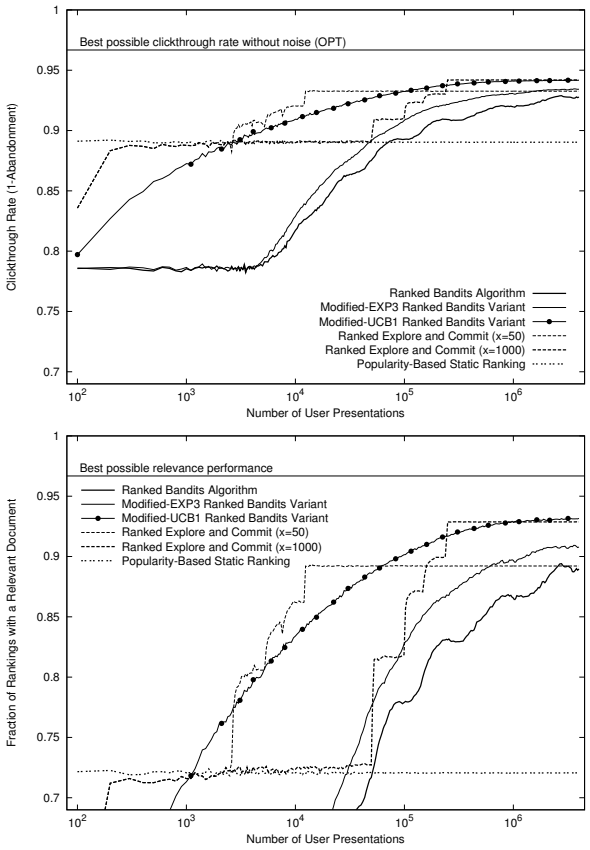

Figure 3. In a practical setting, it may be beneficial to use a variant of RBA to obtain improved performance at the cost of weaker theoretical guarantees. Performance is shown in realistic settings $p_R = 0.8$, $p_{NR} = 0.2$.

tigate if the bandits at different ranks can be coupled to improve the rate at which RBA converges.

Abstract

Finding good representations of text documents is crucial in information retrieval and classification systems. Today the most popular document representation is based on a vector of word counts in the document. This representation neither captures dependencies between related words, nor handles synonyms or polysemous words. In this paper, we propose an algorithm to learn text document representations based on semi-supervised autoencoders that are stacked to form a deep network. The model can be trained efficiently on partially labeled corpora, producing very compact representations of documents, while retaining as much class information and joint word statistics as possible. We show that it is advantageous to exploit even a few labeled samples during training.

1. Introduction

Document representations are a key ingredient in all information retrieval and processing systems. The goal of the representation is to make certain aspects of the document readily accessible, e.g. the document topic. To identify a document topic, we cannot rely on specific words in the document, as it may use other synonymous words or misspellings. Likewise, the presence of a word does not warrant that the document is related to it, as it may be taken out of context, or polysemous, or unimportant to the document topic.

The most widespread representations for document classification and retrieval today are based on a vector of counts. These include various term-weighting retrieval schemes, such as tf-idf and BM25 (Robertson and Walker, 1994), and bag-of-words generative models such as naive Bayes text classifiers. The pertinent feature of these representations is that they represent individual words. A serious drawback of the basic tf-idf and BM25 representations is that all dimensions are treated as independent, whereas in reality word occurrences are highly correlated.

There have been many attempts at modeling word correlations by rotating the vector space and projecting documents onto principal axes that expose related words. Methods include LSI (Deerwester et al., 1990) and pLSI (Hofmann, 1999). These methods constitute a linear re-mapping of the original vector space, and while an improvement, still can only capture very limited relations between words. As a result they need a large number of projections in order to give an appropriate representation.

Other models, such as LDA (Blei et al., 2003), have shown superior performance over pLSI and LSI. However, inferring the representation is computationally expensive because of the "explaining away" effect that plagues all directed graphical models.

More recently, a number of authors have proposed undirected graphical models that can make inference efficient at the cost of more complex learning due to a global (rather than local) partition function whose exact gradient is intractable. These models build on Restricted Boltzmann Machines (RBMs) by adapting the conditional distribution of the input visible units to model discrete counts of words (Hinton and Salakhutdinov, 2006; Gehler et al., 2006; Salakhutdinov and Hinton, 2007a,b). These models have shown state-of-the-art performance in retrieval and clustering, and can be easily used as a building block for deep multi-layer networks (Hinton et al., 2006). This might allow the

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

top-level representation to capture high-order correlations that would be difficult to efficiently represent with similar but shallow models (Bengio and LeCun, 2007). Many authors have pointed out that RBMs are robust to uncorrelated noise in the input since they model the distribution of the input data, and they implicitly perform automatic model selection by not using unnecessary hidden units. But they are also somewhat cumbersome to train, relying on two disparate steps: unsupervised pre-training using an approximate sampling technique such as contrastive divergence (Hinton, 2000), followed by supervised back-propagation. It is rather difficult to predict when training can be stopped and how long the Markov Chain has to run. An alternative is to replace RBMs with autoencoders (Bengio et al., 2006), or special autoencoders that produce sparse representations (Ranzato et al., 2007b). According to these authors, the performance of RBMs and standard autoencoders is quite similar as long as the dimensionality of the latent space is smaller than the input. Seeking an algorithm that can be trained efficiently, and that can produce a representation with just a few matrix multiplications, we propose a deep network whose building blocks are autoencoders, with a specially designed first layer for modeling discrete counts of words.

Previously, deep networks have been trained either from fully labeled data, or purely unlabeled data. Neither method is ideal, as it is expensive to label large collections, whereas purely unsupervised learning may not capture the relevant class information in the data. Inspired by the experiments by Bengio, Lamblin et al. (2006), we learn the parameters of the model by using *both a supervised and an unsupervised objective*. In other words, we require the representation to produce good reconstructions of the input documents and, at the same time, to give good predictions of the document class labels. Besides demonstrating better accuracy in retrieval, we also extend the deep network framework to a *semi-supervised* setting where we deal with partially labeled collections of documents. This allows us to use relatively few labeled documents yet leverage language structure learned from large corpora, see Sec. 3.1.

Finally, we study the relative advantages of different deep models. For instance, we investigate when deep models are better than shallow ones. Our experiments in Sec. 3.2 show that for learning compact representations of documents, deep architectures greatly outperform shallow models. Compact representations are beneficial because they require less storage (an important consideration for large search engines), and they are more computationally efficient when used in indexing. We also explored the possibility to use deep networks to learn binary *high-dimensional* representations instead of *compact* representations. These high-dimensional representations were trained using the Symmetric Encoding Sparse Machine (SESM) (Ranzato et al., 2007b). However, the compact representations proved to be far more efficient in terms of memory usage and CPU time, as described in Sec. 3.3. Also, training is more computationally efficient than for related models such as RBMs.

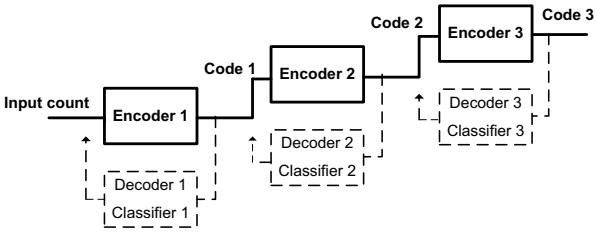

Figure 1. Architecture of a model with three stages. The system is trained layer by layer. During the training of the n-th layer, the n-th encoder is coupled with the n-th decoder and classifier (shown in dashed line). The n-th encoder will provide the codes to train the layer above. After training, the feedback decoding modules are discarded and the system is used to produce very compact codes by a feed-forward pass through the chain of encoders.

2. The model

The input to the system is a bag of words representation of each text document in the form of a count vector. The length of the vector equals the number of unique words in the collection, and its i-th entry stores the number of times the corresponding word occurs in the document. The goal of the system is to extract a *compact* representation from this very high-dimensional but sparse input vector. A compact representation is good because it requires less storage, and allows fast index lookup. Since the representation is produced by a deep multi-layer model, it can efficiently discover latent topics by grouping similar words and by activating features whenever some "interesting" combination of words is detected (see visualization in Sec. 3.4).

We propose a system that is composed of multiple layers. Each layer computes a weighted sum of its input followed by a logistic nonlinearity. Each layer can be seen as an *encoder* producing a representation, or *code*, from its input. This code will be propagated and used as the input to the next layer of the model. This architecture is quite similar to a neural network model, but is trained differently and has a special first layer able to encode discrete count data. The goal of training is to find the parameters in each layer.

In order to successfully learn the parameters we follow the strategy advocated by recent work (Hinton et al., 2006; Hinton and Salakhutdinov, 2006; Bengio et al., 2006) on deep multi-layer models. Learning proceeds greedily layer by layer. When the parameters of one layer have been found, the data is fed through that layer and the output becomes the input for the next layer, which is trained subsequently.

Let us consider a generic layer in the model, and let $\boldsymbol{x}$ be its input and let $\boldsymbol{z}$ be the representation produced by the layer. In order to warrant the fidelity of the code $\boldsymbol{z}$, we attach a feedback module which aims to reconstruct the input $\boldsymbol{x}$ from the code $\boldsymbol{z}$. The reason is that if the model achieves a good reconstruction from the code $\boldsymbol{z}$, then we can be sure that the representation has preserved most of the information from $\boldsymbol{x}$. The original layer can then be interpreted as an *encoder* that computes a code from the input, while the feedback module can be seen as a *decoder* that reconstructs the input $\boldsymbol{x}$ from the code $\boldsymbol{z}$. Learning consists of minimizing a reconstruction error E_R with respect to the parameters in the encoder and decoder when the input $\boldsymbol{x}$ is drawn from the training dataset. Since we learn by stochastic gradient descent, any type of encoder and decoder is allowed as long as it is differentiable.

Some inputs may have labels specifying the class to which they belong. In order to incorporate this information, we add another module to the decoder. The feedback module now not only has a decoder reconstructing the input $\boldsymbol{x}$, but also a *classifier* predicting the label y from the code $\boldsymbol{z}$, see Fig. 1. During training the parameters of the encoder, classifier and decoder are learned by minimizing the loss

$$L = E_R + \alpha_c E_C, \tag{1}$$

where E_R and E_C are terms measuring the reconstruction and classification error respectively, and α_c is a coefficient balancing them. The first term is common to many unsupervised learning algorithms and makes the system model the structure and the dependencies among the input components of $\boldsymbol{x}$. The second term represents the supervised goal ensuring that codes are also going to be good for discriminating between classes.

For the classifier module we used a linear classifier trained by cross-entropy error E_C. Denoting with $(W_C)_i$ the i-th row of the classifier weight matrix, with b_{Ci} the i-th bias of the classifier, and with h_j the j-th output unit of the classifier passed through a soft-max:

$$h_j = \frac{\exp((W_C)_j \cdot \boldsymbol{z} + b_{Cj})}{\sum_i \exp((W_C)_i \cdot \boldsymbol{z} + b_{Ci})},$$

we define $E_C = -\sum_i y_i \log h_i$, where $\boldsymbol{y}$ is a 1-of-N encoding of the target class label.

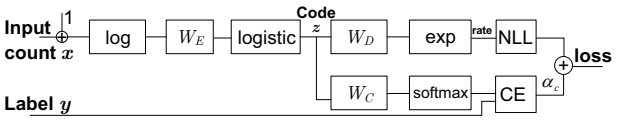

Figure 2. The architecture of the first stage has three components: (1) an encoder, (2) a decoder (Poisson regressor), and (3) a classifier. The loss is the weighted sum of cross-entropy (CE) and negative log-likelihood (NLL) under the Poisson model.

2.1. Training the First Stage

The first stage is special because the input $\boldsymbol{x}$ is a discrete vector of word counts, with x_i counting the number of occurrences of the i-th word in the document. The decoder is a *Poisson regression model* aiming to predict $\boldsymbol{x}$ from the code $\boldsymbol{z}$. A Poisson regressor is a log-linear model which assigns the following probability to an observed $\boldsymbol{x}$:

$$P(\boldsymbol{x}) = \prod_i P(x_i) = \prod_i \mathrm{e}^{-\lambda_i} \frac{\lambda_i^{x_i}}{x_i!}, \tag{2}$$

where the set of rates is given by $\lambda = \beta \mathrm{e}^{W_D \boldsymbol{z} + \boldsymbol{b}_D}$, with a decoder weight matrix W_D, decoder biases $\boldsymbol{b}_D$, and a constant β proportional to the document length. This normalization handles documents of different lengths and makes learning stable. The reconstruction error E_R minimized at the first stage (eq. 1) is the negative log-likelihood of the data

$$E_R = \sum_i (\beta \mathrm{e}^{((W_D)_i \cdot \boldsymbol{z} + b_{Di})} - x_i (W_D)_i \cdot \boldsymbol{z} - x_i b_{Di} + \log x_i!), \tag{3}$$

averaged over the samples $\boldsymbol{x}$ in the training dataset.

We design the encoder by "reverse-engineering" the decoder to make the machine symmetric. Since the decoder computes an exponential of a weighted sum, the encoder performs a weighted sum of the log-transformed input $\boldsymbol{x}$. In addition to this, the encoder applies a logistic nonlinearity. Hence, the code $\boldsymbol{z}$ is given by $\boldsymbol{z} = \boldsymbol{\sigma}(W_E \log(\boldsymbol{x}) + \boldsymbol{b}_E)$, where W_E and $\boldsymbol{b}_E$ are the weight matrix and the biases in the encoder, and $\boldsymbol{\sigma}$ is the logistic. Since many components in $\boldsymbol{x}$ are zero (because only a few dictionary words are actually present in a given document), and since the rate at which a word might appear is generally fairly low, this architecture is prone to numerical problems in the evaluation of the logarithm, and would possibly require large negative weights in W_D (in order to make the rate λ small). Thus, we shift the Poisson regression by adding one to the input. As a result, if a word does not occur in the document, the input to the encoder weight matrix W_E will be zero (and not minus infinity), and

if a word is rare its rate will be one forcing the corresponding weights in W_D to be close to zero (and not to minus infinity). Fig. 2 shows the final architecture of the first stage.

2.2. Training the Upper Stages

The outputs of earlier layers are fed as inputs of subsequent layers. The architecture of the subsequent layers differs from the first one in that the decoder uses a Gaussian regressor instead of a Poisson regressor. Accordingly, the encoder computes a weighted sum of its input and applies a logistic nonlinearity. This architecture is similar to an autoencoder neural network, but here the feedback layer also includes a supervised classifier. If $\boldsymbol{z}^{(n-1)}$ is the input to the n-th layer, the code $\boldsymbol{z}^{(n)}$ produced at this stage is $\boldsymbol{z}^{(n)} = \boldsymbol{\sigma}(W_E \boldsymbol{z}^{(n-1)} + \boldsymbol{b}_E)$. The reconstruction error E_R in the loss of eq. 1 can be written as $E_R = \|\boldsymbol{z}^{(n-1)} - W_D \boldsymbol{z}^{(n)} - \boldsymbol{b}_D\|_2^2$.

2.3. Training the Whole Model

Learning consists of determining the parameters at each layer of the deep model. The algorithm proceeds as follows:
(1) attach a Poisson regressor and a linear classifier to the first layer, and minimize the loss in eq. 1 with respect to the parameters $(W_E, b_E, W_D, b_D, W_C, b_C)$ by stochastic gradient descent;
(2) transform the training samples $\boldsymbol{x}$ into codes $\boldsymbol{z}^{(1)}$ using the trained encoder of the first layer;
(3) train the second layer by attaching a Gaussian regressor and a linear classifier to the encoder, using the codes $\boldsymbol{z}^{(1)}$ as input;
(4) use the trained encoder of the second layer to transform the codes $\boldsymbol{z}^{(1)}$ into the higher-level codes $\boldsymbol{z}^{(2)}$;
(5) repeat the previous two steps for as many layers as desired.

When the input sample is not accompanied by a label, the classifier is not updated and the loss function simply reduces to $L = E_R$. In order to minimize the loss with respect to the parameters we use stochastic gradient descent and we back-propagate the derivatives through the decoder, classifier and encoder (LeCun et al., 1998).

The learning algorithm is particularly efficient. The computational cost of learning is linear in the number of training samples (sublinear for redundant datasets, which are frequent). For each training document at any given layer, the cost is given by a forward and backward pass through encoder, decoder and classifier. Each pass is dominated by a matrix-vector multiplication whose complexity depends on the size of the matrix. Since at each layer we reduce the dimensionality of the input, the first layer dominates the computational cost. However, the sparsity of the input count vector can be exploited to speed-up the computation by taking into account only those rows in W_E that are involved in the computation. In general, the computational cost at a given layer scales as $4MN + 2NK$, where M is the dimensionality of the input, N is the dimensionality of the code, and K is the number of classes.

