Preface

This volume contains the papers accepted to the 25^{th} International Conference on Machine Learning (ICML 2008). ICML is the annual conference of the International Machine Learning Society (IMLS), and provides a venue for the presentation and discussion of current research in the field of machine learning. These proceedings can also be found online at `http://www.machinelearning.org`.

This year, ICML was held July $5-9$ at the University of Helsinki, in Helsinki, Finland, and was co-located with COLT-2008, the 21^{st} Annual Conference on Computational Learning Theory, and UAI-2008, the 24^{th} Conference on Uncertainty in Artificial Intelligence.

No less than 583 papers were submitted to ICML 2008. There was a very thorough review process, in which each paper was reviewed double-blind by three program committee (PC) members. Authors were able to respond to the initial reviews, and the PC members could then modify their reviews based on online discussions and the content of this author response. There were two discussion periods led by the senior program committee (SPC), one just before and one after the submission of author responses. At the end of the second discussion period, the SPC members gave their recommendations and provided a summary review for each of their papers. Some papers were checked by the SPCs to ensure that reviewer comments had been addressed. Apart from the length restrictions on papers and the compressed time frame, the review process for ICML resembles that of many journal publications. In total, 158 papers were accepted to ICML this year, including a small number of papers which were initially conditionally accepted, yielding an overall acceptance rate of 27%.

ICML authors presented their papers both orally and in a poster session, allowing time for detailed discussions with any interested attendees of the conference. Each day of the main conference included one or two invited talks by a prominent researcher. We were very fortunate to be able to host Michael Collins, of the Massachusetts Institute of Technology; Andrew Ng, of Stanford University; and Luc De Raedt, of the Katholieke Universiteit Leuven, and John Winn of Microsoft Research Cambridge. In addition to the technical talks, ICML-2008 also included nine tutorials held before the main conference, presented by Alex Smola, Arthur Gretton, and Kenji Fukumizu; Bert Kappen and Marc Toussaint; Neil Lawrence; Martin Wainwright; Ralf Herbrich and Thore Graepel; Andreas Krause and Carlos Guestrin; Shai Shalev-Shwartz and Yoram Singer; Rob Fergus; and Matthias Seeger. This year our workshops were organized jointly with COLT and UAI as part of a special "overlap day," consisting of eleven workshops selected and arranged collaboratively by the respective workshop chairs of the three conferences. This day provided a rich opportunity for interaction among the attendees of the conferences.

This year, ICML enlarged its award offerings to match several other well-established conferences. We hope these will help build our community, celebrate our advances, and encourage applications and long-term thinking. In addition to our previously traditional "Best Paper" and "Best Student Paper" awards, we also gave awards for "Best Application Paper" and "10-year Best Paper" (for the best paper of ICML 1998, optionally given in conjunction with

a co-located conference). We thank the Machine Learning Journal for sponsoring some of our paper awards.

The organization of ICML-2008 involved efforts from many people, to whom we are extremely grateful. As program chairs, we worked closely with the general chair, William Cohen, and the local arrangements chair, Hannu Toivonen. The tutorials chair, Chris Williams, and the workshop co-chairs, Sanjoy Dasgupta and Michael Littman, also made valuable contributions to the program, and the publication chair, Ricardo Silva, performed a substantial and invaluable service in arranging for publication of the proceedings and ensuring the quality and uniformity of the papers it contained. We wish to thank Lise Getoor and Rich Caruana, the funding co-chairs for IMLS, who secured numerous sponsors for ICML; Noah Smith, the student funding chair, who dispersed student travel awards; and Matti Kääriäinen, the volunteer chair, who arranged for student volunteers, and made sure the conference ran smoothly, and Carlos Guestrin, who chaired our awards sub-committee. We also wish to thank Steven Scott, the treasurer of IMLS, for his support and advice on financial issues, and Greger Lindén for his work as webmaster for ICML-2008. We also wish to thank Rich Gerber and Paolo Gai, of SoftConf.com, who administered the START V2 software used for the conference.

For more general support, we are grateful to the members of IMLS for their advice. We are also very grateful to the many financial sponsors of ICML (who are listed elsewhere in these proceedings) for their support of this conference.

No technical conference is possible without the efforts of reviewers, so we wish to thank the Senior Program Committee, the Program Committee, and the additional reviewers for ICML-2008 for their careful and conscientious reviewing, which ensured the technical quality of the papers in these proceedings. Finally, and perhaps most importantly, we wish to thank the authors who elected to submit their work to ICML-2008, and the people who attended the conference. We hope that this volume will be a useful resource to them, and the other members of the machine learning community.

Sincerely,

Andrew McCallum and Sam Roweis
ICML 2008 Program Co-chairs

ICML 2008 Invited Talks

Structured Prediction Problems in Natural Language Processing

Michael Collins
Massachussets Institute of Technology, U.S.A.

Abstract:
Modeling language at the syntactic or semantic level is a key problem in natural language processing, and involves a challenging set of structured prediction problems. In this talk I'll describe work on machine learning approaches for syntax and semantics, with a particular focus on lexicalized grammar formalisms such as dependency grammars, tree adjoining grammars, and categorial grammars. I'll address key issues in the following areas: 1) the design of learning algorithms for structured linguistic data; 2) the design of representations that are used within these learning algorithms; 3) the design of efficient approximate inference algorithms for lexicalized grammars, in cases where exact inference can be very expensive. In addition, I'll describe applications to machine translation, and natural language interfaces.

STAIR: The STanford Artificial Intelligence Robot Project

Andrew Ng
Stanford University, U.S.A.

Abstract:
This talk will describe the STAIR home assistant robot project, and several satellite projects that led to key STAIR components such as (i) robotic grasping of previously unknown objects, (ii) depth perception from a single still image, and (iii) apprenticeship learning for control.

Since its birth in 1956, the AI dream has been to build systems that exhibit broad-spectrum competence and intelligence. STAIR revisits this dream, and seeks to integrate onto a single robot platform tools drawn from all areas of AI including learning, vision, navigation, manipulation, planning, and speech/NLP. This is in distinct contrast to, and also represents an attempt to reverse, the 30 year old trend of working on fragmented AI sub-fields. STAIR's goal is a useful home assistant robot, and over the long term, we envision a single robot that can perform tasks such as tidying up a room, using a dishwasher, fetching and delivering items, and preparing meals.

STAIR is still a young project, and in this talk I'll report on our progress so far on having STAIR fetch items from around the office. Specifically, I'll describe: (i) learning to grasp previously unseen objects (including its application to unloading items from a dishwasher); (ii) probabilistic multi-resolution maps, which enable the robot to open/use doors; (iii) a robotic foveal+peripheral vision system for object recognition and tracking. I'll also outline some of the main technical ideas − such as learning 3-d reconstructions from a single still image, and reinforcement learning algorithms for robotic control − that played key roles in enabling these STAIR components.

Logical and Relational Learning Revisited

Luc De Raedt
Katholieke Universiteit Leuven, Belgium

Abstract:
I use the term *logical and relational learning* (LRL) to refer to the subfield of machine learning and data mining that is concerned with learning in expressive logical or relational representations. It is the union of inductive logic programming, (statistical) relational learning and multi-relational data mining and constitutes a general class of techniques and methodology for learning from structured data (such as graphs, networks, relational databases) and background knowledge.

During the course of its existence, logical and relational learning has changed dramatically. Whereas early work was mainly concerned with logical issues (and even program synthesis from examples), in the 90s its focus was on the discovery of new and interpretable knowledge from structured data, often in the form of rules or patterns. Since then the range of tasks to which logical and relational learning has been applied has significantly broadened and now covers almost all machine learning problems and settings. Today, there exist logical and relational learning methods for reinforcement learning, statistical learning, distance- and kernel-based learning in addition to traditional symbolic machine learning approaches.