If we are interested in classification we can also use the trained classifier to predict the labels from the features (at any layer), without training a separate supervised system (see Sec. 3.1 for an example). Also, our experiments show that there is not much advantage in "fine-tuning" the parameters by doing global non-greedy supervised training of the machine as performed by Hinton et al. (2006). The label injection during the greedy training of each layer renders this final supervised training stage unnecessary. This saves a lot of time because it is expensive to do forward and backward propagation through a large and deep network.

Inference is also very efficient. Once the model is trained the encoders are stacked and the decoder and classifier modules are removed. A feature vector is computed by a forward propagation of the input sparse count vector through the sequence of encoders. This computation requires a few matrix vector multiplications, where the most expensive one is at the first layer, which can benefit further from a sparse computation.

3. Experiments

In our experiments we considered three standard datasets: 20 Newsgroups, Reuters-21578, and Ohsumed[1]. The 20 Newsgroups dataset contains 18845 postings taken from the Usenet newsgroup collection. Documents are partitioned into 20 topics. The dataset is split into 11314 training documents and 7531 test documents. Training and test articles are separated in time. Reuters has a predefined ModApte split of the data into 11413 training documents and 4024 test documents. Documents belong to one of 91 topics. The Ohsumed dataset has 34389 documents with 30689 words and each document might be assigned to more than one topic, for a total of 23 topics. The dataset is split into training and test by randomly selecting the 67% and the 33% of the data. Rainbow[2] was used to pre-process these datasets by stemming the documents,

[1] These corpora were downloaded from `http://people.csail.mit.edu/jrennie/20Newsgroups`, and `http://www.kyb.mpg.de/bs/people/pgehler/rap`

[2] Rainbow is available at `http://www.cs.cmu.edu/~mccallum/bow/rainbow`

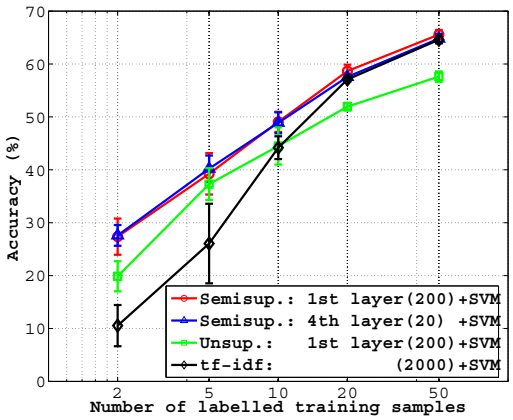

Figure 3. SVM classification of documents from the 20 Newsgroups dataset (2000 word vocabulary) trained with between 2 and 50 labeled samples per class. The SVM was applied to representations from the deep model trained in a semi-supervised or unsupervised way, and to the tf-idf representation. The numbers in parentheses denote the number of code units. Error bars indicate one standard deviation. The fourth layer representation has only 20 units, and is much more compact and computationally efficient than all the other representations.

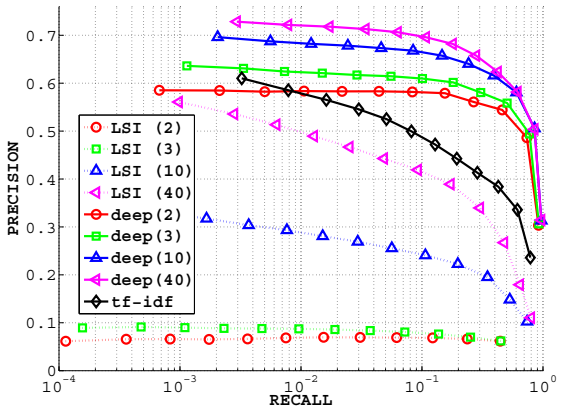

Figure 4. Precision-recall curves for the Reuters dataset comparing a linear model (LSI) to the nonlinear deep model with the same number of code units (in parentheses). Retrieval is done using the k most similar documents according to cosine similarity, with $k \in [1 \dots 4095]$.

removing stop words and words appearing less than three times or in only a single document, and retaining between 1000 and 30,000 words with the highest mutual information.

Unless stated otherwise, we trained each layer of the network for only 4 epochs over the whole training dataset. Convergence took only a couple of epochs, and was robust to the choice of the learning rate. This was set to about 10^{-4} when training the first layer, and to 10^{-3} when training the layers above. The learning rate was exponentially decreased by multiplying it by 0.97 every 1000 samples. A small L1 regularizer on the parameters was added to the loss. Each weight was randomly initialized, and was updated by taking a gradient step with a regularizer given by the value of the learning rate times $5 \cdot 10^{-4}$ the sign of the weight. The value of α_c in eq. 1 was set to the ratio between the number of input units in the layer and the number of classes in order to make the two error terms E_R and E_C comparable. Its exact value did not affect the performance as long as it had the right order of magnitude.

3.1. The Value of Labels

In order to assess whether semi-supervised training was better than purely unsupervised training, we trained the deep model on the 20 Newsgroup dataset using only 2, 5, 10, 20 and 50 samples per class. During training we showed the system 10 labeled samples every 100 examples by sweeping more often over the labeled data. This procedure was repeated at each layer during training. We trained 4 layers for 10 epochs with an architecture of 2000-200-100-50-20, denoting 2000 inputs, 200 hidden units at the first layer, 100 at the second, 50 at the third, and 20 at the fourth. Then, we trained a Support Vector Machine[3] (SVM) with a Gaussian kernel on (1) the codes that corresponded to the labeled documents, and we compared the accuracy of the semi-supervised model to the one achieved by a Gaussian SVM trained on the features produced by (2) the same model but trained in an unsupervised way, and by (3) the tf-idf representation of the same labeled documents. The SVM was generally tuned by five-fold cross validation on the available labeled samples (but two-fold cross validation when using only two samples per class). Fig. 3 demonstrates that the learned features gave much better accuracy than the tf-idf representation overall when labeled data was scarce. The model was able to exploit the very few labeled samples producing features that were easier to discriminate. The performance actually improved when the dimensionality of the code was reduced and only 2 or 5 labeled samples per class were available, probably because a more compact code implicitly enforces a stronger regularization. Semi-supervised training outperformed unsupervised training, and the gap widened as we increased the number of labeled samples, indicat-

[3]We used libsvm package available at `http://www.csie.ntu.edu.tw/~cjlin/libsvm`

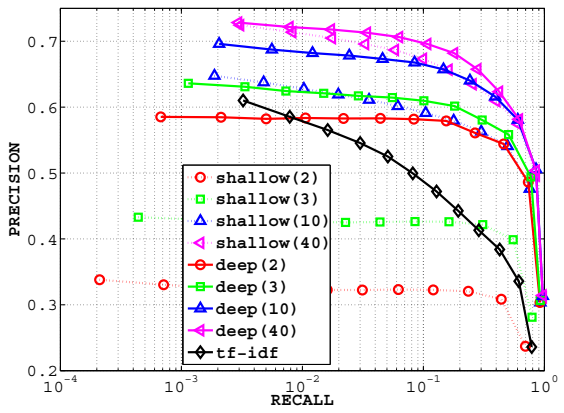

Figure 5. Precision-recall curves for the Reuters dataset comparing one-layer models (shallow) to deep models with the same numbers of code units. The deep models are more accurate overall when the codes are extremely compact. This also suggests that the number of hidden units has to be *gradually* decreased from layer to layer.

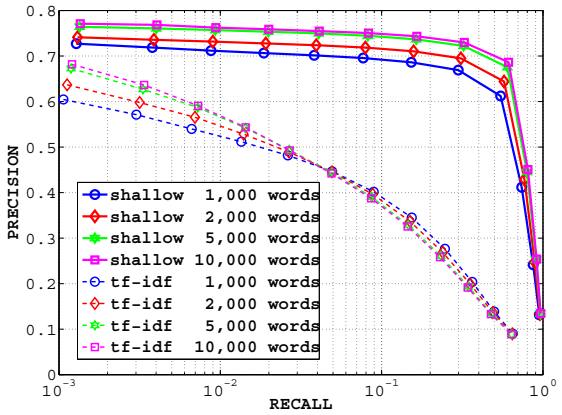

Figure 6. Precision-recall curves for the 20 Newsgroups dataset comparing the performance of tf-idf versus a one-layer shallow model for varying sizes of the word dictionary (from 1000 to 10000 words).

ing that the unsupervised method had failed to model information relevant for classification when compressing to a low-dimensional space.

Interestingly, if we classify the data using the classifier of the feedback module we obtain a performance similar to the one achieved by the Gaussian SVM. For example, when *all* training samples are labeled the classifier at the first stage achieves accuracy of 76.3% (as opposed to 75.5% of the SVM trained either on the learned representation or on tf-idf), while the one on the fourth layer achieves accuracy of 74.8%. Hence, the training algorithm provides an accurate classifier as a side product of the training, reducing the overall learning time.

3.2. Deep or Shallow?

In all the experiments discussed in this section the model was trained using fully labeled data (still, training also includes an unsupervised objective as discussed earlier). In order to retrieve documents after training the model, all documents are mapped into the latent low-dimensional space, the cosine similarity between each document in the test dataset and each document in the training dataset is measured, and the k most similar documents are retrieved. k is chosen to be equal to 1, 3, 7, ..., 4095. Based on the topic label of the documents, we assess the performance by computing the *recall* and the *precision* averaged over the whole test dataset.

In the first experiment, we compared the linear mapping produced by LSI to the nonlinear mapping produced by our model. We considered the Reuters dataset with a 12317 word vocabulary and trained a network with 3 layers. The first layer had 100 code units, the second layer had 40 units in one experiment and 10 in another, the third layer was trained with either 3 or 2 code units. As shown in Fig. 4, the nonlinear representation is more powerful than the linear one, when the representation is very compact.

Another interesting question is whether adding layers is useful. Fig. 5 shows that for a given dimensionality of the output latent space the deep architecture outperforms the shallow one. The deep architecture is capable of capturing more complex dependencies among the input variables than the shallow one, while the representation remains compact. The compactness allows us to efficiently handle very large vocabularies (more than 30,000 words for the Ohsumed, see Sec. 3.4). Fig. 6 shows that increasing the number of words (i.e. the dimensionality of the input) does give better retrieval performance.

3.3. Compact or Binary High-Dimensional?

The most popular representation of documents is tf-idf, a very high-dimensional and sparse representation. One might wonder whether we should learn a high-dimensional representation instead of a compact representation. Unfortunately, the autoencoder based learning algorithm forces us to map data into a lower-dimensional space at each layer, as without additional constraints (Ranzato et al., 2007a) the trivial identity function would be learned. We used the sparse encod-

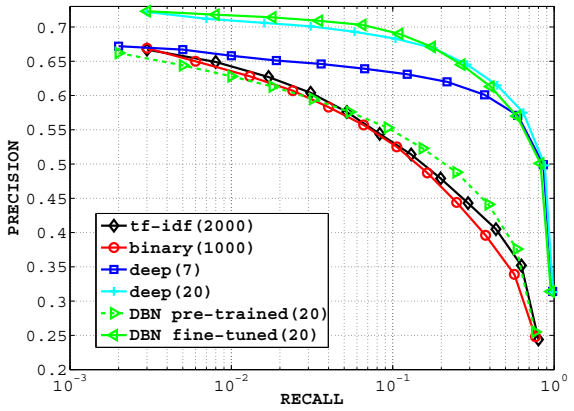

Figure 7. Precision-recall curves comparing compact representations vs. high-dimensional binary representations. Compact representations can achieve better performance using less memory and CPU time.

ing symmetric machine (SESM) (Ranzato et al., 2007b) as a building block for training a deep network producing sparse features. SESM is a symmetric autoencoder with a sparsity constraint on the representation, and it is trained unsupervised. In order to make the sparse representation at the final layer computationally appealing we thresholded it to make it binary. We trained a 2000-1000-1000 SESM network on the Reuters dataset. In order to make a fair comparison with our compact representation, we fixed the information content of the code in terms of precision[4] at $k = 1$. We measured the precision and recall of the binary representation of a test document by computing its Hamming distance from the representation of the training documents. We then trained our model with the following number of units 2000-200-100-7. The last number of units was set to match the precision of the binary representation at $k = 1$. Fig. 7 shows that our compact representation outperforms the high-dimensional and binary representation at higher values of k. Just 7 continuous units are able to achieve better retrieval than 1000 binary units! Storing the Reuters dataset with the compact representation takes less than half the memory space than using the binary representation, and comparing a test document against the whole training dataset is five times faster with the compact representation. The best accuracy for our model is given with a 20-unit representation. Fig. 7 shows the performance of a representation with the same number of units learned by a deep belief network (DBN) following Salakhutdinov and Hinton's constrained Poisson model (2007). Their model was greedily pre-trained for one epoch in an unsupervised way (200 pre-training epochs gave similar fine-tuned accuracy), and then fine-tuned with supervision for 100 epochs. While fine-tuning does not help our model, it significantly improves the DBN which eventually achieves the same accuracy as our model. Despite the similar accuracy, the computational cost of training a DBN (with our implementation using conjugate gradient on mini-batches) is several times higher due to this supervised training through a large and deep network. By looking at how words are mapped to the top-level feature space, we can get an intuition about the learned mapping. For instance, the code closest to the representation of the word "jakarta" corresponds to the word "indonesia", similarly,"meat" is closest to "beef" (table 1). As expected, the model implicitly clusters synonymous and related words.

[4]The entropy of the representation would be more natural, but its value depends on the quantization level.

Table 1. Neighboring word stems for the model trained on Reuters. The number of units is 2000-200-100-7.

Word stem	Neighboring word stems
livestock	beef, meat, pork, cattle
lend	rate, debt, bond, downgrad
acquisit	merger, stake, takeov
port	ship, port, vessel, freight
branch	stake, merger, takeov, acquisit
plantat	coffe, cocoa, rubber, palm
barrel	oil, crude, opec, refineri
subcommitte	bill, trade, bond, committe
coconut	soybean, wheat, corn, grain
meat	beef, pork, cattl, hog
ghana	cocoa, buffer, coffe, icco
varieti	wheat, grain, agricultur, crop
warship	ship, freight, vessel, tanker
edibl	beef, pork, meat, poultri

3.4. Visualization

The deep model can also be used to visualize documents. When the top layer is two-dimensional we can visualize high-dimensional nonlinear manifolds in the space of bags of words. Fig. 8 shows how documents in the Ohsumed test set are mapped to the plane. The model exposes clusters documents according to the topic class, and places similar topics next to each other. The dimensionality reduction is extreme in this case, from more than 30000 to 2.

4. Conclusions

We have proposed and demonstrated a simple and efficient algorithm to learn document representations from

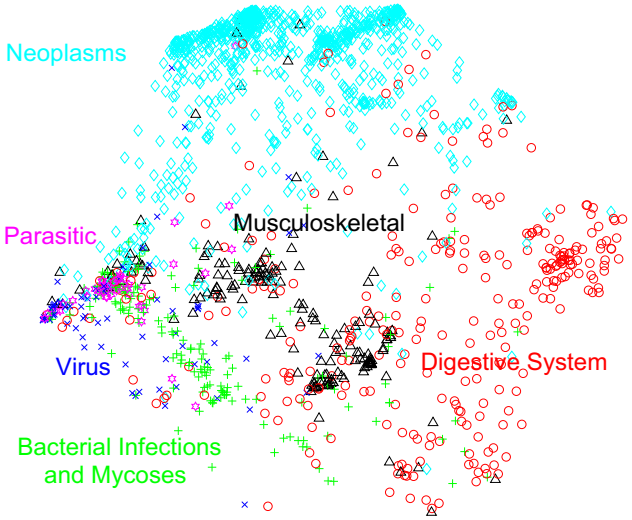

Figure 8. Two-dimensional codes produced by the deep model 30689-100-10-5-2 trained on the Ohsumed dataset (only the 6 most numerous classes are shown). The codes results from propagating documents in the test set through the four-layer network.

partially labeled datasets. The representation is rich in that it can model complex dependencies between words, which allows us to capture higher-level semantic aspects of documents than is possible with linear models. Capturing such complex structure would not be possible based on labeled data alone; by leveraging unlabeled documents we get access to a much larger amount data.

This algorithm trains faster than a similar model based on RBMs, and it finds more efficient representations than a network trained with SESMs that produce high-dimensional binary features. We have shown that these deep models greatly outperform similar but shallow models when the learning task is very hard, such as learning very compact representations. Compact representations are very important for search engines because they are cheap to store, and fast to compute and to compare. Also, we have shown that even a few labels can be exploited to make the features more discriminative.

For future work, we are interested in applying the representation for clustering and ranking. It would also be interesting to go beyond the bag of words model to capture word proximity.

Abstract

A large body of past work has focused on the first-order tree-based LP relaxation for the MAP problem in Markov random fields. This paper develops a family of super-linearly convergent LP solvers based on proximal minimization schemes using Bregman divergences that exploit the underlying graphical structure, and so scale well to large problems. All of our algorithms have a double-loop character, with the outer loop corresponding to the proximal sequence, and an inner loop of cyclic Bregman divergences used to compute each proximal update. The inner loop updates are distributed and respect the graph structure, and thus can be cast as message-passing algorithms. We establish various convergence guarantees for our algorithms, illustrate their performance, and also present rounding schemes with provable optimality guarantees.

1. Introduction

A key computational challenge associated with discrete Markov random fields (MRFs) is the problem of *maximum a posteriori* (MAP) estimation: computing the most probable configuration(s). For general graphs, this MAP problem includes a large number of classical NP-complete problems, including MAX-CUT independent set, and satisfiability problems, among various others.

This intractability motivates the development and analysis of methods for obtaining approximate solutions. The ordinary max-product algorithm is a form of non-serial dynamic-programming, exact for trees, and also widely used as a heuristic for obtaining approximate solutions to the MAP problem, but it suffers from convergence failures, and despite some local optimality results (Freeman & Weiss, 2001), it has no general correctness guarantees. For certain MRFs arising in computer vision, Boykov et al. (2001) studied graph-cut based search algorithms that compute a local maximum over two classes of moves. A related class of methods are those based on various types of convex relaxations, in which the discrete MAP problem is relaxed some type of convex optimization problem over continuous variables. Examples include linear programming (LP) relaxations (Wainwright et al., 2005; Chekuri et al., 2005), as well as quadratic, semidefinite and other conic programming relaxations (Ravikumar & Lafferty, 2006; Kumar et al., 2006; Wainwright & Jordan, 2003).

Among convex relaxations, LP relaxation is the least computationally expensive and best understood. The primary focus of this paper is a well-known tree-based LP relaxation (Chekuri et al., 2005; Wainwright et al., 2005) of the MAP estimation problem for pairwise Markov random fields, based on optimizing over a set of locally consistent pseudomarginals on edges and vertices of the graph. In principle, this LP relaxation can be solved by any standard solver, including simplex or interior-point methods (Bertsimas & Tsitsiklis, 1997). However, such generic methods fail to exploit the graph-structured nature of the LP, and hence do not scale favorably to large-scale problems.

Wainwright et al. (2005) established a connection between this tree-based LP relaxation and the class of tree-reweighted max-product (TRW-MP) algorithms, showing that suitable TRW-MP fixed points specify optimal solutions to the LP relaxation. Subsequent work has extended this basic connection in various in-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

teresting ways. For instance, Kolmogorov (2005) developed a serial form of TRW-MP with some convergence properties but as with the ordinary TRW-MP updates, no guarantees of LP optimality. Weiss et al. (2007) connected convex forms of sum-product and exactness of reweighted max-product algorithms. Globerson and Jaakkola (2007) developed a convergent dual-ascent algorithm, but its fixed points are guaranteed to be LP-optimal only for binary problems, as is also the case for the TRW-MP algorithm (Kolmogorov & Wainwright, 2005), and the rate of convergence is not analyzed. Other authors (Komodakis et al., 2007; Feldman et al., 2002) have proposed subgradient methods, but such methods typically have sub-linear convergence rates.

The goal of this paper is to develop and analyze various classes of message-passing algorithms that always solve the LP, and are provably convergent with at least a geometric rate. The methods that we develop are flexible, in that new constraints can be incorporated in a relatively seamless manner, with new messages introduced to enforce them. All of the algorithms in this paper are based on the notion of *proximal minimization*: instead of directly solving the original linear program itself, we solve a sequence of so-called proximal problems, with the property that the sequence of associated solutions is guaranteed to converge to the LP solution. We describe different classes of algorithms, based on different choices of the proximal function: quadratic, entropic, and reweighted Bethe entropies. For all choices, we show how the intermediate proximal problems can be solved by message-passing updates on the graph, guaranteed to converge but with a distributed nature that scales favorably. An additional desirable feature, given the wide variety of lifting methods for further constraining LP relaxations (Wainwright & Jordan, 2003), is that additional constraints are easily incorporated within the framework.

2. Background

We begin by introducing some background on Markov random fields, and the LP relaxations that are the focus of this paper. Given a discrete space $\mathcal{X} = \{0, 1, 2, \ldots, m\}$, let $X = \{X_1, \ldots, X_p\} \in \mathcal{X}^p$ denote a $p-$dimensional discrete random vector. We assume that its distribution $\mathbb{P}$ is a Markov random field, meaning that it factors according to the structure of an undirected graph $G = (V, E)$, with each variable X_s associated with one node $s \in V$, in the following way. Letting $\theta_s : \mathcal{X} \rightarrow$ and $\theta_{st} : \mathcal{X} \times \mathcal{X} \rightarrow$ be singleton and edgewise potential functions respectively, we assume that the distribution takes the form $\mathbb{P}(x; \theta) \propto \exp\big\{\sum_{s\in V} \theta_s(x_s) + \sum_{(s,t)\in E} \theta_{st}(x_s, x_t)\big\}$.

The problem of *maximum a posteriori* (MAP) estimation is to compute a configuration with maximum probability—i.e., an element

$$x^* \in \arg\max_{x\in\mathcal{X}^p} \Big\{ \sum_{s\in V} \theta_s(x_s) + \sum_{(s,t)\in E} \theta_{st}(x_s, x_t)\Big\} \quad (1)$$

This problem is an integer program, since it involves optimizing over the discrete space $\mathcal{X}^p$. The functions $\theta_s(\cdot)$ and $\theta_{st}(\cdot)$ can always be represented in the form

$$\theta_s(x_s) = \sum_{j\in\mathcal{X}} \theta_{s;j} \mathbb{I}[x_s = j] \quad (2a)$$

$$\theta_{st}(x_s, x_t) = \sum_{j,k\in\mathcal{X}} \theta_{st;jk} \mathbb{I}[x_s = j;\, x_t = k], \quad (2b)$$

where the m-vectors $\{\theta_{s;j}, j \in \mathcal{X}\}$ and $m \times m$ matrices $\{\theta_{st;jk},\ (j,k) \in \mathcal{X} \times \mathcal{X}\}$ parameterize the problem.

The basic linear programming (LP) relaxation of this problem is based on a set of pseudomarginals μ_s and μ_{st}, associated with the nodes and vertices of the graph. These pseudomarginals are constrained to be non-negative, as well to normalize and be locally consistent in the following sense:

$$\sum_{x_s} \mu_s(x_s) = 1, \qquad \text{for all } s \in V \quad (3a)$$

$$\sum_{x_t} \mu_{st}(x_s, x_t) = \mu_s(x_s) \qquad \text{for all } (s,t) \in E.$$

The polytope defined in this way is denoted LOCAL(G), or $\mathbb{L}(G)$ for short. The LP relaxation is based on solving maximizing the linear function

$$\sum_s \sum_{x_s} \theta_s(x_s)\mu_s(x_s) + \sum_{(s,t)\in E} \sum_{x_s, x_t} \theta_{st}(x_s, x_t)\mu_{st}(x_s, x_t),$$

subject to the constraint $\mu \in \mathbb{L}(G)$. In the sequel, we write this LP more compactly in the form $\max_{\mu\in\mathbb{L}(G)} \theta^T\mu$. By construction, this relaxation is guaranteed to be exact for any problem on a tree-structured graph (Wainwright et al., 2005), so that it can be viewed as a tree-based relaxation. The main goal of this paper is to develop efficient and distributed algorithms for solving this LP relaxation, as well as strengthenings based on additional constraints. For instance, one natural strengthening is by "lifting": view the pairwise MRF as a particular case of a more general MRF with higher order cliques, define higher-order pseudomarginals on these cliques, and use them to impose higher-order consistency constraints. This particular progression of tighter relaxations underlies the Bethe to Kikuchi (sum-product to generalized sum-product) hierarchy.

3. Proximal Minimization Schemes

We begin by defining the notion of a proximal minimization scheme, and the Bregman divergences that we use to define our proximal sequences. Instead of referring to the maximization problem $\max_{\mu \in \mathbb{L}(G)} \theta^T \mu$, it is convenient to consider the equivalent minimization problems $\min_{\mu \in \mathbb{L}(G)} -\theta^T \mu$.

3.1. Proximal Minimization

The class of methods that we develop are based on the notion of proximal minimization (Bertsekas & Tsitsiklis, 1997). Instead of attempting to solve the LP directly, we solve a sequence of problems of the form

$$\mu^{n+1} = \arg \min_{\mu \in \mathbb{L}(G)} \left\{ -\theta^T \mu + \frac{1}{\omega^n} D_f(\mu \,\|\, \mu^n) \right\}, \quad (4)$$

where for each $n = 0, 1, 2, \ldots$, μ^n denotes current iterate, $\{\omega^n\}$ denotes a sequence of positive weights, and D_f is a certain type of generalized distance, known as the proximal function. The purpose of introducing the proximal function is to convert the original LP—a convex optimization problem but non-differentiable in dual space —into a strictly convex optimization problem that can be solved relatively easily. This scheme appears similar to an annealing scheme, in that it involves a choice of weights $\{\omega^n\}$. However, although the weights $\{\omega^n\}$ can be adjusted for faster convergence, they can also be set to a constant, unlike for annealing procedures, which would typically require that $1/\omega^n \to 0$. The reason is that $D_f(\mu \,\|\, \mu^{(n)})$, as a generalized distance, itself converges to zero when the method gets closer to the optimum, thus providing an "adaptive" annealing. For appropriate choice of weights and proximal functions, these proximal minimization schemes converge to the LP optimum with at least geometric and possibly superlinear rates (Bertsekas & Tsitsiklis, 1997; Iusem & Teboulle, 1995).

In this paper, we focus exclusively on proximal functions that are Bregman divergences (Censor & Zenios, 1997), a class that includes various well-known divergences (e.g., quadratic norm, Kullback-Leibler divergence etc.). More specifically, we say that a function f is a Bregman function if it is continuously differentiable, strictly convex, and has bounded level sets. It then induces a Bregman divergence

$$D_f(\mu \,\|\, \nu) := f(\mu) - f(\nu) - \langle \nabla f(\nu), \mu - \nu \rangle \quad (5)$$

This function satisfies $D_f(\mu \,\|\, \nu) \geq 0$ with equality iff $\mu = \nu$, but need not be symmetric or satisfy the triangle inequality, so it is known as a generalized distance.

We study the sequence $\{\mu^n\}$ of proximal iterates (4) for the following choices of Bregman divergences.

Quadratic Distances: This choice is the simplest, corresponding to the quadratic norm across nodes and edges

$$Q(\mu \,\|\, \nu) := \sum_{s \in V} \|\mu_s - \nu_s\|^2 + \sum_{(s,t) \in E} \|\mu_{st} - \nu_{st}\|^2, \quad (6)$$

where we have used the shorthand

$$\|\mu_s - \nu_s\|^2 = \sum_{x_s} |\mu_s(x_s) - \nu_s(x_s)|^2,$$

and similarly for the edges. The Bregman function this corresponds to is the quadratic function,

$$f(\mu) = \frac{1}{2} \left\{ \sum_{s, x_s} \mu_s^2(x_s) + \sum_{s,t,x_s,x_t} \mu_{st}^2(x_s, x_t) \right\} \quad (7)$$

Weighted Entropic Distances: Here we consider a (possibly weighted) sum of Kullback-Leibler (KL) divergences across the nodes and edges:

$$D(\mu \,\|\, \nu) = \sum_{s \in V} \rho_s D(\mu_s \,\|\, \nu_s) + \sum_{s,t} \rho_{st} D(\mu_{st} \,\|\, \nu_{st}) \quad (8)$$

where $D(p \,\|\, q) := \sum_x \big(p(x) \log \frac{p(x)}{q(x)} - \big[p(x) - q(x) \big] \big)$ is the KL divergence, and $\{\rho_s, \rho_{st}\}$ are positive node and edge weights, respectively. An advantage of the KL distance, in contrast to the quadratic norm, is that it automatically acts to enforce non-negativity constraints on the pseudomarginals. The Bregman function this corresponds to is the entropy function,

$$f(\mu) = \sum_s H_s(\mu_s) + \sum_{s,t} H_{st}(\mu_{st}) \quad (9)$$

where H_s and H_{st} are singleton and edge-based entropies, respectively.

An extension of define a Bregman function based on a convex combination of tree-structured entropy functions (Wainwright & Jordan, 2003), and using expressions such as the reweighted Bethe entropy which are equivalent to the convex combination of tree entropies within the local polytope, we can derive an iterative procedure involving tree-reweighted message passing to solve the outer proximal steps. We defer further details to a full-length version.

3.2. Proximal Sequences via Bregman Projection

The key in designing an efficient proximal minimization scheme is ensuring that the proximal sequence $\{\mu^n\}$ can be computed efficiently. In this section, we

first describe how the sequence of each proximal minimization can be reformulated as a particular Bregman projection. We then describe how this Bregman projection can itself be computed iteratively, in terms of a sequence of cyclic Bregman projections based on a decomposition of the constraint set LOCAL(G). In the sequel, we then show how this cyclic Bregman projections reduce to very simple message-passing updates.

Given a Bregman divergence D, the *Bregman projection* of the vector ν onto a convex set C is given by

$$\widehat{\mu} \quad := \quad \arg\min_{\mu \in C} D_f(\mu \,\|\, \nu) \tag{10}$$

By taking derivatives and using standard conditions for optima over convex sets (Bertsekas & Tsitsiklis, 1997), the defining optimality condition for $\widehat{\mu}$ is

$$\big(\nabla f(\widehat{\mu}) - \nabla f(\nu)\big)^T \big(\mu - \widehat{\mu}\big) \quad \geq \quad 0 \tag{11}$$

for all $\mu \in C$. Now consider the proximal minimization problem to be solved at step n, namely the strictly convex problem

$$\min_{\mu \in \mathbb{L}(G)} \left\{ -\theta^T \mu + \frac{1}{\omega^n} D_f(\mu \,\|\, \mu^n) \right\}. \tag{12}$$

By taking derivatives and using the same convex optimality, we see that the optimum μ^{n+1} is defined by the conditions

$$\big(\nabla f(\mu^{n+1}) - \nabla f(\mu^n) - \omega^n \theta\big)^T (\mu - \mu^{n+1}) \quad \geq \quad 0$$

for all $\mu \in C$. Note that these optimality conditions are of the same form as the Bregman projection conditions (11), with the vector $\nabla f(\mu^n) + \omega^n \theta$ taking the role of $\nabla f(\nu)$; in other words, with $(\nabla f)^{-1}(\nabla f(\mu) + \omega^n \theta)$ being substituted for ν. Consequently, efficient algorithms for computing the Bregman projection (11) can be leveraged to compute the proximal update (12). In particular, our algorithms leverage the fact that Bregman projections can be computed efficiently in a *cyclic manner*—that is, by decomposing the constraint set $C = \cap_i C_i$ into an intersection of simpler constraint sets, and then performing a sequence of projections onto these simple constraint sets (Censor & Zenios, 1997).

To simplify notation, for any Bregman function f, let us define the operator

$$\mathrm{J}_f(\mu, \nu) = (\nabla f)^{-1}(\nabla f(\mu) + \nu)$$

and for any Bregman divergence D with Bregman function f and any convex set C, define the projection operator

$$\Pi_{D_f}(\gamma; C) \quad := \quad \arg\min_{\mu \in C} D_f(\mu \,\|\, \gamma)$$

With this notation, we can write the proximal update in a compact manner as a type of projection

$$\mu^{n+1} \quad = \quad \Pi_{D_f}\left(\mathrm{J}_f(\mu^n, \omega^n \theta); \mathbb{L}(G)\right).$$

Now consider a decomposition of the constraint set as an intersection—say $\mathbb{L}(G) = \cap_{k=1}^T \mathbb{L}_k(G)$. By the method of cyclic Bregman projections (Censor & Zenios, 1997), we can compute μ^{n+1} in an iterative manner, by performing the sequence of projections onto the simpler constraint sets, initializing $\mu^{n,0} = \mu^n$ and updating from $\mu^{n,\tau} \mapsto \mu^{n,\tau+1}$ by projecting $\mu^{n,\tau}$ onto constraint set $\mathbb{L}_{i(\tau)}(G)$, where $i(\tau) = \tau \mod T$, for instance. This procedure is summarized in Algorithm 1.

Algorithm 1 Basic proximal-Bregman LP solver

Given a Bregman distance D, weight sequence $\{\omega^n\}$ and problem parameters θ:

- Initialize $\mu_s^{(0)}(x_s) = \frac{1}{m}$, $\mu_{st}^{(0)}(x_s, x_t) = \frac{1}{m^2}$.
- **Outer loop:** For iterations $n = 0, 1, 2, \ldots$, update $\mu^{n+1} = \Pi_D\left(\mathrm{J}_f(\mu^n, \omega^n\theta); \mathbb{L}(G)\right)$.
  - Solve outer loop via **Inner loop:**
    (a) Initialize $\mu^{n,0} = \mathrm{J}_f(\mu^n, \omega^n\theta)$.
    (b) For $\tau = 0, 1, 2, \ldots$, set $i(\tau) = \tau \mod T$.
    (c) Set $\mu^{n,\tau+1} = \Pi_D\left(\mu^{n,\tau}; \mathbb{L}_{i(\tau)}(G)\right)$.