At the same time, logical and relational learning problems are appearing everywhere. Advances in intelligent systems are enabling the generation of high-level symbolic and structured data in a wide variety of domains, including the semantic web, robotics, vision, social networks, and the life sciences, which in turn raises new challenges and opportunities for logical and relational learning,

These developments have led to a new view on logical and relational learning and its role in machine learning and artificial intelligence. In this talk, I shall reflect on this view by identifying some of the lessons learned in logical and relational learning and formulating some challenges for future developments.

Probabilistic Models for Understanding Images

John Winn
Microsoft Research Cambridge, United Kingdom

Abstract:
Getting a computer to understand an image is challenging due to the numerous sources of variability that influence the imaging process. The pixels of a typical photograph will depend on the scene type and geometry, the number, shape and appearance of objects present in the scene, their 3D positions and orientations, as well as effects such as occlusion, shading and shadows. The good news is that research into physics and computer graphics has given us a detailed understanding of how these variables affect the resulting image. This understanding can help us to build the right prior knowledge into our probabilistic models of images. In theory, building a model containing all of this knowledge would solve the image understanding problem. In practice, such a model would be intractable for current inference methods. The open challenge for machine learning and machine vision researchers is to create a model which captures the imaging process as accurately as possible, whilst remaining tractable for accurate inference. To illustrate this challenge, I will show how different aspects of the imaging process can be incorporated into models for object detection and segmentation, and discuss techniques for making inference tractable in such models.

ICML 2008
Workshop and Tutorial Summaries

Overview of Workshops and Tutorials

Once again, ICML solicited and hosted world-class workshops on topics related to machine learning. This year, we were delighted to collaborate with the workshop chairs of the UAI (Nando de Freitas) and COLT (John Langford) conferences to put together an exciting joint program. We constructed a slate of 13 workshops that represent a wide range of perspectives and fields, as seen in the summaries below. All workshops were held on July 9th, immediately after the main conference days. We would like to thank all of the workshop organizers for their service to the community in putting together these high-quality meetings. We also thank the outstanding local arrangement chairs and the general and program chairs for ICML and the other conferences for creating another exciting and successful conference.

Sanjoy Dasgupta and Michael L. Littman
ICML 2008 Workshop Chairs

As in previous years we were pleased to have a strong programme of tutorials for ICML 2008. These were held on 5 July, immediately preceding the main conference. The programme featured nine tutorials covering a wide range of methods in and applications of machine learning. There were tutorials on: embedding distributions in reproducing kernel Hilbert spaces (Smola, Gretton, Fukumizu); stochastic optimal control theory (Kappen, Toussaint); probabilistic dimensionality reduction (Lawrence); message-passing and relaxations in graphical models (Wainwright); machine learning applications in computer games (Herbrich, Graepel); submodularity in machine learning (Krause, Guestrin); theory and applications of online learning (Shalev-Shwartz, Singer); visual object recognition and retrieval (Fergus); and sparse linear models (Seeger). We would like to thank the community for the high-quality tutorial proposals that were received, the presenters for their extensive efforts in preparing and delivering the selected tutorials, and the local arrangements, programme and general chairs of ICML for their hard work in organizing such a stimulating conference.

Chris Williams
ICML 2008 Tutorial Chair

Workshops

W1: Bayesian Modelling Applications

Suzanne M. Mahoney, Innovative Decisions, Inc, U.S.A.
Silja Renooij, Utrecht University, the Netherlands
Hermi J.M. Tabachneck-Schijf, Utrecht University, the Netherlands

The Bayesian Modelling Applications Workshop provides a focused but informal forum for

fruitful exchanges among theorists, practitioners and tool developers, covering research questions and insights, methodologies, techniques, and experiences with applications of Bayesian models to any particular problem domain. Apart from an overall focus on Bayesian modelling, this years 6th edition has as special theme "HOW BIASED ARE OUR NUMBERS?". This theme focusses on issues relating to (probability) biases in applications of Bayesian networks. We seek insight in and examples of and solutions to encountered biases in sources of probabilistic information, or introduced by the methods, new or existing, for obtaining and communicating the numbers. In addition, we are interested in methods for identifying biases in the numbers, and for establishing their effect on model behaviour.

W2: The 3rd Workshop on Evaluation Methods for Machine Learning

Chris Drummond, NRC Institute for Information Technology, Canada
Nathalie Japkowicz, University of Ottawa, Canada
William Klement, University of Ottawa, Canada
Sofus A. Macskassy, Fetch Technologies, U.S.A.

This workshop is the third in a series, the previous ones having taken place at AAAI over the past two years. Our continuing goal is to encourage debate within the machine learning community into how we experimentally evaluate new algorithms. The earlier workshops were successful in that they began the process of presentation, and discussion, of new ideas for evaluation. However, they did not raise all the high-level questions we believe must be addressed by the community. For this reason, we have changed the format of the workshop. First, we will hold it at ICML. Here, with access to a much larger group of ML researchers we expect to hear from many more voices that have an interesting take on the issue. Second, we solicited position papers rather than research papers. This way instead of getting lost into the nitty-gritty details of particular new evaluation methods, we can address the important, high-level, issues surrounding machine learning evaluation.

W3: International Workshop on Machine Learning and Music (MML 2008)

Rafael Ramirez, Universitat Pompeu Fabra, Spain
Christina Anagnostopoulou, University of Athens, Greece
Darrell Conklin, City University, United Kingdom
José Manuel Iñesta, Alicante University, Spain
Xavier Serra, Universitat Pompeu Fabra, Spain

With the current explosion and quick expansion of music in digital formats, research on machine learning and music is gaining increasing popularity. As complexity of the problems investigated by researchers on this area increases, there is a need to develop new algorithms and methods to solve these problems. Machine learning has proved to provide efficient solutions to many music-related problems. The application of related techniques to the development of music processing systems is an active, exciting and significant area of research which has become an established field of research. The goal of the workshop is to bring together researchers who are using machine learning in musical applications, providing the opportunity to promote, present and discuss ongoing work in the area.

W4: Machine Learning for Health Care Applications

Milos Hauskrecht, University of Pittsburgh, U.S.A.
Dale Schuurmans, University of Alberta, Canada
Csaba Szepesvári, University of Alberta, Canada

Health-care applications have been and continue to be the source of inspiration for many areas of artificial intelligence research. Many advances in various sub-specialties of AI have been inspired by challenges posed by medical problems. A new challenge for AI in general, but machine learning in particular, arises from the wealth and variety of data generated in modern medical and health-care settings. Extensive electronic health and medical records − with thousands of fields recording patient conditions, diagnostic tests, treatments, outcomes, and so on − provide an unprecedented source of information that can provide clues leading to potential improvements in disease detection, chronic disease management, design of clinical trials, and other aspects of health-care. The purpose of this workshop is to bring together machine learning researchers interested in problems and applications in health-care, with the goal of exchanging ideas and perspectives, identifying important and challenging applications, and raising awareness of potential health-care applications in the machine learning community. The workshop program will consists of presentations by invited speakers and authors of the papers submitted and accepted to the workshop. A panel session focusing on the main challenges and open problems in the field will be held at the end of the workshop.

W5: Nonparametric Bayes

Yee Whye Teh, University College London, United Kingdom
Romain Thibaux, University of California, Berkeley, U.S.A.
Athanasios Kottas, University of California, Santa Cruz, U.S.A.
Zoubin Ghahramani, University of Cambridge, United Kingdom
Michael Jordan, University of California, Berkeley, U.S.A.

One of the major problems driving current research in statistical machine learning is the search for ways to exploit highly-structured models that are both expressive and tractable. Nonparametric Bayesian methodology provides significant leverage on this problem. In the nonparametric Bayesian framework, the prior distribution is not a fixed parametric form, but is rather a general stochastic process − a distribution over a possibly uncountably infinite number of random variables. This generality makes it possible to work with prior and posterior distributions on objects such as trees of unbounded depth and breadth, graphs, partitions, sets of monotone functions, sets of smooth functions and sets of general measures. Applications of nonparametric Bayesian methods have begun to appear in disciplines such as information retrieval, natural language processing, machine vision, computational biology, cognitive science and signal processing. This workshop is intended to bring together the growing community of nonparametric Bayesian researchers. The issues we wish to address include: development of general-purpose software packages for nonparametric Bayesian models, efficient inference, and new models, methodologies, theoretical frameworks and applications.

W6: PASCAL Large Scale Learning Challenge

Soeren Sonnenburg, Fraunhofer Institute FIRST, Germany
Vojtech Franc, Fraunhofer Institute FIRST, Germany
Elad Yom-Tov, IBM Haifa Research Lab, Israel
Michele Sebag, LRI, France

With the exceptional increase in computing power, storage capacity and network bandwidth of the past decades, ever growing datasets are collected. While the data size growth leaves computational methods as the only viable way of dealing with data, it poses new challenges to ML methods. The PASCAL Large Scale Learning challenge is concerned with the scalability and efficiency of existing ML approaches with respect to computational, memory or communication resources.

Indeed many comparisons are presented in the literature; however, these usually focus on assessing few algorithms and aspects. As a result it is difficult to determine how a method compares to others in terms of test error, training time and memory requirements, which are the practically relevant criteria.

The workshop will serve to disseminate the challenge results and announce the winners of the competition. Authors of the best and most original contributions will present their work. Furthermore a panel discussion will be devoted to establishing a principled framework for the validation of large scale learning methods.

W7: Second Planning to Learn Workshop (PlanLearn)

Pavel Brazdil, University of Porto, Portugal
Avi Bernstein, University of Zurich, Switzerland
Larry Hunter, University of Colorado at Denver and Health Sciences Center, USA

The task of constructing composite systems, that is systems composed of more than one part, can be seen as interdisciplinary area which builds on expertise in different domains. The aim of this workshop is to explore the possibilities of constructing such systems with the aid of Machine Learning and exploiting the know-how of Data Mining. One way of producing composite systems is by inducing the constituents and then by putting the individual parts together. This problem can be seen as a problem of planning to resolve multiple (possibly interacting) tasks. So, one important issue that needs to be addressed is how these multiple learning processes can be coordinated. Each task is resolved using certain ordering of operations. Meta-learning and knowledge transfer can be useful in this process. It can help us to retrieve previous solutions conceived in the past and re-use them in new settings. The aim of the workshop is to explore the possibilities of this new area, offer a forum for exchanging ideas and experience concerning the state-of-the art, permit to bring in knowledge gathered in different but related and relevant areas and outline new directions for research.

W8: Prior Knowledge for Text and Language Processing

Marc Dymetman, Xerox Research Centre Europe, France
Guillaume Bouchard, Xerox Research Centre Europe, France
Hal Daumé III, University of Utah, U.S.A.
Yee Whye Teh, University College London, United Kingdom

The aim of the workshop is to present and discuss recent advances in machine learning approaches to text and natural language processing that capitalize on rich prior knowledge models in these domains.

Traditionally, in Machine Learning, a strong focus has been put on data-driven methods that assume little a priori knowledge on the part of the learning mechanism. Such techniques have proven quite effective not only for simple pattern recognition tasks, but also, more surprisingly, for such tasks as language modeling in speech recognition using basic n-gram models. However, when the structures to be learned become more complex, even large training sets become sparse relative to the task, and this sparsity can only be mitigated if some prior knowledge comes into play to constrain the space of fitted models. We currently see a strong emerging trend in the field of machine learning for text and language processing to incorporate such prior knowledge for instance in language modeling (e.g. through non-parametric Bayesian priors) or in document modeling (e.g. through hierarchical graphical models). There are complementary attempts in the field of statistical computational linguistics (e.g in statistical machine translation) to build hybrid systems that do not rely uniquely on corpus data, but also exploit some form of a priori grammatical knowledge, bridging the gap between purely data-oriented approaches and the traditional purely rule-based approaches, that do not rely on automatic corpus training, but only indirectly on human observations about linguistic data. The domain of text and language processing thus appears as a very promising field for studying the interactions between prior knowledge and raw training data, and this workshop aims at providing a forum for discussing recent theoretical and practical advances in this area.

W9: Recent Breakthroughs in Minimum Description Length Learning

Tim van Erven, CWI, the Netherlands
Peter Grünwald, CWI, the Netherlands
Petri Myllymäki, University of Helsinki, Finland
Teemu Roos, Helsinki Institute for Information Technology, Finland
Ioan Tabus, Tampere University of Technology, Finland

During the last few years (2004-2007), there have been several breakthroughs in the area of Minimum Description Length (MDL) modeling, learning and prediction. These breakthroughs concern the efficient computation and proper formulation of MDL in parametric problems based on the ”normalized maximum likelihood”, as well as altogether new, and better, coding schemes for nonparametric problems. This essentially solves the so-called AIC-BIC dilemma, which has been a central problem in statistical model selection for more than 20 years now. The goal of this workshop is to introduce these exciting new developments to the ML and UAI communities, and to foster new collaborations between interested researchers.

W10: Second Annual Reinforcement Learning Competition (RL 2008)

Shimon Whiteson, Universiteit van Amsterdam, the Netherlands
Adam White, University of Alberta, Canada
Rich Sutton, University of Alberta, Canada
Doina Precup, McGill University, Canada
Peter Stone, University of Texas at Austin, U.S.A.
Michael Littman, Rutgers University, U.S.A.
Nikos Vlassis, Technical University of Crete, Greece
Martin Riedmiller, Universität Osnabrück, Germany

The Second Annual Reinforcement Learning Competition is an opportunity for reinforcement learning researchers to rigorously compare the performance of their methods on a suite of challenging domains, including: the game of Tetris; robot soccer keepaway, based on the RoboCup simulator; a real-time strategy (RTS) game; and a helicopter control problem, based on the work of Andrew Ng and collaborators. This year's competition will utilize new evaluation paradigms designed to encourage algorithms that generalize well to previously unseen tasks. In particular, each domain will be parameterized and test parameters will differ from those used for training. As a result, only learning algorithms that are robust across a range of parameters can expect to perform well. The competition concludes with a workshop at which the winners will be announced. Top competitors will give short presentations about their methods and several moderated discussions will be held on topics including the challenges of empirical RL and the future of the competition.

W11: Sparse Optimization and Variable Selection

Irina Rish, IBM T. J. Watson Research Center, U.S.A.
Guillermo Cecchi, IBM T. J. Watson Research Center, U.S.A.
Rajarshi Das, IBM T. J. Watson Research Center, U.S.A.
Tony Jebara, University of Columbia, U.S.A.
Gerry Tesauro, IBM T. J. Watson Research Center, U.S.A.
Martin Wainwright, University of California, Berkeley, U.S.A.

Variable selection is an important issue in many applications of machine learning and statistics where the main objective is discovering predictive patterns in data that would enhance our understanding of underlying physical, biological and other natural processes, beyond just building accurate 'black-box' predictors. Examples include biomarker selection in biological applications, identifying brain areas related to various 'mental states' based on brain imaging data, identifying a small number of bottlenecks in a large-scale computer network that best explain the network performance, and so on. Recent years have witnessed a flurry of research on algorithms and theory for variable selection and estimation involving sparsity constraints. Various types of convex relaxation, particularly L1-regularization, have proven very effective: examples include the LASSO, Elastic Net, L1-regularized GLMs, sparse classifiers such as sparse (1-norm) SVM, as well as sparse dimensionality reduction methods (e.g. sparse component analysis such as sparse PCA and sparse NMF). Applications of these methods are wide-ranging, including computational biology, neuroscience, graphical model selection, and the rapidly growing area of compressed sensing. Theoretical work has provided some conditions when various relaxation methods are capable of recovering an underlying sparse

signal, provided bounds on sample complexity, and investigated trade-offs between different choices of design matrix properties that guarantee good performance. The goal of this workshop is to bring together researchers working on the methodology, theory and applications of sparse models and selection methods to share their experiences and insights into both the basic properties of the methods, and the properties of the application domains that make particular methods more (or less) suitable. We hope to further explore connections between variable selection and related areas such as dimensionality reduction, optimization and compressed sensing.