As shown in the following sections, by using a decomposition of $\mathbb{L}(G)$ over the edges of the graph, the inner loop steps correspond to local message-passing updates, slightly different in nature depending on the choice of Bregman distance. Iterating the inner and outer loops yields a provably convergent message-passing algorithm for the LP. Convergence follows from the convergence properties of proximal minimization (Bertsekas & Tsitsiklis, 1997), combined with convergence guarantees for cyclic Bregman projections (Censor & Zenios, 1997). In the following section, we derive the message-passing updates corresponding to various Bregman functions of interest. We also give rates of convergence for the cyclic projection updates in the inner loop.

3.3. Quadratic Projections

Consider the proximal sequence with the quadratic distance Q from equation (6); the Bregman function inducing this distance is the quadratic function $f(y) = \frac{1}{2}y^2$, whose gradient is given by $\nabla f(y) = y$.

The Map $\nu = \mathbf{J}_f(\mu, \omega\theta)$: In this case, it can

be derived as,

$$\nabla f(\nu) = \nabla f(\mu) + \omega\theta \quad (13)$$
$$\Rightarrow \nu = \mu + \omega\theta \quad (14)$$

whence we get the initialization in Equation 18.

The Projections $\mu^{n,\tau+1} = \Pi_Q(\mu^{n,\tau}, \mathbb{L}_i(G))$: onto the individual constraints $\mathbb{L}_i(G)$; the associated local update takes the form

$$\mu^{n,\tau+1} = \min_{\alpha \in \mathbb{L}_i(G)} \{f(\alpha) - \alpha^\top \nabla f(\mu^{n,\tau})\} \quad (15)$$

Consider the edge marginalization constraint for edge (s,t), $\mathbb{L}_i(G) \equiv \sum_{x_t} \mu_{st}(x_s, x_t) = \mu_s(x_s)$. Denoting the dual (Lagrange) parameter corresponding to the constraint by $\lambda_{st}(x_s)$, the KKT conditions for (15) are given by

$$\begin{aligned}
\nabla f(\mu_{st}^{n,\tau+1}(x_s,x_t)) &= \nabla f(\mu_{st}^{n,\tau}(x_s,x_t)) + \lambda_{st}(x_s) \\
\nabla f(\mu_{s}^{n,\tau+1}(x_s)) &= \nabla f(\mu_{s}^{n,\tau}(x_s)) - \lambda_{st}(x_s) \\
\mu_{st}^{n,\tau+1}(x_s,x_t) &= \mu_{st}^{n,\tau}(x_s,x_t) + \lambda_{st}(x_s) \\
\mu_{s}^{n,\tau+1}(x_s) &= \mu_{s}^{n,\tau}(x_s) - \lambda_{st}(x_s),
\end{aligned}$$

while the constraint itself gives

$$\sum_{x_t} \mu_{st}^{n,\tau+1}(x_s,x_t) = \mu_s^{n,\tau}(x_s) \quad (17)$$

Solving for $\lambda_{st}(x_s)$ yields equation (20). The node marginalization follows similarly, so that overall, we obtain message-passing algorithm (2) for the inner loop.

3.4. Entropic Projections

Consider the proximal sequence with the Kullback-Leibler distance $D(\mu \,\|\, \nu)$ defined in equation (8); the Bregman function inducing the distance is a sum of negative entropy functions $f(\mu) = \mu \log \mu$, and its gradient is given by $\nabla f(\mu) = \log(\mu) + \mathbf{1}$.

The derivation of the updates mirrors the previous section, and defering the details to a full-length version, we get the message passing algorithm (3) for the inner loop.

There are also interesting similarities between our corresponding dual updates and sum-product updates—which are updates to the dual parameters—details of which we defer to a full-length version of this paper due to lack of space.

3.5. Reweighted Entropy Projections

The message passing updates here are "reweighted" versions of those in the previous section for the unweighted entropy induced Kullback-Leibler divergence proximal iterates.

Algorithm 2 Quadratic Messages for μ^{n+1}

Initialization:

$$\mu_{st}^{(n,0)}(x_s,x_t) = \mu_{st}^{(n)}(x_s,x_t) + w^n\theta_{st}(x_s,x_t) \quad (18)$$
$$\mu_{s}^{(n,0)}(x_s) = \mu_{s}^{(n)}(x_s) + w^n\theta_{s}(x_s) \quad (19)$$

repeat
for each edge $(s,t) \in E$ **do**

$$\mu_{st}^{(n,\tau+1)}(x_s,x_t) = \mu_{st}^{(n,\tau)}(x_s,x_t) + (1/L+1)\left(\mu_s^{(n,\tau)}(x_s) - \sum_{x_t}\mu_{st}^{(n,\tau)}(x_s,x_t)\right) \quad (20)$$

$$\mu_{s}^{(n,\tau+1)}(x_s) = \mu_{s}^{(n,\tau)}(x_s) + (1/L+1)\left(-\mu_s^{(n,\tau)}(x_s) + \sum_{x_t}\mu_{st}^{(n,\tau)}(x_s,x_t)\right) \quad (21)$$

end for
for each node $s \in V$ **do**

$$\mu_s^{(k+1)}(x_s) = \mu_s^{(k)}(x_s) + \frac{1}{L}(1 - \sum_{x_s}\mu_s^{(k)}(x_s))$$
$$\mu_s^{(k+1)}(x_s) = \max(0, \mu_s^{(k+1)}(x_s))$$

end for
until convergence

Initialization of Proximal Steps:

$$\mu_{st}^{(n,0)}(x_s,x_t) = \mu_{st}^{(n)}(x_s,x_t)\exp(\omega^n/\rho_{st}\theta_{st}(x_s,x_t))$$
$$\mu_{s}^{(n,0)}(x_s) = \mu_{s}^{(n)}(x_s)\exp(\omega^n/\rho_{s}\theta_{s}(x_s)).$$

Projections: The node normalization update remains the same as in the previous section, while the marginalization update changes as,

$$\mu_{st}^{(n,\tau+1)}(x_s,x_t) = \mu_{st}^{(n,\tau)}(x_s,x_t)\left(\frac{\mu_s^{(n,\tau)}(x_s)}{\sum_{x_t}\mu_{st}^{(n,\tau)}(x_s,x_t)}\right)^{\frac{\rho_s}{\rho_s+\rho_{st}}}$$
$$\mu_{s}^{(n,\tau+1)}(x_s) = \mu_{s}^{(n,\tau)}(x_s)^{\frac{\rho_s}{\rho_s+\rho_{st}}}\left(\sum_{x_t}\mu_{st}^{(n,\tau)}(x_s,x_t)\right)^{\frac{\rho_{st}}{\rho_s+\rho_{st}}}$$

4. Rounding with Optimality Certificates

A key practical issue in applying LP relaxation is how round the fractional solution; a standard approach is

Algorithm 3 Entropic Messages for μ^{n+1}

Initialization:

$$\mu_{st}^{(n,0)}(x_s, x_t) = \mu_{st}^{(n)}(x_s, x_t) \exp(\omega^n \theta_{st}(x_s, x_t))$$
$$\mu_s^{(n,0)}(x_s) = \mu_s^{(n)}(x_s) \exp(\omega^n \theta_s(x_s))$$

repeat
for each edge $(s,t) \in E$ **do**

$$\mu_{st}^{(n,\tau+1)}(x_s, x_t) = \mu_{st}^{(n,\tau)}(x_s, x_t) \sqrt{\frac{\mu_s^{(n,\tau)}(x_s)}{\sum_{x_t} \mu_{st}^{(n,\tau)}(x_s, x_t)}}$$
$$\mu_s^{(n,\tau+1)}(x_s) = \sqrt{\mu_s^{(n,\tau)}(x_s) \sum_{x_t} \mu_{st}^{(n,\tau)}(x_s, x_t)}$$

end for
for each node $s \in V$ **do**

$$\mu_s^{(n,\tau+1)}(x_s) = \frac{\mu_s^{(n,\tau)}(x_s)}{\sum_{x_s} \mu_s^{(n,\tau)}(x_s)}$$

end for
until convergence

to round the node marginals to the nearest integer solution. However, in general, such rounding procedures need not always output the optimal integer configuration. An attractive feature of our proximal Bregman procedures is the existence of rounding schemes which, assuming that the LP relaxation is tight, can produce the LP integral optimum and certify that it is correct, even before the pseudomarginals converge to the LP solution. Here we describe two rounding schemes, and state the optimality certificate associated with each.

Node-based Rounding: This method applies to any of our proximal schemes. Given the vector μ^n of pseudomarginals at iteration n, define an integer configuration x^n by choosing, for each vertex $s \in V$, a value $x_s^n \in \arg\max_{x_s} \mu_s^n(x_s)$. Say that such a rounding is *edgewise-consistent* if for all edges $(s,t) \in E$, we have $(x_s^n, x_t^n) \in \arg\max_{(x_s, x_t)} \mu_{st}^n(x_s, x_t)$.

Tree-based Rounding: We describe this method in application to the unweighted entropic proximal updates. Let $T_1, \ldots, T_M$ be a set of spanning trees that cover the graph (meaning that each edge appears in at least one tree); for each edge (s,t), define the edge weight $\alpha_{st} = \frac{1}{M} \sum_{i=1}^{M} \mathbb{I}[(s,t) \in T_i]$. Then for each tree $i = 1, \ldots, M$:

(a) Define the tree-structured energy function $E_i(x) := \sum_s \mu^n(x_s) + \sum_{(s,t) \in E(T_i)} \frac{1}{\alpha_{st}} \mu_{st}^n(x_s, x_t)$.

(b) Run the ordinary max-product problem on energy $E_i(x)$ to find a MAP-optimal configuration $x^n(T_i)$.

Say that such a rounding is *tree-consistent* if the tree MAP solutions $\{x^n(T_i), i = 1, \ldots, M\}$ are all equal.

The following result characterizes the optimality guarantees associated with these rounding schemes:

Theorem 1 (Rounding with optimality certificates)**.** *At any iteration $n = 1, 2, \ldots$, any edge-consistent configuration obtained from node-rounding, or any tree-consistent configuration obtained from tree-rounding is guaranteed to be MAP optimal for the original problem.*

The proof is based on a certain energy-invariance property of the proximal updates; in particular, at any iteration n, the pseudomarginals μ^n have an associated function $F(x; \mu^n)$ which is proportional to the energy $E(\theta; x) = \sum_s \theta_s(x_s) + \sum_{st} \theta_{st}(x_s, x_t)$ of the graphical model. For instance, for the entropic proximal scheme, at any iteration n, the function $F(x; \mu^n) := \prod_{s \in V} \mu_s^n(x_s) \prod_{(s,t) \in E} \mu_{st}^n(x_s, x_t)$ is proportional to the exponential of $E(\theta; x)$. (See the technical report (Ravikumar et al., 2008) for full details.)

Both rounding schemes require relatively little computation. Of course, the node-rounding scheme is purely local, and so trivial to implement. With reference to the tree-rounding scheme, many graphs can be covered with a small number M of trees (e.g. $M = 2$ for grid graphs). Consequently, the tree-rounding scheme requires running the ordinary max-product algorithm twice, certainly more expensive than node-rounding but doable. In practice, we find that tree-rounding tends to find LP optima more quickly than node rounding.

5. Convergence Rates

The convergence of our message passing updates follows from two sets of results: (a) convergence of proximal algorithms (Bertsekas & Tsitsiklis, 1997) and (b) convergence of cyclic Bregman projections (Censor & Zenios, 1997). Our outer loop is a proximal algorithm; which has been well-studied in the optimization literature. A sequence $\mu^{(t)}$ is said to have superlinear convergence to the optimum μ^* if $\lim_{k \to \infty} \frac{\|\mu^{(t+1)} - \mu^*\|}{\|\mu^{(t)} - \mu^*\|} = 0$. Note that such convergence is faster than a multiplicative contraction ($\lim_{k \to \infty} \frac{\|\mu^{(t+1)} - \mu^*\|}{\|\mu^{(t)} - \mu^*\|} \leq \alpha < 1$). Bertsekas and Tsistiklis (1997) show that a proximal

algorithm with a quadratic proximity has a superlinear convergence under mild conditions, whereas Iusem and Teboulle (1995) show the same for the entropy proximity. Under the assumption that inner loops are solved exactly, these convergence results then show that our outer iterates converge superlinearly. Our inner loop message updates use cyclic Bregman projections; Censor and Zenios (1997) show that with dual feasibility correction, projections onto general convex sets are convergent. For Euclidean (quadratic) projections onto linear constraints (half-spaces), Deutsch et al. (2006) establish a geometric rate of convergence, dependent on angles between the half-spaces. The intuition is that the more orthogonal the half-spaces are, the faster the convergence; for instance, a single iteration suffices for completely orthogonal constraints. Our inner updates thus converge geometrically to an $\epsilon-$suboptimal solution for any outer proximal step. As noted earlier, the proximal convergence results assume that the inner loop has been solved exactly, while the Bregman projection results yield geometric convergence to but an $\epsilon-$suboptimal solution. While with ϵ small enough, e.g. 10^{-6} as in our experiments, this issue might not be practically relevant, there has been some recent work, e.g. (Solodov & Svaiter, 2001), showing that under mild conditions, superlinear rates still hold for $\epsilon-$suboptimal proximal iterates.

6. Experiments

We performed experiments on a 4-nearest neighbor grid graphs with sizes varying from $p = 100$ to $p = 900$, in all cases using models with 5 labels. The edge potentials were set to Potts functions, $\theta_{st}(x_s, x_t) = \beta_{st}\, \mathbb{I}[x_s = x_t]$, which penalize disagreement of labels by β_{st}. The Potts weights on edges β_{st} were chosen randomly as Uniform$(-1, +1)$, while the node potentials $\theta_s(x_s)$ were set as Uniform$(-\,\mathrm{SNR}, \mathrm{SNR})$, where the parameter SNR ≥ 0 controls the ratio of node to edge strengths, and thus corresponds roughly to a signal-to-noise ratio.

Figure 1 shows plots of the logarithmic distance between the current iterate μ^n and the LP optimum μ^n for grids of different sizes. In all cases, note how the curves have an inverted quadratic shape, corresponding to superlinear convergence.

Figure 2 shows the fraction of edges for which the node-based rounding is edgewise inconsistent for grids of different sizes. Note how the fraction converges to zero in a small number of iterations. Figure 3 shows the fraction of the energy of the rounded solution to the energy of the MAP optimum, or the suboptimality factor. Note again, the small number of iterations for convergence.

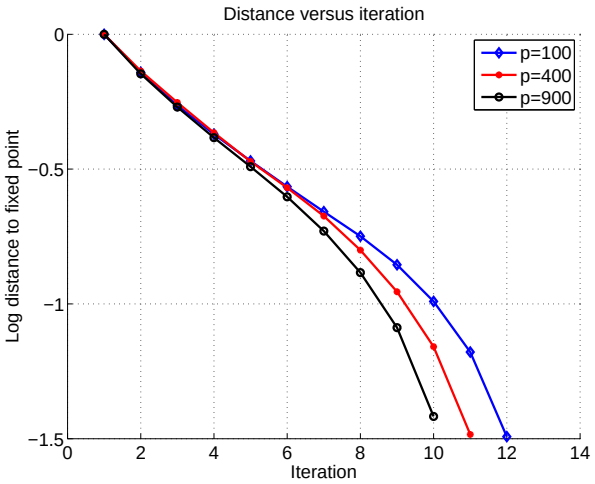

Figure 1. Plot of distance $\log_{10} \|\mu^n - \mu^*\|_2$ between the current iterate μ^n and the LP optimum μ^* versus iteration number for Potts models on grids with $p \in \{100, 400, 900\}$ vertices, and SNR $= 1$. Note the superlinear rate of convergence.

7. Discussion

In this paper, we have developed distributed algorithms, based on the notion of proximal sequences, for solving graph-structured linear programming (LP) relaxations. Our methods respect the graph structure, and so can be scaled to large problems, and they exhibit a superlinear rate of convergence. We also developed rounding schemes that can be used to generate integral solutions along with a certificate of optimality. These optimality certificates allow the algorithm to be terminated in a finite number of iterations.

The structure of our algorithms naturally lends itself to incorporating additional constraints, both linear and other types of conic constraints. It would be interesting to develop an adaptive version of our algorithm, which selectively incorporated new constraints as necessary, and then used the same proximal schemes to minimize the new conic program.