Tutorials

T1: Painless Embeddings of Distributions: the Function Space View

Alex Smola, NICTA, Australia
Arthur Gretton, Max Planck Institute for Biological Cybernetics, Germany
Kenji Fukumizu, Institute of Statistical Mathematics, Japan

In the early days of kernel machines research, the "kernel trick" was considered a useful way of constructing nonlinear algorithms from linear ones. More recently, however, it has become clear that a potentially more far reaching use of kernels is as a linear way of dealing with higher order statistics. For instance, in kernel independent component analysis, general nonlinear dependencies show up as linear correlations once they are computed in a suitable reproducing kernel Hilbert space. This tutorial provides an introduction to embeddings of probability distributions into reproducing kernel Hilbert spaces, as a way of painlessly dealing with high order statistics. We will cover both theoretical issues, such as conditions under which different probability distributions have unique mappings; as well as practical applications ranging from tests of distribution properties (homogeneity, independence, conditional independence) to density estimation to causal inference.

T2: Stochastic Optimal Control Theory

Bert Kappen, Radboud University, the Netherlands
Marc Toussaint, Technical University, Germany

Stochastic optimal control theory concerns the problem of how to act optimally when reward is only obtained at a later time. The stochastic optimal control problem is central to modeling of intelligent behavior in animals or machines. Examples are the control of multi-joint robot arms, navigation of vehicles, coordination of multi-agent systems, and decision making in financial applications. Classical optimal control theory is based on principles like the Hamilton-Jacobi-Bellman equation, the Pontryagin maximum principle, and special cases like the LQ-case and the Ricatti equations. More familiar to the Machine Learner are Reinforcement Learning or (Partially Observable) Markov Decision Processes which can be viewed as special cases of stochastic control theory. This tutorial aims to introduce to the classical principles as well as the more modern frameworks and thereby to provide an integrative view on the different notions. Special emphasis is given on newer approaches of

using inference techniques to solving stochastic optimal control problems. The tutorial is introductory and aimed at the 'average' machine learning researcher. No background in control theory and/or reinforcement learning is assumed. A basic understanding of Bayesian networks and statistical inference is assumed.

T3: Dimensionality Reduction, the Probabilistic Way

Neil Lawrence, University of Manchester, United Kingdom

The main focus of this tutorial will be probabilistic interpretations of dimensional reduction. It is aimed to complement the tutorial given by Lawrence Saul at NIPS 2005 on "Spectral Methods for Dimensional Reduction". Its particular focus will be probabilistic approaches to dimensional reduction based on generative models. These approaches have become increasingly popular in graphics and vision through the Gaussian Process Latent Variable Model. However, there also is a history to these methods which is perhaps less widely known amoungst the newer generation of researchers. In particular the Generative Topographic Mapping and Latent Density Networks. This tutorial will give grounding to these methods through unifying them in the context of probabilistic latent variable models. This will involve a introduction to these approaches through the mechanism of probabilistic PCA, then a discussion of density networks leading into the generative topographic mapping. Finally the dual interpretation of probabilistic PCA and its extension to the GP-LVM will be given. Throughout the tutorial we will develop intuition about the methods with an ongoing set of example data sets. A particular focus of these example data sets will be motion capture data. Motion capture data is a nice example to use because it is easy for the human eye to tell when samples from the model are realistic. One aspect of the tutorial will be the difference between the probabilistic approaches and the more commonly applied spectral approaches. In particular we will emphasise the distance preservation character of the probabilistic approaches: namely that local distances in the data are not necessarily preserved in the latent space. This contrasts with spectral algorithms which typically aim to preserve such local distances. These different characteristics mean that probabilistic approaches complement the spectral approaches, but the bring their own range of associated problems, in particular local minima in the optimisation space. Heuristics for avoiding these local minima will also be discussed.

T4: Graphical Models and Variational Methods: Message-passing and Relaxations

Martin Wainwright, University of California, Berkeley, U.S.A.

Graphical models provide a flexible framework for capturing dependencies among large collections of random variables, and are by now an essential component of the statistical machine learning toolbox. Any application of graphical models involves a core set of computational challenges, centered around the problems of marginalization, mode-finding, parameter estimation, and structure estimation. Although efficiently solvable for graphs without cycles (trees) and graphs of low treewidth more generally, exact solutions to these core problems are computationally challenging for general graphical models with large numbers of nodes and/or state space sizes. Consequently, many applications of graphical models require efficient methods for computing approximate solutions to these core problems. The past decade and a half has witnessed an explosion of activity on approximate algorithms for graphical

models. This tutorial will show how a wide class of methods − including mean field theory, sum-product or belief propagation algorithms, expectation-propagation, and max-product algorithms − are all variational methods, meaning that they can be understood as algorithms for solving particular optimization problems on graphs. The perspective also forges connections to convex optimization, including linear programming and other type of conic relaxations.

T5: Playing Machines: Machine Learning Applications in Computer Games

Ralf Herbrich, Microsoft Research Cambridge, United Kingdom
Thore Graepel, Microsoft Research Cambridge, United Kingdom

The tutorial will give an introduction to the emerging area of applying machine learning to computer games and of using computer games as test beds for machine learning. One of the key problems in computer games is the creation of AI driven agents that interact with the player so as to create a great interactive gaming experience. As a consequence a substantial part of the tutorial will consider adaptive and learning game AI based on supervised and reinforcement learning. However, computer games also offer a great variety of other challenges including problems in graphics, sound, networking, player rating and matchmaking, interface design, narrative generation etc. Selected problems from some of these areas will be discussed together with machine learning approaches to solve them. Since this is an application area, the tutorial will focus on past and recent applications, open problems and promising avenues for future research. It will also provide resources available to people who would like to work in this fascinating and fun research space.

T6: Beyond Convexity: Submodularity in Machine Learning

Andreas Krause, Carnegie Mellon University, U.S.A.
Carlos Guestrin, Carnegie Mellon University, U.S.A.

Convex optimization has become a main workhorse for many machine learning algorithms during the past ten years. When minimizing a convex loss function for, e.g., training a Support Vector Machine, we can rest assured to efficiently find an optimal solution, even for large problems. In recent years, another fundamental problem structure, which has similar beneficial properties, has emerged as very useful in a variety of machine learning applications: Submodularity is an intuitive diminishing returns property, stating that adding an element to a smaller set helps more than adding it to a larger set. Similarly to convexity, submodularity allows one to efficiently find provably (near-)optimal solutions. In this tutorial, we will give an introduction to the concept of submodularity, discuss algorithms for optimizing submodular functions and − as the main focus − illustrate their usefulness in solving difficult machine learning problems, such as active learning and sparse experimental design, informative path planning, structure learning, clustering, influence maximization and ranking.

T7: Tutorial on Theory and Applications of Online Learning

Shai Shalev-Shwartz, Toyota Technological Institute, U.S.A.
Yoram Singer, Google, U.S.A.

Online learning is a well established learning paradigm which has both theoretical and practical appeals. The goal of online learning is to make a sequence of accurate predictions

given knowledge of the correct answer to previous prediction tasks and possibly additional available information. The roots of online learning goes back to Hannan's work in the 50s. Online learning became of great interest to practitioners due the recent emergence of large scale web applications. Notable examples of web-based applications are online advertisement placement and online web ranking. The tutorial is targeted at people from all areas of machine learning and covers the formal foundations along with algorithmic and practical aspects of online learning. The goal is to provide a high-level, broad, and rigorous overview of the formal framework. By the end of tutorial the attendees should have acquired enough knowledge to be able to pin-point an online algorithm that best matches an application.

The tutorial starts with a simple example of predicting the next element of a binary sequence. We then formally introduce the basic definitions of online learning and the notion of regret analysis. Next we describe the problem of predicting with experts advice by analyzing a few algorithms and contrasting them with an impossibility result. This basic setting is then re-examined in the context of online learning of general linear predictors. We give a recent analysis which reveals an underlying primal-dual apparatus for the analysis of online algorithms. We conclude the formal part of the tutorial with a description of extensions and generalizations of online learning tasks while underscoring connections to game theory, information theory, and reinforcement learning. We recap the tutorial with two complete examples that demonstrate the usage of online learning for portfolio selection and for text filtering.

T8: Visual Object Recognition and Retrieval

Rob Fergus, New York University, U.S.A.

The tutorial will address the problem of recognizing visual object classes in images, currently the focus of much interest in Computer Vision. As recent innovations in the area draw heavily on machine learning concepts, the tutorial will attempt to highlight the growing intersection between the two areas. The material will be divided five sections, covering (i) bag of words models; (ii) parts and structure models; (iii) discriminative methods; (iv) combined recognition and segmentation and (v) retrieval schemes for large datasets. The emphasis will be on the important general concepts rather than in depth coverage of contemporary papers. The tutorial is a revised version of the prize-winning short course given at ICCV 2005 and CVPR 2007 in conjunction with Fei-Fei Li (Princeton) and Antonio Torralba (MIT).

T9: Sparse Linear Models: Bayesian Inference and Experimental Design

Matthias Seeger, Max Planck Institute for Biological Cybernetics, Germany

Sparse linear models are cornerstones of applied statistics, embodying fundamental ideas such as feature selection, shrinkage, and automatic relevance determination. While much progress has been made recently in understanding point estimation of sparse signals, Bayesian inference is needed to drive higher-level tasks such as experimental design, where valid uncertainties and covariances are more important than point estimates. In this tutorial, the major determnistic inference approximations to date (expectation propagation, sparse Bayesian learning, variational mean field Bayes) will be introduced for the sparse linear model, and their mathematics (scale mixtures, convex duality, moment matching) will be clarified. Sequential Bayesian design, with the application to optimizing an image measurement architecture, serves as motivation for this effort.

ICML 2008 Papers

Gaussian Process Product Models for Nonparametric Nonstationarity

Ryan Prescott Adams RPA23@CAM.AC.UK
Oliver Stegle OS252@CAM.AC.UK
Cavendish Laboratory, University of Cambridge, Cambridge CB3 0HE, UK

Abstract

Stationarity is often an unrealistic prior assumption for Gaussian process regression. One solution is to predefine an explicit nonstationary covariance function, but such covariance functions can be difficult to specify and require detailed prior knowledge of the nonstationarity. We propose the Gaussian process product model (GPPM) which models data as the pointwise product of two latent Gaussian processes to nonparametrically infer nonstationary variations of amplitude. This approach differs from other nonparametric approaches to covariance function inference in that it operates on the outputs rather than the inputs, resulting in a significant reduction in computational cost and required data for inference. We present an approximate inference scheme using Expectation Propagation. This variational approximation yields convenient GP hyperparameter selection and compact approximate predictive distributions.

1. Introduction

The Gaussian process (Rasmussen & Williams, 2006) is a useful and popular prior for nonlinear regression. It can be used to construct a distribution over scalar functions via a prior on smoothness. This prior is specified through a positive-definite kernel, which determines the covariance between two outputs as a function of their corresponding inputs. Often, this covariance function is taken to be stationary, i.e., a function only of the distance between the input points. Stationary covariance functions are appealing due to their intuitive interpretation and their relative ease of construction via Bochner's Theorem (Gibbs, 1997).

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Unfortunately, stationarity is often an unrealistic assumption. We expect many problems of interest to have nontrivial nonstationarity in the form of input-dependent noise, length scale or amplitude. While input-dependent noise and length-scale have been well-studied in the literature, nonstationarity in the form of varying amplitude has received relatively little attention.

One approach to modeling such data is to directly specify a covariance function with nonstationary properties (Gibbs, 1997; Higdon et al., 1999). In machine learning, however, we find it undesirable to need to specify the covariance nonstationarity *a priori*; rather we wish to infer it. Moreover, as the objective with Gaussian process regression is to perform nonparametric inference, we would prefer a representation of the nonstationarity which is also nonparametric.

Several approaches have been proposed to solve the problem of learning a length scale that varies across the input space. One of the first techniques was that of Sampson and Guttorp (1992), who model a spline-based mapping to a latent input space in which the data are stationary. This approach was given a nonparametric Bayesian treatment by Schmidt and O'Hagan (2003). Recently, Paciorek and Schervish (2004) extended the work of Higdon et al. (1999) to learn nonparametric variation of the covariance kernel. Other approaches involve Gaussian process mixtures (Rasmussen, 2000), augmentation of the input space (Pfingsten et al., 2006), and weighted sums of locally-stationary processes (Nott & Dunsmuir, 2002).

A related problem is input-dependent observation noise in the Gaussian process, addressed by Goldberg et al. (1998), who model a log-noise term in the covariance function with another Gaussian process, and by Le et al. (2005) who model nonstationary noise by performing regression in the natural parameter space of the exponential family. Snelson and Ghahramani (2006) achieve nonstationary noise as a side effect of the combination of input dimensionality reduction and a sparse approximation using pseudo-data.

In this paper, we propose the Gaussian process product model (GPPM) to address smooth input-dependent changes in amplitude. The GPPM models the data as the pointwise product of two latent stationary Gaussian processes. This approach has the notable computational advantage over remappings of the input space in that high dimensional problems pose no intrinsic scalability problems. Remapping the input nonparametrically while maintaining the input dimension requires at least as many latent processes as input dimensions. In contrast, the GPPM uses only a single additional GP regardless of input dimension. We develop a quadrature-based Expectation Propagation (EP) algorithm for efficient approximate inference in the GPPM model. The EP approach allows us to use the estimated marginal likelihood of the model to learn empirical settings of the Gaussian process hyperparameters. The approximate inference procedure we describe yields uncertainty in the nonstationarity, while avoiding expensive MCMC methods that are typically required. We additionally develop useful approximations for the predictive distribution arising from the EP approximation, and discuss rapid learning of a MAP estimate of the nonstationarity when observations can be considered noise free. This model is similar to that presented by Turner and Sahani (2008), who modulate sounds with Gaussian processes, however the GPPM is intended for the general regression problem and our inference approach differs significantly.

2. Gaussian Process Regression

In Gaussian process regression, we find a distribution over functions of the form $f : \mathcal{X} \to \mathbb{R}$, $\mathcal{X} = \mathbb{R}^m$. For a comprehensive introduction see Rasmussen and Williams (2006). The data consist of N input/output pairs $\mathcal{D} = \{\boldsymbol{x}_n, y_n\}^N$, $\boldsymbol{x}_n \in \mathcal{X}$, $y_n \in \mathbb{R}$. A vector of output points has a Gaussian prior distribution with a mean function $\mu(\boldsymbol{x})$, which we take to be zero, and a positive-definite covariance function $C(\boldsymbol{x}, \boldsymbol{x}'; \boldsymbol{\theta})$. This construction gives an analytic Gaussian predictive distribution for an unseen output $y_\star \sim \mathcal{N}(\mu_\star, v_\star)$:

$$\mu_\star = \boldsymbol{k}_N^\mathsf{T} \boldsymbol{C}_N^{-1} \boldsymbol{y}_N, \quad v_\star = C(\boldsymbol{x}_\star, \boldsymbol{x}_\star) - \boldsymbol{k}_N^\mathsf{T} \boldsymbol{C}_N^{-1} \boldsymbol{k}_N,$$

where $\boldsymbol{k}_N = [C(\boldsymbol{x}_\star, \boldsymbol{x}_1; \boldsymbol{\theta}), \ldots, C(\boldsymbol{x}_\star, \boldsymbol{x}_N; \boldsymbol{\theta})]^\mathsf{T}$, and $\boldsymbol{C}_N$ is the covariance matrix formed from the observed data. The log evidence, or log marginal likelihood after integrating out all possible functions is

$$\mathcal{L} = -\frac{1}{2} \ln |\boldsymbol{C}_N| - \frac{1}{2} \boldsymbol{y}_N^\mathsf{T} \boldsymbol{C}_N^{-1} \boldsymbol{y}_N - \frac{N}{2} \ln 2\pi. \qquad (1)$$

Stationary covariance functions only depend on a distance measure d between $\boldsymbol{x}$ and $\boldsymbol{x}'$, for example the Mahalanobis distance $d(\boldsymbol{x}, \boldsymbol{x}') = (\boldsymbol{x} - \boldsymbol{x}')^\mathsf{T} \boldsymbol{W} (\boldsymbol{x} - \boldsymbol{x}')$ with positive definite $\boldsymbol{W}$. Covariance functions that depend only on distance are appealing due to the intuition that the outputs of the function should covary in inverse proportion to how far the inputs are from each other. The model proposed in this paper attempts to retain this intuition while providing a mechanism for the relationship between distance and covariance to vary across the input space.