Abstract

We propose a novel Bayesian multiple instance learning (MIL) algorithm. This algorithm automatically identifies the relevant feature subset, and utilizes inductive transfer when learning multiple (conceptually related) classifiers. Experimental results indicate that the proposed MIL method is more accurate than previous MIL algorithms and selects a much smaller set of useful features. Inductive transfer further improves the accuracy of the classifier as compared to learning each task individually.

1. Multiple Instance Learning

In a single instance learning scenario we are given a training set $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$ containing N instances, where $x_i \in \mathcal{X}$ is an instance (the feature vector) and $y_i \in \mathcal{Y} = \{0, 1\}$ is the corresponding known label. The task is to learn a classification function $f : \mathcal{X} \rightarrow \mathcal{Y}$.

In the *multiple instance learning* framework the training set consists of *bags*. A bag contains many instances. All the instances in a bag share the same bag-level label. A bag is labeled positive if it contains *at least* one positive instance. A negative bag means that *all* instances in the bag are negative. The goal is to learn a classification function that can predict the labels of unseen instances and/or bags.

MIL is a natural framework to model many real-life tasks like drug activity prediction (Dietterich et al., 1997), image retrieval (Andrews et al., 2002), face detection (Viola et al., 2006), scene classification, text categorization, etc and is often found to be superior than a conventional supervised learning approaches (Ray & Craven, 2005). The concept of MIL was first introduced by (Dietterich et al., 1997) in the context of drug activity prediction. (Maron & Lozano-Perez, 1998) proposed a framework called Diverse Density algorithm. Since then various variants of standard single instance learning algorithms like Boosting (Xin & Frank, 2004; Viola et al., 2006), SVMs (Andrews et al., 2002; Fung et al., 2007), Logistic Regression (Ray & Craven, 2005; Settles et al., 2008), nearest neighbor (Wang & Zucker, 2000) etc. have been modified to adapt to the MIL scenario.

Our motivation for this work comes from the area of computer aided diagnosis (CAD) (see section § 10)– where the task is to build a classifier to predict whether a suspicious region (instance) on a computed tomography (CT) scan is a pulmonary embolism/nodule/lesion or not. This was proposed as a MIL problem by (Fung et al., 2007) by recognizing the fact that all instances which are within a certain distance to a radiologist mark (ground truth) can be considered as a positive bag. A requirement is that run time of the classifier during testing be as small as possible. Hence we would like the final classifier to use *as few features as possible*.

In this paper we propose a novel multiple instance algorithm which performs *automatic feature selection* and *classifier design* jointly. In particular we start out with the well-known logistic regression as our classifier and demonstrate how it can be modified for the MIL framework (§ 3–6). We use the feature selection method originally proposed for the *relevance vector machine* (RVM) (Tipping, 2001) single-instance classifier, in a manner that is optimal for multiple-instance classification(§ 7). We extend the algorithm to handle multi-task learning in § 8.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

2. Novel Contributions

Our method differs from the substantial body of previous literature on MIL in the following crucial aspects.

a. **Baseline-model:** We use Logistic Regression as our baseline (single instance) classifier, similar to two previous papers. However, our model for combining the positive instances is quite different from the soft-max (Ray & Craven, 2005) or the averaging approach (Xin & Frank, 2004) used by others. We directly enforce the definition that at least one of the instances in a positive bag is positive.

b. **Feature selection:** Relying on the Bayesian automatic relevance determination paradigm, our learning algorithm selects the relevant subset of features that is most useful for accurate *multiple instance* classification. Experimental results demonstrate that the number of features chosen for optimizing the accuracy of multiple-instance classification *is much smaller* than that selected in a corresponding single instance learning algorithm. While MI Boost (Xin & Frank, 2004) also does feature selection, results indicate that our our approach is more accurate than MI Boost.

c. **Inductive transfer:** The proposed method is easily extended to statistically exploit information from other data sets while learning multiple related classifiers. This inductive-transfer approach results in substantial improvements in accuracy in real-life problems with limited training data. We are not aware of previous work which accomplishes inductive transfer in the context of multiple-instance classification.

3. Notation

We represent an instance as a feature vector $x \in \mathbb{R}^d$. A bag which contains K instances is denoted by boldface $\mathbf{x} = \{x_j \in \mathbb{R}^d\}_{j=1}^K$. The label of a bag is denoted by $y \in \{0, 1\}$.

Training Data The training data $\mathcal{D}$ consists of N bags $\mathcal{D} = \{\mathbf{x}_i, y_i\}_{i=1}^N$, where $\mathbf{x}_i = \{x_{ij} \in \mathbb{R}^d\}_{j=1}^{K_i}$ is a bag containing K_i instances that share the same label $y_i \in \{0, 1\}$.

Classifier We consider the family of linear discriminating functions: $\mathcal{F} = \{f_w\}$, where for any $x, w \in \mathbb{R}^d$, $f_w(x) = w^T x$. The final classifier can be written in the following form

$$y = \begin{cases} 1 & \text{if } w^T x > \theta \\ 0 & \text{if } w^T x < \theta \end{cases} . \qquad (1)$$

Ties are resolved by flipping a fair coin. The *threshold parameter* θ determines the operating point of the classifier. The ROC curve is obtained as θ is swept from $-\infty$ to ∞. A bag is labeled positive if at least one instance is positive and negative if all instances are negative. Learning a classifier implies choosing the weight vector w given the training data $\mathcal{D}$.

4. Logistic Generalized Linear Model

The posterior probability for the positive class is modeled as a *logistic sigmoid* acting on the linear classifier f_w, *i.e.*, $p(y = 1|x) = \sigma(w^\top x)$. The logistic sigmoid function is defined as $\sigma(z) = 1/(1 + e^{-z})$. This classification model is known as *logistic regression* in the statistics community. Also $p(y = 0|x) = 1 - p(y = 1|x) = 1 - \sigma(w^\top x)$.

4.1. Logistic Model for MIL

In the MIL framework we have the concept of bags– where all the examples in a bag share the same label. A positive bag means at least one example in the bag is positive. The probability that a bag contains at least one positive instance is one minus the probability that all of them are negative. Hence the posterior probability for the positive bag can be written as

$$p(y = 1|\mathbf{x}) = 1 - \prod_{j=1}^{K} \left[1 - \sigma(w^\top x_j)\right], \qquad (2)$$

where the bag $\mathbf{x} = \{x_j\}_{j=1}^K$ contains K examples.This model is sometimes referred to as the $noisy-OR$ and has been previously used by (Viola et al., 2006) in a boosting framework and (Maron & Lozano-Perez, 1998) in the Diverse Density algorithm. We use this model for Logistic Regression. A negative bag means that *all* examples in the bag are negative. Hence

$$p(y = 0|\mathbf{x}) = \prod_{j=1}^{K} \left[1 - \sigma(w^\top x_j)\right]. \qquad (3)$$

5. Maximum Likelihood Estimator

Given the training data $\mathcal{D}$ the maximum likelihood (ML) estimate for w is given by

$$\widehat{w}_{\text{ML}} = \arg\max_w p(\mathcal{D}/w) = \arg\max_w \left[\log p(\mathcal{D}/w)\right]. \quad (4)$$

Define $p_i = p(y_i = 1|\mathbf{x}_i) = 1 - \prod_{j=1}^{K_i} \left[1 - \sigma(w^\top x_{ij})\right]$– the probability that the i^{th} bag $\mathbf{x}_i$ is positive. Assuming that the training bags are independent the log-likelihood can be written as

$$\log p(\mathcal{D}/w) = \sum_{i=1}^{N} y_i \log p_i + (1 - y_i) \log(1 - p_i). \quad (5)$$

A similar likelihood was also maximized by (Viola et al., 2006) using the AnyBoost framework, which views boosting as gradient descent in function space.

6. The MAP Estimator

The ML solution in practice can exhibit severe overfitting especially for high-dimensional data. This can be addressed by using a prior on w.

Prior We will assume zero mean Gaussian prior ($\mathcal{N}(w|0, \mathbf{A}^{-1})$) on the weights w with inverse covariance matrix $\mathbf{A} = diag(\alpha_1 \dots \alpha_d)$ (also referred to as the *hyper-parameters*).

$$p(w) = (2\pi)^{-d/2}|\mathbf{A}^{-1}|^{-1/2}\exp\left(-\frac{w^\top \mathbf{A} w}{2}\right). \quad (6)$$

This encapsulates our prior belief that the individual weights in w are independent and close to zero with a variance parameter $1/\alpha_i$.

Posterior Once we observe the training data $\mathcal{D}$ we will update the prior to compute the posterior $p(w/\mathcal{D})$, which can be written as follows (using Bayes's rule)– $p(w/\mathcal{D}) = p(\mathcal{D}/w)p(w)/\int p(\mathcal{D}/w)p(w)dw$. This posterior can then be used to compute predictive distributions, which will typically involve high dimensional integrals. For computational efficiency we could use point estimates of w. In particular the *maximum a-posteriori* (MAP) estimate is given by

$$\widehat{w}_{\text{MAP}} = \arg\max_w \left[\log p(\mathcal{D}/w) + \log p(w)\right]. \quad (7)$$

Substituting for the log likelihood and the prior we have $\widehat{w}_{\text{MAP}} = \arg\max_w L(w)$, where

$$L(w) = \left[\sum_{i=1}^{N} y_i \log p_i + (1-y_i)\log(1-p_i)\right] - \frac{w^\top \mathbf{A} w}{2}. \quad (8)$$

Optimization Due to the non-linearity of the sigmoid we do not have a closed form solution and we have to use gradient based optimization methods. We use the Newton-Raphson update given by $w^{t+1} = w^t - \eta \mathbf{H}^{-1}\mathbf{g}$, where $\mathbf{g}$ is the gradient vector, $\mathbf{H}$ is the Hessian matrix, and η is the step length. The gradient is given by

$$\mathbf{g}(w) = \sum_{i=1}^{N}[y_i\beta_i - (1-y_i)]\sum_{j=1}^{K_i} x_{ij}\sigma(w^\top x_{ij}) - \mathbf{A}w, \quad (9)$$

where $\beta_i = \frac{1-p_i}{p_i}$. Note that $\beta_i = 1$ corresponds to the derivatives of the standard logistic regression updates. These term β_i can be thought of as the bag weight by which each instance weight gets modified. The Hessian matrix is given by

$$\mathbf{H}(w) = \sum_{i=1}^{N}[y_i\beta_i - (1-y_i)]\sum_{j=1}^{K_i} x_{ij}x_{ij}^T\sigma(w^\top x_{ij})\sigma(-w^\top x_{ij}) - \sum_{i=1}^{N} y_i\beta_i(\beta_i+1)\left[\sum_{j=1}^{K_i} x_{ij}\sigma(w^\top x_{ij})\right]\left[\sum_{j=1}^{K_i} x_{ij}\sigma(w^\top x_{ij})\right]^T - \mathbf{A}. \quad (10)$$

Note that the Hessian matrix depends on the class labels also–unlike in regular logistic regression.

7. Bayesian MIL: Feature Selection

We imposed a prior of the form $p(w) = \mathcal{N}(w|0, \mathbf{A}^{-1})$, parameterized by d hyper-parameters $\mathbf{A} = diag(\alpha_1 \dots \alpha_d)$. Clearly, as the precision $\alpha_k \to \infty$, *i.e*, the variance for w_k tends to zero (thus concentrating the prior sharply at zero). Hence, regardless of the evidence of the training data, the posterior for w_k will also be sharply concentrated on zero, thus that feature will not affect the classification result-hence, it is effectively removed out via feature selection. Therefore, the discrete optimization problem corresponding to feature selection (should each feature be included or not?), can be more easily solved via an easier continuous optimization over hyper-parameters . If one could maximize the marginal likelihood $p(\mathcal{D}|\mathbf{A})$ this would perform optimal feature selection. This approach is also known as the *type-II maximum likelihood* method in the Bayesian literature.

We choose the hyper-parameters to maximize the marginal likelihood.

$$\widehat{\mathbf{A}} = \arg\max_{\mathbf{A}} p(\mathcal{D}|\mathbf{A}) = \arg\max_{\mathbf{A}} \int p(\mathcal{D}|w)p(w|\mathbf{A})dw. \quad (11)$$

Since this integral is not easy to compute for our MIL model we use an approximation to the marginal likelihood via the Taylor series expansion. The marginal likelihood $p(\mathcal{D}|\mathbf{A})$ can be written as $p(\mathcal{D}|\mathbf{A}) = \int e^{\Psi(w)}dw$, where $\Psi(w) = \log p(\mathcal{D}|w) + \log p(w|\mathbf{A})$. Approximating Ψ using a second order Taylor series around $\widehat{w}_{\text{MAP}}$,

$$\Psi(w) \approx \Psi(\widehat{w}_{\text{MAP}}) + \frac{1}{2}(w-\widehat{w}_{\text{MAP}})\mathbf{H}(\widehat{w}_{\text{MAP}}, \mathbf{A})(w-\widehat{w}_{\text{MAP}})^\top. \quad (12)$$

Hence we have the following approximation to the

Input: $\{\mathbf{x}_i, y_i\}_{i=1}^N$, where $\mathbf{x}_i = \{x_{ij} \in \mathbb{R}^d\}_{j=1}^{K_i}$ is a bag containing K_i instances that share the same label $y_i \in \{0, 1\}$.

Output: A list of selected features and weight vector w for the linear classifier.

Initialize $\alpha_i = 1$ and $w_i = 0$ for $i = 1, \ldots, d$.
repeat
  If $\alpha_i > \tau$ remove feature w_i.
  MAP estimate using the selected features.
  repeat
    Compute the gradient vector $\mathbf{g}$. (Eq. 9)
    Compute the Hessian matrix $\mathbf{H}$. (Eq. 10)
    Determine η using a line search.
    Update $w \leftarrow w - \eta \mathbf{H}^{-1}\mathbf{g}$.
  until $\|\mathbf{g}\|/d < \epsilon_1$
  Update the hyper-parameters using $\alpha_i \leftarrow 1/(w_i^2 + \Sigma_{ii})$. (Eq. 17)
until $\max_i |\log \alpha_i^{curr} - \log \alpha_i^{prev}| < \epsilon_2$
In the experiments reported in this paper we use $\tau = 10^{12}$, $\epsilon_1 = 10^{-5}$, and $\epsilon_2 = 10^{-3}$.

Algorithm 1: The proposed algorithm

marginal likelihood

$$\begin{aligned} & p(\mathcal{D}|\mathbf{A}) \\ \approx\ & e^{\Psi(\widehat{w}_{\mathrm{MAP}})} \int e^{\frac{1}{2}(w-\widehat{w}_{\mathrm{MAP}})\mathbf{H}(\widehat{w}_{\mathrm{MAP}},\mathbf{A})(w-\widehat{w}_{\mathrm{MAP}})^\top} dw \\ \approx\ & p(\mathcal{D}|\widehat{w}_{\mathrm{MAP}}) p(\widehat{w}_{\mathrm{MAP}}|\mathbf{A})(2\pi)^{d/2} |-\mathbf{H}^{-1}(\widehat{w}_{\mathrm{MAP}}, \mathbf{A})|^{1/2} \end{aligned} \quad (13)$$

Using the prior $p(w|\mathbf{A}) = \mathcal{N}(w|0, \mathbf{A}^{-1})$, the log marginal likelihood can be written as

$$\begin{aligned} \log p(\mathcal{D}|\mathbf{A}) \ &\approx\ \log p(\mathcal{D}|\widehat{w}_{\mathrm{MAP}}) - \frac{1}{2}\widehat{w}_{\mathrm{MAP}}^\top \mathbf{A} \widehat{w}_{\mathrm{MAP}} \\ &+\ \frac{1}{2}\log|\mathbf{A}| - \frac{1}{2}\log|-\mathbf{H}(\widehat{w}_{\mathrm{MAP}}, \mathbf{A})|. \end{aligned} \quad (14)$$

The hyper-parameters $\mathbf{A}$ are found by maximizing this approximation to the log marginal likelihood. There is no closed-form solution for this. Hence we use a iterative re-estimation method by setting the first derivative to zero. The derivative can be written as

$$\begin{aligned} \frac{\partial \log p(\mathcal{D}|\mathbf{A})}{\partial \mathbf{A}} \ &=\ -\frac{1}{2}\widehat{w}_{\mathrm{MAP}}\widehat{w}_{\mathrm{MAP}}^\top + \frac{1}{2}\mathbf{A}^{-1} \\ &-\ \frac{1}{2}\mathbf{H}^{-1}(\widehat{w}_{\mathrm{MAP}}, \mathbf{A}). \end{aligned} \quad (15)$$

Since $\mathbf{A} = diag(\alpha_1 \ldots \alpha_d)$, we can further simplify

$$\frac{\partial \log p(\mathcal{D}|\mathbf{A})}{\partial \alpha_i} = -\frac{1}{2}\widehat{w}_i^2 + \frac{1}{2\alpha_i} - \frac{1}{2}\Sigma_{ii}, \quad (16)$$

where Σ_{ii} is the i^{th} diagonal element of $\mathbf{H}^{-1}(\widehat{w}_{\mathrm{MAP}}, \mathbf{A})$. Assuming Σ_{ii} does not depend on $\mathbf{A}$ a simple update rule for the hyper-parameters can be written by equating the first derivative to zero.

$$\alpha_i^{\mathrm{new}} = \frac{1}{w_i^2 + \Sigma_{ii}}. \quad (17)$$

The final algorithm has two levels of iterations (see Algorithm 1): in an outer loop we update the hyper-parameters α_i and in an inner loop we find the MAP estimator $\widehat{w}_{\mathrm{MAP}}$ given the hyper-parameters. After a few iterations we find that the hyper-parameters–the inverse variances of the priors–for several features tend to infinity causing numerical problems in implementation. This means that those $w_i \to 0$ we can simply remove those irrelevant features from further consideration in future iterations. The proposed algorithm with feature selection can be considered as the extension of the Relevance Vector Machine (RVM) (Tipping, 2001) to multiple-instance learning framework.