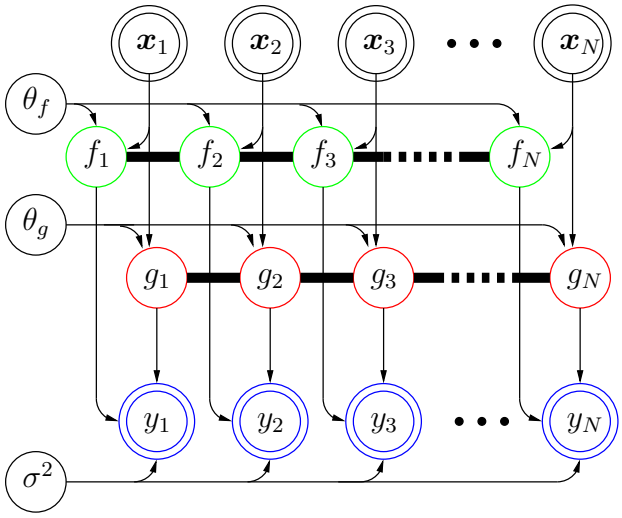

Figure 1. A graphical model describing the GPPM. The thick lines connecting the values of $\boldsymbol{f}$ and $\boldsymbol{g}$ represent undirected connections associated with the Gaussian process. The double-lined circles around the $\boldsymbol{y}$ values represent observables. Both $f(x)$ and $g(x)$ have the same input space.

3. The Gaussian Process Product Model

In the Gaussian process product model (GPPM), the observed outputs $\{y_n\}^N$ are modeled by a pointwise product of two latent functions, plus independent zero-mean Gaussian noise with variance σ^2. One latent function $f : \mathcal{X} \to \mathbb{R}$, is modulated by the other function $g : \mathcal{X} \to \mathbb{R}$ that has been exponentiated, so that

$$y_n \sim \mathcal{N}(f(\boldsymbol{x}_n) e^{g(\boldsymbol{x}_n)}, \, \sigma^2). \qquad (2)$$

We place independent zero-mean Gaussian process priors on $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$, with covariance functions $C_f(\boldsymbol{x}, \boldsymbol{x}'; \boldsymbol{\theta}_f)$ and $C_g(\boldsymbol{x}, \boldsymbol{x}'; \boldsymbol{\theta}_g)$, respectively. Figure 1 shows a graphical interpretation of this model. Our convention is that $f(\boldsymbol{x})$ captures local near-stationary variations in the observed function and $g(\boldsymbol{x})$ captures slowly-varying amplitude nonstationarity. The length-scale hyperparameters of these covariance functions (and their hyperpriors) should be chosen to reflect prior beliefs about such variations. To give the flavor of this model, Figure 2 shows several samples from the GPPM.

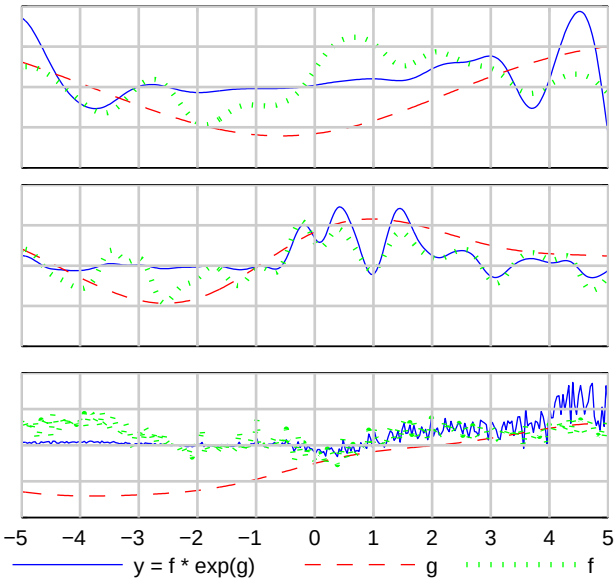

Figure 2. Three samples from the GPPM with different parameters. In the top plot, the length scales are $l_f = 0.5$ and $l_g = 4.0$. In the middle plot, both are shorter: $l_f = 0.25$ and $l_g = 2.0$. In the bottom plot, $l_f = 0.5$ and $l_g = 2.0$, but $f(x)$ also has additive noise.

Note that the pointwise product of a Gaussian process prior with any known function $a(\boldsymbol{x})$ results in a covariance function given by $C'(\boldsymbol{x}, \boldsymbol{x}') = a(\boldsymbol{x})C(\boldsymbol{x}, \boldsymbol{x}')a(\boldsymbol{x}')$ and that this function is guaranteed to be positive definite. In the GPPM we use an exponentiated form $a(\boldsymbol{x}) = \exp\{g(\boldsymbol{x})\}$ in order to reduce the multimodality of the posterior on the latent functions, but this is not critical for the validity of the covariance function. Without restricting the sign of one of the functions, there would be at least 2^N posterior modes, as each observation could be explained by the same latent function values with flipped signs.

4. Factor Inference in the GPPM

The basic GPPM inference task is to determine the posterior distribution over the values of the latent functions $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$ at the input locations $\{\boldsymbol{x}_n\}^N$. These latent function values will be denoted $f_n = f(\boldsymbol{x}_n)$ and $g_n = g(\boldsymbol{x}_n)$ for brevity. Additionally we will write the vectors of these latent values in bold type: $\boldsymbol{f} = [f_1, \ldots, f_N]^\mathsf{T}$ and $\boldsymbol{g} = [g_1, \ldots, g_N]^\mathsf{T}$. With this notation and with $\boldsymbol{C}_f$ and $\boldsymbol{C}_g$ representing the GP-derived covariance matrices on $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$ respectively, the posterior distribution of the latent functions is

$$p(\boldsymbol{f}, \boldsymbol{g} \,|\, \mathcal{D}, \boldsymbol{\theta}) \propto \mathcal{N}(\boldsymbol{f};\, \boldsymbol{0}, \boldsymbol{C}_f)\mathcal{N}(\boldsymbol{g};\, \boldsymbol{0}, \boldsymbol{C}_g) \times \prod_{n=1}^{N} \mathcal{N}(y_n;\, f_n e^{g_n},\, \sigma^2). \quad (3)$$

4.1. Approximate Inference

Approximate inference via variational methods is appealing due to its determinism and potential computational savings. In the GPPM, several properties affect our choice of approximation. First, we expect that the posterior will be approximately Gaussian, as we have strong Gaussian process priors and a near-Gaussian likelihood. Second, the likelihood factorizes to N independent terms, each involving one point from the two latent functions. Third, these likelihood factors introduce nontrivial dependencies between $\boldsymbol{f}$ and $\boldsymbol{g}$ so that a factorized approximation is inappropriate. We address these properties using Expectation Propagation.

4.1.1. Expectation Propagation

Expectation Propagation (Minka, 2001) makes successive *local* approximations of factors in a joint density, typically using exponential-family distributions, to yield a *global* approximation that is optimal under a divergence measure. EP is particularly well-suited for approximation of Bayesian posterior distributions with i.i.d. data as in Equation 3, as each factor only involves a few of the unknown parameters.