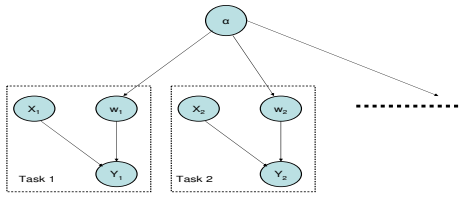

Figure 1. In multi-task learning tasks share the same prior.

8. Multi-task Learning

We are often faced with a shortage of training data for learning classifiers for a task. However we may have additional data for closely related, albeit non-identical tasks. For example in our CAD applications where we have to identify early stage cancers from CT scans, our data set includes images from CT scanners with two different reconstruction kernels–B50 and B60.

While training the classifier we could ignore this information and pool all the data together. However, there are some systematic differences that make the feature distributions slightly different. Alternatively, we could train a separate classifier for each kernel, but a large part of our data set is from one particular kernel (B60) and we have a smaller data set for the other (B50).

Here, we discuss another approach–*multi-task learning* (Caruana, 1997)– that tries to estimate models w^j for several classification tasks j in a joint manner. Multi-task learning can compensate for small sample size by using additional samples from related tasks, and exchanging statistical information between tasks. In a hierarchical Bayesian approach, the clas-

Dataset	d	positive		negative	
		examples	bags	examples	bags
Musk1	166	207	47	269	45
Musk2	166	1017	39	5581	63
Elephant	230	762	100	629	100
Tiger	230	544	100	676	100

sifiers share a common prior $p(w^j|\mathbf{A})$ (See Figure 1). A separate classifier is trained for each task. However the optimal hyper-parameters of the shared prior are estimated from all the data sets simultaneously during the training. The update equation becomes (in place of Eq. 17): $\alpha_i^{\text{new}} = 1/\sum_{\text{task}j}(\widehat{w}_i^j)^2 + \Sigma_{ii}^j$.

9. Experimental Results

9.1. Datasets

Experiments were performed on four common benchmark data sets from the MIL literature (see Table 1).

Musk1 and Musk2 (Asuncion & Newman, 2007) The task is to predict whether a new drug molecule will bind to a target protein. However each molecule (bag) can have many different low energy shapes (instances) of which only one can actually bind with the target.

Elephant and Tiger The task is to search a repository to find images that contain objects of interest. An image is represented as a bag. An instance in a bag corresponds to a segment in the image; the object of interest is contained in at least one segment.

9.2. Competing Algorithms

Various learning algorithms have been adapted to the multiple learning scenario. We compare our proposed algorithm with a variant of Boosting, SVM, and Logistic Regression. Specifically we perform our experimental comparison for the following algorithms.

MI RVM The proposed multiple-instance algorithm with feature selection. This is completely automatic and does not require tuning any parameters.

RVM The proposed algorithm without multiple instance learning. This is same as MI RVM but every example is assigned to a unique bag.

MI The proposed multiple-instance algorithm without feature selection. We set $\mathbf{A} = \lambda\mathbf{I}$, where $\mathbf{I}$ is the identity matrix and λ is chosen by five-fold cross-validation.

MI Boost (Xin & Frank, 2004) This is a variant of the AdaBoost algorithm adapted for the multiple instance learning scenario. We boosted for 50-100 rounds.

Table 2. The AUC for different algorithms and datasets.

Set	MIRVM	RVM	MIBoost	MILR	MISVM	MI
Musk1	0.942	**0.951**	0.899	0.846	0.899	0.922
Musk2	**0.987**	0.985	0.964	0.795	-	0.982
Elephant	0.962	**0.979**	0.828	0.814	0.959	0.953
Tiger	**0.980**	0.970	0.890	0.890	0.945	0.956

Table 3. The average number of features selected per fold by different algorithms.

Dataset	Number of features	selected by RVM	selected by MI RVM	selected by MI Boost
Musk1	166	39	**14**	33
Musk2	166	90	**17**	32
Elephant	230	42	**16**	33
Tiger	230	56	**19**	37

MI SVM (Andrews et al., 2002) This is a bag-level SVM variant for MIL. We used the implementation publicly available at (Yang, 2006). We used a linear kernel and the regularization parameters was chosen by 5-fold cross-validation.

MI LR (Settles et al., 2008; Ray & Craven, 2005) This is a variant of Logistic Regression which uses the soft-max function to combine posterior probabilities over the instances of a bag. We used $\alpha = 3$ in the soft-max function. Non-linear conjugate gradient with tolerance set at 10^{-3} was used as the optimization routine.

Of all the above algorithms only our proposed method and the boosting one does automatic feature selection. We are not aware of any other multiple-instance algorithms which does automatic feature selection.

9.3. Evaluation Procedure

The results are shown for a 10-fold stratified cross-validation. The folds are split at the positive bag level, so that examples in the same positive bag will not be split. We plot the Receiver Operating Characteristics (ROC) curve for various algorithms (see Figure 2). The ROC curve is a plot of False Positive Rate (FPR) vs True Positive Rate (TPR) as the decision threshold of the classifier θ is varied from ∞ to $-\infty$. The TPR is computed on a bag level–*i.e.*, a bag is predicted as positive if at least one on the instances in classified as positive. The ROC curve is plotted by pooling the prediction of the algorithm across all folds as in (Ray & Craven, 2005). We also report the area under the ROC curve (AUC) in Table 2.

9.4. Results

Comparison with other methods. From Figure 2 and Table 2 we see that among other MIL algorithms the ROC for the proposed method clearly dominates

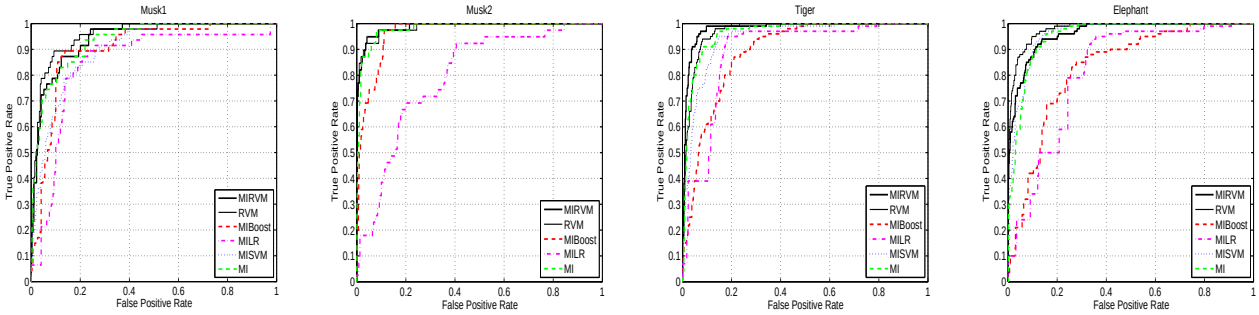

Figure 2. The ROC Curves for the different data sets and the different algorithms.

the other methods. However it is interesting to note that plain RVM is better than MI RVM for Musk 1 and Elephant data sets. This confirms the surprising observation in (Ray & Craven, 2005) that for some MIL benchmarks standard supervised learning algorithm may be more accurate than MIL algorithms.

Number of features selected. Table 3 compares the number of features selected by MI RVM, RVM, and the MI Boost algorithm. It can be seen that the proposed MI RVM algorithm selects the least number of features. Selecting features in a multiple instance setting reduces the number of features selected by half.

Does feature selection help? From Table 2 we see that the AUC with feature selection is higher than that without feature selection. Thus we are able to achieve better performance and at the same time use a smaller set of features.

Runtime The proposed algorithm and the MI Boost are orders of magnitude faster than other MIL methods. As a result MI SVM and MI LR could not be run on our CAD experiments described in the next section. Also the proposed method has no free parameters to tune. The runtime of our algorithm scales as $\mathcal{O}(d^3)$ with the number of features. This is because we need to compute the inverse of the $d \times d$ Hessian matrix.

10. Computer Aided Diagnosis

In computer aided diagnosis (CAD) the goal is to detect potentially malignant nodules, tumors, emboli, or lesions in medical images like computed tomography (CT), X-ray, MRI etc. A CAD system aids the radiologist by marking the location of likely anomaly on a medical image. Figure 3 shows two pulmonary emboli (PE) in a CT scan. PE (blood clots in the lung), is a potentially life-threatening condition. An early and accurate diagnosis is the key to survival. Computed tomography angiography (CTA) has emerged as an accurate diagnostic tool.

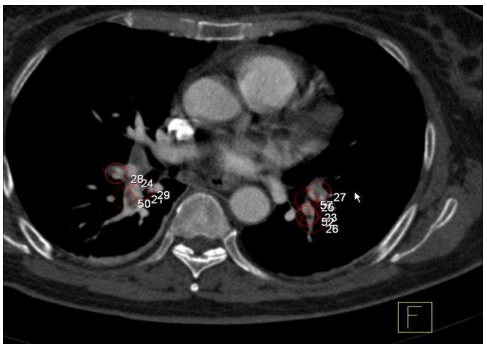

Figure 3. Sample pulmonary emboli in a Lung CT scan along with the candidates which point to it.

Most CAD systems consist of the following three steps–(1) *Candidate generation*–this step identifies potentially unhealthy regions of interest. While this step can detect most of the anomalies, the number of false positives will be extremely high (60-100 false positives/ patient). (2) *Feature computation*–computation of a set of descriptive morphological features for each of the candidates. (3) *Classification*–labeling of each candidate as a nodule or not by a classifier. The goal of the classifier is to reduce the number of false positives without appreciable decrease in the sensitivity.

In order to train a classifier, a set of CT scans is collected from hospitals. These scans are then read by expert radiologists who mark the pulmonary emboli locations–this constitutes our ground truth for learning. The candidate generation step generates a lot of potential candidates. Any candidate which is close to the radiologist mark (for example within a certain distance) is considered a positive example for training and the rest of the candidates are considered as negative examples. Based on a set of features computed for these candidates we intend to train a classifier.

Table 4. Datasets used in our PE CAD MIL experiments.

Dataset	Features	positive		negative
		examples	bags	examples
Training	134	514	312	4619
Validation	134	305	214	3246

10.1. Multiple Instance Learning for CAD

The candidate generation step very often produces a lot of candidates which are spatially close to each other (See Figure 3 for two PE appearing in a CT scan). All these candidates point to the same ground truth and can considered to share the same label for training. A single instance classifier can be trained using the labeled candidates. In this work we use the multiple instance learning algorithm by recognizing the fact that all candidates which point to the same radiologist mark can be considered as a positive bag (Fung et al., 2007). There is another important reason why MIL is a natural framework for CAD. The candidate generation algorithm produces a lot of spatially close candidates. Even if one of these is highlighted to the radiologist and other adjacent or overlapping candidates are missed, the underlying embolism would still have been detected. Hence while evaluating the performance of CAD systems we use the bag level sensitivity, *i.e.*, a classifier is successful in detecting an embolism if at least one of the candidates pointing to it is predicted as a PE. MIL naturally lends itself to model our desired accuracy measure during training itself.

Another important requirement is that run time of the classifier during testing should be as small as possible. The candidate generation step generally produces thousands of candidates for a CT scan. Computing all the features can be very time-consuming. Hence it is imperative that the final classifier uses as few features as possible without any decrease in the sensitivity. The proposed classifier automatically selects features for multiple-instance classification.

10.2. Experiments

Table 4 summarizes the PE CAD data sets we use in our experiments. Note that unlike the previous four data sets we do not have negative bags. Every negative example is considered a negative bag. The classifier is trained on the training set and tested on a separate validation set. Since we are interested in the number of False Positives per volume (patient) we plot Free response ROC (FROC) curves for the validation set (see Figure 4). MI RVM gives a substantial improvement over the single instance RVM approach and also the MI Boost method. The MI SVM and MI LR could not be run for the large CAD data set. MI RVM algorithm selected 21 features in contrast to the 34 features selected by the single instance RVM algorithm

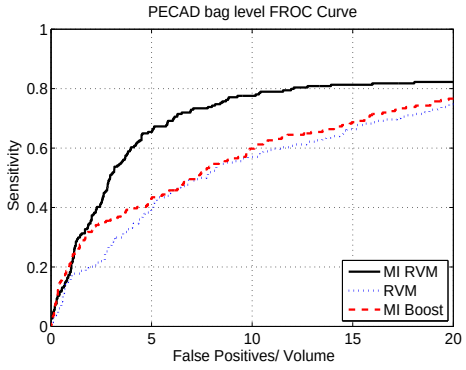

Figure 4. The bag level FROC curve for the PECAD validation set.

10.3. Multi-task Learning Experiments

Lung cancer is a leading cause of cancer related death in western countries. However early detection can substantially improve survival. Automatic CAD systems can be developed to identify suspicious regions such as solid nodules or ground-glass opacities (GGO) in CT scans of the lung. A solid nodule is defined as an area of increased opacity more than 5mm in diameter which completely obscures underlying vascular marking. Ground-glass opacity(GGO) is defined as an area of a slight, homogenous increase in density, which did not obscure underlying bronchial and vascular markings. Figure 5 shows an example nodule and GGO.

Detecting nodules and GGOs are two closely related tasks although each has its own respective characteristics. Hence multi-task learning is likely to be beneficial, even when building a specific model for each task. To train such a system we used 15 CT scans which included GGOs and 23 CT scans that included nodules. The model accuracy was validated on a held out set of 86 CT scans that included nodules. Figure 6 compares the FROC curves for nodule detection system designed in two different ways. (1) Single task learning: the classifier was learnt only using nodule data. (2) Multi-task learning: the classifier was learnt using nodule data and GGO data. As Figure 6 shows, inductive transfer using the proposed scheme the improves accuracy of the multiple instance learning system, when we have a limited amount of training data.

11. Conclusion

In this paper we proposed a novel MIL algorithm that automatically selects the features relevant for *multi-*

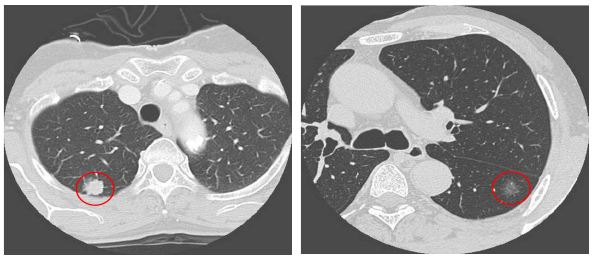

Figure 5. Lung CT image showing a sample (a)nodule and (b) GGO. Figure reprinted from (Suzuki et al., 2006).

ple instance classification. The proposed algorithm is more accurate than other competing MIL methods, both on benchmark data sets and on real life CAD problems. Our experiments also validate the previous observation of (Ray & Craven, 2005) that on some multiple instance benchmarks the single instance classifier is slightly more accurate. For all domains, the number of features selected by our algorithm is much smaller than that for the corresponding single instance classifier. Inductive transfer improves accuracy in data poor CAD applications.

Acknowledgements

We would like to thank Sangmin Park, Vikram Anand, Anna Jerebko, and Marcos Salgonicoff for help with the CAD data sets. We would also like to thank the reviewers for their suggestions which helped to improve the overall quality of the paper.

Abstract

Kernel-based Bayesian methods for Reinforcement Learning (RL) such as Gaussian Process Temporal Difference (GPTD) are particularly promising because they rigorously treat uncertainty in the value function and make it easy to specify prior knowledge. However, the choice of prior distribution significantly affects the empirical performance of the learning agent, and little work has been done extending existing methods for prior model selection to the online setting. This paper develops Replacing-Kernel RL, an online model selection method for GPTD using sequential Monte-Carlo methods. Replacing-Kernel RL is compared to standard GPTD and tile-coding on several RL domains, and is shown to yield significantly better asymptotic performance for many different kernel families. Furthermore, the resulting kernels capture an intuitively useful notion of prior state covariance that may nevertheless be difficult to capture manually.