Our construction of the EP approximation is similar to that used by Rasmussen and Williams (2006) for binary Gaussian process classification. The prior on $\boldsymbol{f}$ and $\boldsymbol{g}$ is Gaussian with zero mean and a block covariance matrix arising from the independent Gaussian process priors. For notational convenience, we will write $\boldsymbol{\phi}$ to be the concatenation of $\boldsymbol{f}$ and $\boldsymbol{g}$ so that $\boldsymbol{\phi} = [f_1, \ldots, f_N, g_1, \ldots, g_N]^\mathsf{T}$, and $\boldsymbol{\phi}_n$ to be the nth pair $[f_n\ g_n]^\mathsf{T}$. The prior can now be written

$$p(\boldsymbol{\phi}) = \mathcal{N}(0, \boldsymbol{\Sigma}_{\mathsf{GP}}), \qquad \boldsymbol{\Sigma}_{\mathsf{GP}} = \begin{bmatrix} \boldsymbol{C}_f & 0 \\ 0 & \boldsymbol{C}_g \end{bmatrix}.$$

The aim of EP is to approximate the exact posterior distribution of Equation 3 with a tractable alternative

$$q(\boldsymbol{f}, \boldsymbol{g} \,|\, \mathcal{D}, \boldsymbol{\theta}) \propto \mathcal{N}(0, \boldsymbol{\Sigma}_{\mathsf{GP}}) \prod_{n=1}^{N} \tilde{t}_n(f_n, g_n). \quad (4)$$

Each of the exact likelihood terms

$$\mathcal{L}_n(f_n, g_n) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{1}{2\sigma^2}\left(f_n e^{g_n} - y_n\right)^2\right\}$$

is approximated with an unnormalized bivariate Gaussian on f_n and g_n:

$$\tilde{t}_n(f_n, g_n) = \tilde{Z}_n \exp\left\{-\frac{1}{2}(\boldsymbol{\phi}_n - \tilde{\boldsymbol{\mu}}_n)^\mathsf{T}\tilde{\boldsymbol{\Sigma}}_n^{-1}(\boldsymbol{\phi}_n - \tilde{\boldsymbol{\mu}}_n)\right\}.$$

The product of these likelihood approximations is an unnormalized Gaussian with a block-diagonal covariance matrix.

$$\prod_{n=1}^{N} \tilde{t}_n(\boldsymbol{\phi}_n) = \exp\left\{-\frac{1}{2}(\boldsymbol{\phi} - \tilde{\boldsymbol{\mu}})^\mathsf{T}\tilde{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{\phi} - \tilde{\boldsymbol{\mu}})\right\} \prod_{n=1}^{N} \tilde{Z}_n$$

The overall approximation is Gaussian as well, as it is the product of these Gaussian likelihood approximations and the Gaussian process prior.

$$q(\boldsymbol{f}, \boldsymbol{g} \mid \mathcal{D}, \boldsymbol{\theta}) = \mathcal{N}\left(\boldsymbol{\phi} = \begin{bmatrix}\boldsymbol{f}\\ \boldsymbol{g}\end{bmatrix}; \boldsymbol{\mu}, \boldsymbol{\Sigma}\right) \tag{5}$$
$$\boldsymbol{\Sigma} = \left(\boldsymbol{\Sigma}_{\mathsf{GP}}^{-1} + \tilde{\boldsymbol{\Sigma}}^{-1}\right)^{-1} \qquad \boldsymbol{\mu} = \boldsymbol{\Sigma}\tilde{\boldsymbol{\Sigma}}^{-1}\tilde{\boldsymbol{\mu}}$$

The Expectation Propagation algorithm proceeds by iteratively updating the parameters of the local approximations t_n, leaving all other approximate factors fixed. In this iterative procedure the update of the nth site can be understood as the minimization of the KL divergence between two approximating distributions: the product of the cavity distribution times the *exact* local likelihood, and the product of the cavity distribution times the *approximate* local likelihood. The insight of EP is that the cavity distribution "focuses" the approximation on the most relevant area.

$$\hat{\boldsymbol{\mu}}_n, \hat{\boldsymbol{\Sigma}}_n = \underset{\boldsymbol{\mu}', \boldsymbol{\Sigma}'}{\operatorname{argmin}} \operatorname{KL}\Big[\mathcal{N}(\boldsymbol{\mu}_{/n}, \boldsymbol{\Sigma}_{/n}) \times \overbrace{\mathcal{L}_n(f_n, g_n)}^{\text{exact factor}} \,\Big|\Big|\, \mathcal{N}(\boldsymbol{\mu}_{/n}, \boldsymbol{\Sigma}_{/n}) \times \underbrace{\tilde{t}_n(f_n, g_n | \boldsymbol{\mu}', \boldsymbol{\Sigma}')}_{\text{approximation}}\Big]$$

The cavity distribution for site n is the product of the prior and all approximate sites excluding the nth. This is Gaussian with parameters

$$\boldsymbol{\Sigma}_{/n} = \left(\boldsymbol{\Sigma}_n^{-1} - \tilde{\boldsymbol{\Sigma}}_n^{-1}\right)^{-1} \tag{6}$$
$$\boldsymbol{\mu}_{/n} = \boldsymbol{\Sigma}_{/n}\left(\boldsymbol{\Sigma}_n^{-1}\boldsymbol{\mu}_n - \tilde{\boldsymbol{\Sigma}}_n^{-1}\tilde{\boldsymbol{\mu}}_n\right). \tag{7}$$

As shown by Minka (2001), the minimum of an inclusive KL divergence is achieved when the moments are equal. Thus to find the best-fitting Gaussian, it is sufficient to find the first and second moments of the product of the cavity distribution and the exact likelihood. We also find the "zeroth moment," which is the normalization constant $\hat{Z}_n$. Calculation of these moments is done numerically via Gaussian quadrature, addressed in Section 4.1.2.

Once the moments of the product have been found, we use them to recover the optimal parameters of the local approximation:

$$\begin{aligned}
\tilde{\boldsymbol{\Sigma}}_n &= \left(\hat{\boldsymbol{\Sigma}}_n^{-1} - \boldsymbol{\Sigma}_{/n}^{-1}\right)^{-1} \\
\tilde{\boldsymbol{\mu}}_n &= \tilde{\boldsymbol{\Sigma}}_n\left(\hat{\boldsymbol{\Sigma}}_n^{-1}\hat{\boldsymbol{\mu}}_n - \boldsymbol{\Sigma}_{/n}^{-1}\boldsymbol{\mu}_{/n}\right) \\
\ln \tilde{Z}_n &= \ln \hat{Z}_n - \frac{1}{2}\ln|\tilde{\boldsymbol{\Sigma}}_n| + \frac{1}{2}\ln|\boldsymbol{\Sigma}_{/n}| + \frac{1}{2}\tilde{\boldsymbol{\mu}}_n^{\mathsf{T}}\tilde{\boldsymbol{\Sigma}}_n^{-1}\tilde{\boldsymbol{\mu}}_n \\
&\quad + \frac{1}{2}\boldsymbol{\mu}_{/n}^{\mathsf{T}}\boldsymbol{\Sigma}_{/n}^{-1}\boldsymbol{\mu}_{/n} - \frac{1}{2}\hat{\boldsymbol{\mu}}_n^{\mathsf{T}}\hat{\boldsymbol{\Sigma}}_n^{-1}\hat{\boldsymbol{\mu}}_n.
\end{aligned}$$

Taken together these equations define a fixed-point iteration scheme for approximating the posterior in Equation 3. We initialize the approximations so that the initial estimate of the mean of $\boldsymbol{f}$ is $\boldsymbol{y}$ and the mean of $\boldsymbol{g}$ is zero. We then iterate over each of the N local approximations, and update the overall posterior approximation using Equation 5. To facilitate convergence of EP it is helpful to use damping to update local sites, which we implement in natural parameter space. Convergence of EP is not guaranteed, but given sufficient damping it is found to convergence for the problems we considered so far. Local approximations may not necessarily be positive definite, but as long as the overall approximation remains a valid Gaussian, this does not present a problem. Following from the treatment by Minka (2001) of negative variances, we skip the update of local approximations that would result in invalid global covariance matrices. This has not appeared to affect the accuracy of the global approximation in practice. Figure 3(b) shows the result of applying the EP procedure to a synthetic data set. Marginal error bars are shown for each function and site location.