1. Introduction

Bayesian methods are a natural fit for Reinforcement Learning (RL) because they represent prior knowledge compactly and allow for rigorous treatment of value function uncertainty. Modeling such uncertainty is important because it offers a principled solution for balancing exploration and exploitation in the environment. One particularly elegant Bayesian RL formulation is Gaussian Process Temporal Difference (GPTD) (Engel et al., 2005). GPTD is an efficient adaptation of Gaussian processes (GPs) to the problem of online value-function estimation. In GPs, prior knowledge in the form of value covariance across states is represented compactly by a Mercer kernel (Rasmussen & Williams, 2006), offering a conceptually simple method for biasing learning.

An important open question for Bayesian RL is how to perform model selection efficiently and online. In GPTD, model selection determines the particular form of the prior covariance function and the settings of any hyperparameters. This paper contributes towards answering this question in two ways: (1) It demonstrates empirically the importance of model selection in Bayesian RL; and (2) it outlines *Replacing-Kernel Reinforcement Learning* (RKRL), a simple and effective sequential Monte-Carlo procedure for selecting the model online. RKRL not only improves learning in several domains, but does so in a way that cannot be matched by any choice of standard kernels.

Although conceptually similar to methods combining evolutionary algorithms and RL (Whiteson & Stone, 2006), RKRL is novel for two reasons: (1) The sequential Monte-Carlo technique employed is simpler and admits a clear *empirical Bayesian* interpretation (Bishop, 2006), (2) Since GPs are nonparametric, it is possible to replace kernels online during learning without discarding any previously acquired knowledge, simply by maintaining the dictionary of saved training examples between kernel swaps. This online replacing procedure significantly improves performance over previous methods, because learning does not need to start from scratch for new kernels.

This paper is divided into seven main sections: Section 2 introduces GPTD, Section 3 describes RKRL, Section 4 details the experimental setup using Mountain Car, Ship Steering and Capture Go as example domains, and the last three sections give results, future work and conclusions.

2. Gaussian Process Reinforcement Learning

In RL domains with large or infinite state spaces, function approximation becomes necessary as it is impractical or impossible to store a table of all state values (Sutton & Barto, 1998). Gaussian Processes (GPs) have emerged as a principled method for solving regression problems in Machine Learning (Rasmussen & Williams, 2006), and have recently been extended to performing function approxima-

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

tion in RL as well (Engel et al., 2005). In this section, we briefly review GPs and their application to temporal difference learning.

GPs are a class of statistical generative models for Bayesian nonparametric inference. Instead of relying on a fixed functional form as in parametric model, GPs are defined directly in some (infinite-dimensional) function space (Rasmussen & Williams, 2006). Specifically, an indexed collection of random variables $V : \mathcal{X} \rightarrow \Re$ over a common probability space is a GP if the distribution of any finite subset of V is Gaussian. Gaussian processes are completely specified by prior mean and covariance functions. In this paper, the mean function is assumed to be identically zero and the prior covariance function is specified as a Mercer kernel $k(\cdot, \cdot)$. Mechanistically, a GP is composed of the set of training data and a prior covariance function (kernel) that defines how to interpolate between those points.

Following the formulation of (Engel, 2005), consider a statistical generative model of the form

$$R(\mathbf{x}) = \mathbf{H}V(\mathbf{x}) + N(\mathbf{x}), \tag{1}$$

where V is the unknown function to be estimated, N is a noise model, $\mathbf{H}$ is a linear transformation, and R is the observed regression function. Given a set of data $\mathcal{D} = \{(\mathbf{x}_i, y_i)\}_{i=0}^{t}$, the model reduces to a system of linear equations $R_t = \mathbf{H}_t V_t + N_t$, where $R_t = (R(\mathbf{x}_0), \ldots, R(\mathbf{x}_t))^\top$, $V_t = (V(\mathbf{x}_0), \ldots, V(\mathbf{x}_t))^\top$, and $N_t = (N(\mathbf{x}_0), \ldots, N(\mathbf{x}_t))^\top$.

Assuming that $V \sim \mathcal{N}(\mathbf{0}, \mathbf{K}_t)$ is a zero-mean GP with $[\mathbf{K}_t]_{i,j} \stackrel{\text{def}}{=} k(\mathbf{x}_i, \mathbf{x}_j)$ for $\mathbf{x}_i, \mathbf{x}_j \in \mathcal{D}$ and $N \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma}_t)$, then the Gauss-Markov theorem gives the posterior distribution of V conditional on the observed R:

$$\hat{V}_t(\mathbf{x}) = \mathbf{k}_t(\mathbf{x})^\top \boldsymbol{\alpha}_t, \tag{2}$$

$$P_t(\mathbf{x}) = k(\mathbf{x}, \mathbf{x}) - \mathbf{k}_t(\mathbf{x})^\top \mathbf{C}_t \mathbf{k}_t(\mathbf{x}), \tag{3}$$

where

$$\boldsymbol{\alpha}_t = \mathbf{H}_t^\top (\mathbf{H}_t \mathbf{K}_t \mathbf{H}_t^\top + \mathbf{\Sigma})^{-1} \mathbf{r}_{t-1},$$

$$\mathbf{C}_t = \mathbf{H}_t^\top (\mathbf{H}_t \mathbf{K}_t \mathbf{H}_t^\top + \mathbf{\Sigma})^{-1} \mathbf{H}_t,$$

and $\mathbf{k}_t(\mathbf{x}) \stackrel{\text{def}}{=} (k(\mathbf{x}, \mathbf{x}_1), \ldots, k(\mathbf{x}, \mathbf{x}_t))^\top$. This closed-form posterior can be used to calculate the predicted value of V at some new test point $\mathbf{x}^*$. In RL, the sequence of observed reward values are assumed to be related by some (possibly stochastic) environment dynamics that are captured through the matrix $\mathbf{H}$.

In order to adapt GPs to RL, the standard Markov Decision Process (MDP) framework needs to first be formalized as follows. Let $\mathcal{X}$ and $\mathcal{U}$ be the state and action spaces, respectively. Define $R : \mathcal{X} \rightarrow \Re$ to be the reward function and let $p : \mathcal{X} \times \mathcal{U} \times \mathcal{X} \rightarrow [0, 1]$ be the state transition probabilities. A policy $\mu : \mathcal{X} \times \mathcal{U} \rightarrow [0, 1]$ is a mapping from states to action selection probabilities. The *discounted return* for a state $\mathbf{x}$ under policy μ is defined as

$$D(\mathbf{x}) = \sum_{i=0}^{\infty} \gamma^i R(\mathbf{x}_i) | \mathbf{x}_0 = \mathbf{x},$$

where $\mathbf{x}_{i+1} \sim p^\mu(\cdot|\mathbf{x}_i)$, the policy-dependent state transition probability distribution, and $\gamma \in [0, 1]$ is the discount factor. The goal of RL is to compute a *value function* that estimates the discounted reward for each state under a policy μ, $V(\mathbf{x}) = \mathbf{E}_\mu[D(\mathbf{x})]$.

GPs can be used to model the latent value function given a sequence of observed rewards and an appropriate noise model. Reward is related to value by

$$R(\mathbf{x}) = V(\mathbf{x}) - \gamma V(\mathbf{x}') + N(\mathbf{x}, \mathbf{x}'),$$

where $\mathbf{x}' \sim p^\mu(\cdot|\mathbf{x})$. Extending this model temporally to a series of states $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_t$ yields the system of equations $R_{t-1} = \mathbf{H}_t V_t + N_t$, where R and V are defined as before, and

$$N_t = (N(\mathbf{x}_0, \mathbf{x}_1), \ldots, N(\mathbf{x}_{t-1}, \mathbf{x}_t))^\top,$$

$$\mathbf{H}_t = \begin{bmatrix} 1 & -\gamma & 0 & \ldots & 0 \\ 0 & 1 & -\gamma & \ldots & 0 \\ \vdots & & & & \vdots \\ 0 & 0 & \ldots & 1 & -\gamma \end{bmatrix}$$

and $N_t \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma}_t)$. If the environment dynamics are assumed to be deterministic, the covariance of the state-dependent noise can be modeled as $\mathbf{\Sigma}_t = \sigma^2 \mathbf{I}$. For stochastic environments, the noise model $\mathbf{\Sigma}_t = \sigma^2 \mathbf{H}_{t+1} \mathbf{H}_{t+1}^\top$ is more suitable. See (Engel, 2005) for a complete derivation for these models.

Given $\mathbf{H}_t$, $\mathbf{\Sigma}_t$, and a sequence of states and reward values, the posterior moments $\hat{V}_t$ and P_t can be computed to yield value function estimates. Thus GPs fit naturally into the RL framework: Learning is straightforward and does not require setting unintuitive parameters such as α or λ; prior knowledge of the problem can be built in through the covariance function; the full distribution of the posterior is available, making it possible to select actions in more compelling ways, e.g. via interval estimation. Furthermore, the value estimator $\hat{V}_t$ and covariance P_t can be computed incrementally online as each new state action pair is sampled, without having to invert a $t \times t$ matrix at each step. For details of this procedure, see (Engel et al., 2005).

One issue with using GPs for RL is that the size of $\mathbf{K}_t$, $\mathbf{k}(\cdot)$, $\mathbf{H}_t$ and $\mathbf{r}_t$ each grow linearly with the number of states visited, yielding a computational complexity of $O(|\mathcal{D}|^2)$ for each step. Since it is not practical to remember every single experience in online settings, the GP dictionary size must

be limited in some way. To this end, Engel et al. derive a *kernel sparsification* procedure based on an approximate linear dependence (ALD) test. As the number of observed training examples tends to infinity, the number of examples that need to be saved tends to zero (Engel et al., 2005). A matrix $\mathbf{A}_t$ contains approximation coefficients for the ALD test and a parameter ν controls how "novel" a particular training example must be before it is remembered by the GP, making it possible to tune how compact and computationally efficient the value function representation is.

Finally, note that GPTD can be extended to the case where no environment model is available, simply by defining the covariance function over state-action pairs $k(\mathbf{x}, \mathbf{u}, \mathbf{x}', \mathbf{u}')$. This procedure will be termed GP-SARSA in this paper.

GPTD has been shown to be successful, but in practice performance relies on a good choice of kernel. The next section will focus on a particular online method for performing such kernel selection.

3. Online Model Selection

A common requirement in RL is that learning take place *online*, e.g. the learner must maximize total reward accrued. However, traditional model selection techniques applied to GPs, such as cross-validation, or Bayesian Model Averaging, are not designed to address this constraint. The main contribution of this paper is to introduce *Replacing-Kernel Reinforcement Learning* (RKRL), an online procedure for model selection in RL. In section 3.1 an online sequential Monte-Carlo method developed and used to implement RKRL, as described in section 3.2.

3.1. Sequential Monte-Carlo Methods

Given a set of kernels $\{k_{\boldsymbol{\theta}}(\cdot,\cdot)|\boldsymbol{\theta} \in \mathcal{M}\}$ parameterized by a random variable $\boldsymbol{\theta}$ and a prior $p(\boldsymbol{\theta})$ over these parameterizations, a fully Bayesian approach to learning involves integrating over all possible settings of $\boldsymbol{\theta}$, yielding the posterior distribution

$$p(R|\mathcal{D}) = \iint p(R|V, \mathcal{D}, \boldsymbol{\theta}) p(V|\mathcal{D}, \boldsymbol{\theta}) p(\boldsymbol{\theta}) dV d\boldsymbol{\theta}.$$

The integration over V given $\boldsymbol{\theta}$ is carried out implicitly when using GPs, however, the remaining integral over $\boldsymbol{\theta}$ is generally intractable for all but the most simple cases. Instead of integrating over all possible model settings $\boldsymbol{\theta}$, we can use the data distribution $\mathcal{D}$ to infer reasonable settings for $\boldsymbol{\theta}$ via $p(\boldsymbol{\theta}|\mathcal{D})$. Such *evidence approximation* can is more computationally efficient and is an example of an empirical Bayes approach, where likelihood information is used to guide prior selection (Bishop, 2006).

Monte-Carlo methods can be used to sample from $p(\boldsymbol{\theta}|\mathcal{D})$, however, such methods assume that this distribution is stationary (Bishop, 2006). In the RL case, stationarity implies that when evaluating $\boldsymbol{\theta}$, previous data acquired while evaluating $\boldsymbol{\theta}'$ cannot be used. To avoid this inefficiency, we instead employ a *sequential* Monte-Carlo (SMC) method adapted from (Gordon et al., 1993) that relaxes the stationarity assumption.

Algorithm 1 Sequential Monte Carlo

Parameters: n, μ, τ, Λ

1: Draw $\{\boldsymbol{\theta}_i^{(0)}\}_{i=1}^n \sim p(\boldsymbol{\theta})$
2: **for** $t = 0, 1, \ldots$ **do**
3: Calculate $\{w_i^{(t)}\}_{i=1}^n$ from equation 4.
4: Draw $\{\tilde{\boldsymbol{\theta}}_i^{(t+1)}\}_{i=1}^n$ by resampling $\{(\boldsymbol{\theta}_i^{(t)}, w_i^{(t)})\}_{i=1}^n$.
5: $\boldsymbol{\theta}_i^{(t+1)} \leftarrow \tilde{\boldsymbol{\theta}}_i^{(t+1)} + (c_0\phi_0, \ldots, c_k\phi_k)^\top$ where $c_k \sim$ Bernoulli(μ) and $\phi_k \sim \mathcal{N}(0,1)$.
6: **end for**

SMC approximates the posterior distribution $p(\boldsymbol{\theta}|\mathcal{D})$ at time t empirically via a set of n samples and weights $\{(\boldsymbol{\theta}_i^{(t)}, w_i^{(t)})\}_{i=1}^n$ where

$$w_i \stackrel{\text{def}}{=} \frac{p(\mathcal{D}|\boldsymbol{\theta}_i^{(t)}) p(\boldsymbol{\theta}_i^{(t)})}{\sum_m p(\mathcal{D}|\boldsymbol{\theta}_m^{(t)}) p(\boldsymbol{\theta}_m^{(t)})}, \tag{4}$$

where $p(\mathcal{D}|\boldsymbol{\theta}_i^{(t)})$ is the likelihood of $\boldsymbol{\theta}_i^{(t)}$ and $p(\boldsymbol{\theta}_i^{(t)})$ is the prior. Inference proceeds sequentially with samples for time $t+1$ drawn from the empirical distribution

$$p(\boldsymbol{\theta}^{(t+1)}|\mathcal{D}) = \sum_l w_l^{(t)} p(\boldsymbol{\theta}^{(t+1)}|\boldsymbol{\theta}_l^{(t)}), \tag{5}$$

where $p(\boldsymbol{\theta}^{(t+1)}|\boldsymbol{\theta}^{(t)})$ is the *transition kernel*, defining how the hyperparameter space should be explored. In this paper, the prior over models $p(\boldsymbol{\theta})$ is the uniform distribution over $[0, 1]$ for each of the kernel hyperparameters (listed in table 1) and the transition kernel $p(\boldsymbol{\theta}^{(t+1)}|\boldsymbol{\theta}^{(t)})$ is defined mechanistically as $\boldsymbol{\theta}^{(t+1)} \leftarrow \tilde{\boldsymbol{\theta}}^{(t+1)} + (c_0\phi_0, \ldots, c_k\phi_k)^\top$ where $c_k \sim$ Bernoulli(μ) and $\phi_k \sim \mathcal{N}(0,1)$. Pseudocode for this procedure is given in algorithm 1.

3.2. Replacing-Kernel Reinforcement Learning

In Replacing-Kernel Reinforcement Learning (RKRL), SMC is used to select good kernel hyperparameter settings. Rather than calculating the true model likelihood $p(\mathcal{D}|\boldsymbol{\theta}_i)$ in equation 4, RKRL instead weights models based on their relative *predictive likelihood*, $\tilde{p}(\mathcal{D}|\boldsymbol{\theta}_i)$, where

$$\log \tilde{p}(\mathcal{D}|\boldsymbol{\theta}_i) \stackrel{\text{def}}{=} \tau^{-1} \sum_t r_t,$$

and $(r_0, r_1, \ldots)$ is the sequence of rewards obtained by evaluating the hyperparameter setting $\boldsymbol{\theta}_i$ for Λ episodes.

Table 1. Basic kernel functions and the corresponding extended parameterizations.

KERNEL	BASIC	EXTENDED
NORM	$k(\mathbf{x},\mathbf{x}') = 1 - \frac{\|\|\mathbf{x}-\mathbf{x}'\|\|^2}{\alpha}$	$k(\mathbf{x},\mathbf{x}') = 1 - \sum_i w_i(x_i - x_i')^2$
GAUSSIAN	$k(\mathbf{x},\mathbf{x}') = \exp\left[\frac{-\|\|\mathbf{x}-\mathbf{x}'\|\|^2}{\sigma^2}\right]$	$k(\mathbf{x},\mathbf{x}') = \exp\left[-\sum_i w_i(x_i - x_i')^2\right]$
POLYNOMIAL	$k(\mathbf{x},\mathbf{x}') = (\langle \mathbf{x},\mathbf{x}'\rangle + 1)^d$	$k(\mathbf{x},\mathbf{x}') = (\sum_i w_i x_i x_i' + 1)^d$
TANH NORM	$k(\mathbf{x},\mathbf{x}') = \tanh(v\|\|\mathbf{x}-\mathbf{x}'\|\|^2 - c)$	$k(\mathbf{x},\mathbf{x}') = \tanh(\sum_i w_i(x_i - x_i')^2 - 1)$
TANH DOT	$k(\mathbf{x},\mathbf{x}') = \tanh(v\langle \mathbf{x},\mathbf{x}'\rangle - c)$	$k(\mathbf{x},\mathbf{x}') = \tanh(\sum_i w_i x_i x_i' - 1)$

The parameter τ is introduced to control how strongly model search should focus on hyperparameter settings that yield high reward. Maximizing predictive ability directly is preferable as it is more closely related to the goal of learning than maximizing the fit to the observed data. In tabular methods these two approaches indeed coincide in the limit of large data, however when using function approximation, they may differ.

When using GPTD, the current value function estimate is formed from the combination of the kernel parameterization $\boldsymbol{\theta}$ determining the prior covariance function and the dictionary $\tilde{\mathcal{D}} \subseteq \mathcal{D}$ gathered incrementally from observing state transitions. In this paper we consider two variants of RKRL: Standard RKRL and *Experience-Preserving* RKRL (EP-RKRL) that differ based on their treatment of the saved experience $\tilde{\mathcal{D}}$. In Standard RKRL, $\tilde{\mathcal{D}}$ is discarded at the start of each new kernel evaluation (making $p(\boldsymbol{\theta}|\mathcal{D})$ stationary). In contrast, in EP-RKRL each kernel parameterization sample $\boldsymbol{\theta}^{(t)}$ inherits $\tilde{\mathcal{D}}$[1] from the sample $\boldsymbol{\theta}^{(t-1)}$ that generated it in equation 5.

RKRL naturally spends more time evaluating hyperparameter settings that correspond to areas with high predictive likelihood, i.e. maximizes online reward. Each sampling step increases information about the predictive likelihood in the sample (exploitation), while sampling from the transition kernel reduces such information (exploration).

4. Experimental Setup

Standard RKRL and EP-RKRL are compared against GP-SARSA on three domains. This section gives the parameter settings, kernel classes and domains used.

4.1. Parameters

In all experiments, the TD discount factor was fixed at $\gamma = 1.0$ and ϵ-greedy action selection was employed with $\epsilon = 0.01$. The GP-SARSA parameters for prior noise variance (σ) and dictionary sparsity (ν) were $\sigma = 1.0$ and $\nu = 0.001$. For each RKRL evaluation, GP-SARSA is run for Λ episodes using the specified kernel parameterization. The RKRL parameters were set to $n = 25$, $\mu = 0.01$ and $\tau = 0.5$. Performance of RKRL is insensitive to changes doubling Λ or μ. Higher settings of n improve the initial performance, but reduce the total number of epochs possible given a fixed number of episodes. The setting of τ significantly impacts performance, although the main results of this paper are insensitive for $0.25 \leq \tau \leq 1.0$. All kernels are extended to functions of both the state and action, with actions treated as extra state variables.

[1]For efficiency the sufficient statistics $\tilde{\boldsymbol{\alpha}}$ and $\tilde{\mathbf{C}}$ for sparsified GP-SARSA are also inherited, though they can be recalculated. The matrix of approximation coefficients $\mathbf{A}_t$ is not recalculated, although doing so should lead to be better performance in general.

4.2. Kernels

Although RKRL automates the choice of kernel hyperparameters, there is still a need to choose a set of kernels that represents the search space for RKRL. General kernel classes are derived from basic classes commonly found in the literature (table 1) by replacing the standard inner products and norms with weighted variants (cf. *automatic relevance determination*), yielding kernel classes with significantly more hyperparameters. Setting these hyperparameters is the model selection task; as more hyperparameters are added, the model becomes more general, but the corresponding difficulty of inferring the model parameters increases as well.

In order to give a fair baseline GP-SARSA comparison, the best hyperparameter setting for each basic kernel class was derived manually for each domain using grid search. Note that although they are common, the hyperbolic tangent kernels are not positive semi-definite; however they still yield good performance in practice (Smola & Schölkopf, 2004).

4.3. Test Domains

GP-SARSA, RKRL and EP-RKRL are compared across three domains: Mountain Car, Ship Steering and Capture Go. Each domain highlights a different aspect of complexity found in RL problems: Mountain Car and Ship Steering have continuous state spaces and thus require function approximation, Ship Steering also has a large (discrete) action space, and Capture Go is stochastic with a high-dimensional state space.

4.3.1. MOUNTAIN CAR

In *Mountain Car*, the learning agent must drive an underpowered car up a steep hill (Sutton & Barto, 1998). The available actions are $a \in \{-1, 0, 1\}$, i.e., brake, neutral and accelerate. The state $\mathbf{x}_t = (x_t, \dot{x}_t) \in \Re^2$ is comprised of the position and velocity. The environment is deterministic with state evolution governed by

$$\begin{aligned} x_{t+1} &= x_t + \dot{x}_{t+1} \\ \dot{x}_{t+1} &= \dot{x}_t + 0.001a_t + -0.0025\cos(3x_t) \end{aligned}$$

where $-1.2 \leq x \leq 0.5$ and $|\dot{x}| \leq 0.07$. Reward is -1 for each time step the car has not passed the goal at $x = 0.5$. In all RKRL experiments with Mountain Car, $\Lambda = 100$ (100 episodes per epoch) and each episode is limited to 1000 steps to reduce computation time.

4.3.2. SHIP STEERING

In *Ship Steering*, the learning agent must properly orient a sailboat to a specific heading and travel as fast as possible (White, 2007). Actions are two-dimensional rudder position (degrees) and thrust (Newtons), $\mathbf{a}_t = (r_t, T_t) \in [-90, 90] \times [-1, 2]$. Possible rudder settings are discretized at 3-degree increments and thrust increments are 0.5 Newtons, yielding 427 possible actions. The state is a 3-tuple consisting of the heading, angular velocity and velocity $\mathbf{x}_t = (\theta_t, \dot{\theta}_t, \dot{x}_t) \in \Re^3$. State evolution is described by

$$\begin{aligned} \dot{x}_{t+1} &= \dot{x}_t + \frac{1}{250}(30T_t - 2\dot{x}_t - 0.03\dot{x}_t(5\theta_t + r_t^2)) \\ \dot{\theta}_{t+1} &= \dot{\theta}_t + \frac{\dot{x}_t r_t + \dot{x}_t}{1000} \\ \theta_{t+1} &= \theta_t + 0.5(\dot{\theta}_{t+1} + \dot{\theta}_t) \end{aligned}$$

Reward at time step t is equal to $\dot{x}_t$ if $|\theta_t| < 5$ and zero otherwise. In all RKRL experiments with Ship Steering, $\Lambda = 1$. By comparing results in Ship Steering to Mountain Car, it is possible to elucidate how the learner's performance depends on the size of the action space.

4.3.3. CAPTURE GO

The third domain used in this paper is *Capture Go*, a simplified version of Go played where the first player to make a capture wins.[2] The learner plays against a fixed random opponent on a 5×5 board, and receives reward of -1 for a loss and +1 for a win. The board state $\mathbf{x}_t \in \{-1, 0, 1\}^{25}$ is encoded as a vector where -1 entries correspond to opponent pieces, 0 entries correspond to blank territory and 1 entries correspond to the agent's pieces. The agent is given knowledge of *afterstates*, that is, knowledge of how its moves affect the state. In all RKRL experiments using Capture Go, $\Lambda = 1000$. This domain was chosen because it has a high dimensional state vector and stochastic dynamics.

5. Results

GP-SARSA, RKRL and EP-RKRL were applied to three RL domains. Section 5.1 summarizes asymptotic performance in the three domains, Section 5.2 compares asymptotic dictionary sizes, Section 5.3 evaluates the learned kernel performance as a stand-alone static kernel and Section 5.4 analyzes the learned kernel hyperparameter settings in Capture Go.

5.1. Asymptotic Reward

Asymptotic performance is evaluated across three domains: Mountain Car, Ship Steering and Capture Go. In each domain EP-RKRL significantly outperforms both GP-SARSA and RKRL over most kernel classes.

5.1.1. MOUNTAIN CAR

In Mountain Car, learning trials are run for 125,000 episodes and asymptotic performance is measured as the average reward over the last 100 episodes. EP-RKRL significantly outperforms both GP-SARSA and RKRL across all kernel classes asymptotically (table 2). GP-SARSA performance using the POLYNOMIAL kernel reaches a peak at -51.6 after 33 episodes, which is significantly better than

EP-RKRL ($p < 10^{-5}$). However, performance degrades significantly with more episodes. This is a phenomenon common to neural-network based function approximators (Sutton & Barto, 1998).

The Mountain Car problem has been studied extensively in RL literature. The best asymptotic results from the Reinforcement Learning Library stand at -53.92 (White, 2007). NEAT+Q, a similar method for combining TD and evolutionary algorithms, achieves -52.0 (Whiteson & Stone, 2006). However, in the former case, different values for ϵ and γ are used and in the latter case, the learner is run for significantly more episodes, making direct comparison difficult. Running Mountain Car using a standard tile-coding function approximator (Sutton & Barto, 1998) with 8 tilings and the same RL parameter settings yields asymptotic performance of -108.9, significantly better than GP-SARSA across all kernels except POLYNOMIAL, but significantly worse than EP-RKRL under all kernels except TANH NORM.

Note that EP-RKRL significantly outperforms RKRL because it discards less experience over the course of learning. Since kernels can only describe smoothness properties of the value functions, the data points themselves become more important for learning; hence discarding them at each model selection step significantly reduces performance. This contrasts with Whiteson's NEAT+Q work precisely because neural networks are more expressive.

5.1.2. SHIP STEERING

In Ship Steering, each learner trains for 2500 episodes (1000 steps each) and the asymptotic performance is measured as the average reward obtained in the last 10 episodes. EP-RKRL significantly outperforms GP-SARSA and RKRL in all kernel classes except GAUSSIAN (table 3). In the remaining three cases, however, EP-RKRL outperforms both methods by several orders of magnitude. Tile coding with 8 tilings yields asymptotic performance of 0.17, significantly higher performance than GP-SARSA in all cases[3] except for the POLYNOMIAL kernel class ($p < 10^{-9}$), but significantly worse than EP-RKRL in all cases.

5.1.3. CAPTURE GO

In Capture Go, each learner trains for $3.75 \cdot 10^6$ episodes, and asymptotic performance is measured as the average number of wins over the last 1000 episodes. EP-RKRL outperforms GP-SARSA and RKRL across all kernel classes (table 4). GP-SARSA's average reward peaks early and declines under the TANH DOT kernel, achieving a maximum of 78.7% wins after 10,000 episodes, still significantly lower than EP-RKRL ($p < 10^{-6}$).

[3]Performance values in table 3 are scaled by a factor of 100.

Table 5. Asymptotic dictionary size for Mountain Car. Bold numbers indicate statistical significance.

KERNEL	GP-SARSA	RKRL	EP-RKRL
POLYNOMIAL	21.6 ±0.4	**10.3 ±0.5**	13.6 ±0.2
GAUSSIAN	29.6 ±0.5	**7.2 ±0.6**	12.5 ±0.2
TANH NORM	**2.5 ±0.1**	8.5 ±0.8	12.6 ±0.2
TANH DOT	7.7 ±0.7	**5.1 ±0.4**	11.7 ±0.4

Table 6. Asymptotic dictionary size for Ship steering.

KERNEL	GP-SARSA	RKRL	EP-RKRL
POLYNOMIAL	15.3 ±0.8	**4.0 ±0.1**	6.2 ±0.3
GAUSSIAN	**12.3 ±0.5**	15.5 ±0.3	13.7 ±0.1
TANH NORM	**3.8 ±0.6**	5.1 ±0.2	12.3 ±1.0
TANH DOT	7.7 ±0.8	**3.2 ±0.1**	5.3 ±0.2

Table 7. Asymptotic dictionary size for Capture Go.

KERNEL	GP-SARSA	RKRL	EP-RKRL
NORM	28.5 ±0.2	5.9 $\pm\epsilon$	**3.0** $\pm\epsilon$
POLYNOMIAL	147.1 ±3.3	**25.2 ±1.4**	40.4 ±1.4
GAUSSIAN	**66.1 ±0.5**	71.7 ±3.4	91.9 ±6.1
TANH NORM	62.0 ±1.1	19.6 ±0.4	**17.5 ±0.7**
TANH DOT	329.6 ±14.4	**25.6 ±1.5**	28.7 ±1.2

5.2. Dictionary Size

RKRL and GP-SARSA can be compared in terms of computational complexity by measuring the final dictionary sizes $|\tilde{\mathcal{D}}|$ of each learning agent. At each decision point, the computational complexity of GPTD is $O(|\tilde{\mathcal{D}}|^2)$, arising from matrix-vector multiplications and partitioned matrix inversion (Engel, 2005). Furthermore, in practice the $O(|\tilde{\mathcal{D}}|)$ cost of computing $\mathbf{k}(\mathbf{x}) \stackrel{\text{def}}{=} (k(\mathbf{x}, \mathbf{x}_1), \ldots, k(\mathbf{x}, \mathbf{x}_t))^\top$ for $\mathbf{x}_i \in \tilde{\mathcal{D}}$ can carry a high constant overhead for complex kernels. Thus, keeping $|\tilde{\mathcal{D}}|$ small is critical for online performance.

The dictionary sizes for each kernel and learning algorithm pair is given in table 5. In eight of the thirteen cases, EP-RKRL kernels generate significantly smaller dictionaries for $\nu = 0.001$ than GP-SARSA kernels, and likewise in ten of the thirteen cases RKRL generates significantly smaller dictionaries. Thus in the majority of cases employing model selection yields faster learning both in terms of episodes and in terms of computation. However, these dictionary sizes never differ by more than a single order of magnitude, with the largest difference being between RKRL and GP-SARSA the TANH DOT kernel for Capture Go.

5.3. Generalization

How well a particular kernel hyperparameter setting found by EP-RKRL performs depends on what training examples it encounters during learning. Determining to what degree

Table 8. Generalization performance of EP-RKRL kernel parameterizations for Capture Go. In all cases asymptotic performance declines after the original dictionary is discarded.

KERNEL	BASELINE	RELEARNED
NORM	94.3 ±0.5	68.6 ±1.7
POLYNOMIAL	92.6 ±1.3	72.5 ±0.8
GAUSSIAN	93.3 ±0.1	81.1 ±1.0
TANH NORM	94.5 ±0.6	90.7 ±1.9
TANH DOT	89.1 ±1.1	74.6 ±0.7

this performance depends on the exact set of saved training examples yields a notion of how general the kernel parameterization is. In order to evaluate this generalization in EP-RKRL, final kernel parameterizations for Capture Go were saved and all stored training examples were discarded. Learning was then restarted with the kernel parameterization fixed. Table 8 summarizes the results. Across all kernels, the asymptotic performance decreases significantly. Because most training examples are acquired in the first several hundred episodes, this result indicates that the kernel hyperparameter settings are perhaps overfitting to the particular dictionary of saved experience. In other words RKRL is exploiting the acquired data to pick a highly biased covariance function that has low generalization error given that particular set of stored experience.

Although kernels learned through RKRL overfit the dictionary, this is not a serious problem as it improves generalization performance. Overfitting in this nonparametric case simply means that the learned parameterizations are not transferable between agents with different experience. Thus the saved dictionary should be considered part of the model parameters being optimized.

5.4. Analysis of Learned Kernels

Because the hyperparameter space for kernels in Capture Go is high dimensional, RKRL can exploit many kinds of symmetries and patterns in the value function. It is enlightening to analyze whether the learned kernel parameter settings correspond to intuitively meaning covariance functions. Figure 1 plots the 25 hyperparameter values for the TANH NORM kernel averaged over the entire sample for both RKRL and EP-RKRL. The average pattern of weights at the final epoch differs significantly from the expected average over the prior $p(\boldsymbol{\theta})$. Furthermore, the pattern learned in EP-RKRL has a regular structure: Each weight corresponding to a particular board location takes the opposite sign of its neighbors, yielding a regular "checkerboard" pattern of positive and negative weights. This pattern enforces a simple strategy whereby the learner plays to capture isolated stones. Such a strategy is effective against opponents that do not pay attention to stones in danger of being captured.