4.1.2. Gaussian Quadrature for EP

Unfortunately, the moments that minimize the KL divergence of Section 4.1.1 are not available analytically. To resolve this, we use the approach proposed by Zoeter and Heskes (2005) of approximating the moment integrals using Gaussian quadrature. When a definite integral is the product of a nonnegative "weighting function" $w(v)$ and another function $z(v)$, it can be approximated by a sum of weighted evaluations of $z(v)$

$$\int_b^a dv\; w(v)z(v) \approx \sum_{k=1}^{K} w_k z(v_k)$$

where the weights $\{w_k\}$ and abscissae $\{v_k\}$ are determined by the integration interval, the weighting function $w(v)$, and the number of evaluation points K. This sum is exact where $z(v)$ is a polynomial of degree $2K-1$. In the case of interest here, the weighting function is the Gaussian cavity distribution, which implies Gauss-Hermite quadrature.

One difficulty is that Gaussian quadrature is generally oriented towards univariate definite integrals and we must solve a two-dimensional integral. When the weighting function is factorizable, this is done straightforwardly by defining a lattice of abscissae and using the Cartesian product of the weights. In the GPPM, however, the cavity distribution has nonzero mean and is not generally factorizable, so we must transform

the integrand prior to to performing Gauss-Hermite quadrature. The factorizable form can be recovered by transforming the abscissae with the inverse Cholesky decomposition of the cavity covariance matrix and the cavity mean. The Gaussian parameters resulting from these moment calculations are denoted $\hat{\boldsymbol{Z}}_n$, $\hat{\boldsymbol{\mu}}_n$, and $\hat{\boldsymbol{\Sigma}}_n$ in Section 4.1.1.

4.2. Noise-free MAP Learning

In some applications of the GPPM, it may be that the observations can be considered noise-free. For example, one may model the noise as coming exclusively from the locally-varying function $f(x)$. The appeal of this restricted model is that proposals of the non-stationarity can now be evaluated as $O(N^2)$ rather than $O(N^3)$. This is particularly valuable for finding rapid maximum *a posteriori* (MAP) estimates of the latent modulating function $g(x)$. The computational advantage in the noise-free case comes from the deterministic coupling of the latent functions, given $\boldsymbol{y}$; we can now consider the posterior of $\boldsymbol{g}$ alone:

$$p(\boldsymbol{g} \,|\, \boldsymbol{\theta}_f, \boldsymbol{\theta}_g) \propto p(\mathcal{D} \,|\, \boldsymbol{g}, \boldsymbol{\theta}_f) p(\boldsymbol{g} \,|\, \boldsymbol{\theta}_g). \tag{8}$$

In this form, conditioning on $\boldsymbol{g}$ corresponds to a simple linear transformation of the GP prior on $\boldsymbol{f}$. Using the notational shortcut $\boldsymbol{\mathcal{G}} = \mathrm{diag}([e^{g_1}, e^{g_2}, \ldots, e^{g_N}])$, the log likelihood is

$$\ln p(\mathcal{D} \,|\, \boldsymbol{g}, \boldsymbol{\theta}_f) = -\frac{1}{2} \ln |\boldsymbol{\mathcal{G}} \boldsymbol{C}_f \boldsymbol{\mathcal{G}}| - \frac{1}{2} \boldsymbol{y}^\mathsf{T} [\boldsymbol{\mathcal{G}} \boldsymbol{C}_f \boldsymbol{\mathcal{G}}]^{-1} \boldsymbol{y} - \frac{N}{2} \ln 2\pi.$$

The log posterior over $\boldsymbol{g}$, eliminating irrelevant terms and using $\mathbf{1}$ to indicate a column vector of ones, is

$$\ln p(\boldsymbol{g} \,|\, \mathcal{D}, \boldsymbol{\theta}_f, \boldsymbol{\theta}_g) = -\boldsymbol{g}^\mathsf{T} \mathbf{1} - \frac{1}{2} \boldsymbol{y}^\mathsf{T} [\boldsymbol{\mathcal{G}} \boldsymbol{C}_f \boldsymbol{\mathcal{G}}]^{-1} \boldsymbol{y} - \frac{1}{2} \boldsymbol{g}^\mathsf{T} \boldsymbol{C}_g^{-1} \boldsymbol{g} + \text{const}$$

and the gradient in terms of $\boldsymbol{g}$ is

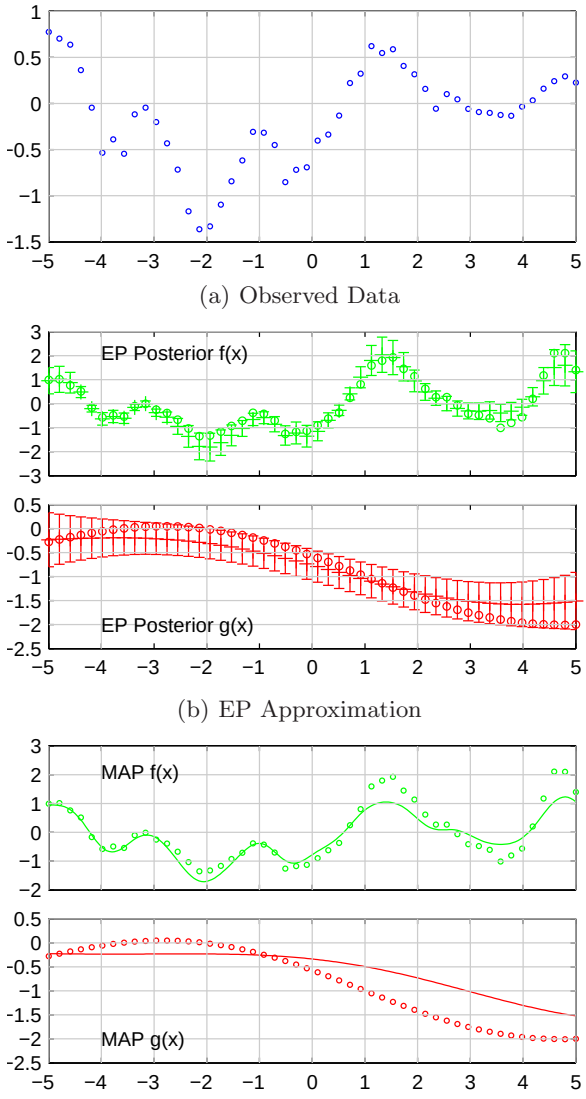
$$\frac{\partial}{\partial \boldsymbol{g}} \ln p(\boldsymbol{g} \,|\, \mathcal{D}, \boldsymbol{\theta}_f, \boldsymbol{\theta}_g) = -\mathbf{1} + \boldsymbol{Y} [\boldsymbol{\mathcal{G}} \boldsymbol{C}_f \boldsymbol{\mathcal{G}}]^{-1} \boldsymbol{y} - \boldsymbol{C}_g^{-1} \boldsymbol{g}$$

where $\boldsymbol{Y} = \mathrm{diag}(\boldsymbol{y})$. As the difficult $O(N^3)$ operations of decomposition or inversion of $\boldsymbol{C}_f$ and $\boldsymbol{C}_g$ can be done in advance, the computational complexity of taking a step in $\boldsymbol{g}$ space is $O(N^2)$. In practice, we have found the MAP estimate to be best when $f(x)$ has additive noise and $g(x)$ is smooth.

5. Making Predictions

As with the standard regression model, the primary task of interest is prediction at locations where data have not been observed. For the GPPM we must make predictions for both latent functions, and find the resulting distribution, integrating out the posterior distribution over the latent functions, as in

$$p(y^\star \,|\, \boldsymbol{x}^\star, \mathcal{D}, \boldsymbol{\theta}_f, \boldsymbol{\theta}_g) = \int_{\boldsymbol{f}, \boldsymbol{g}} p(y^\star \,|\, \boldsymbol{x}^\star, \boldsymbol{f}, \boldsymbol{g}) p(\boldsymbol{f}, \boldsymbol{g} \,|\, \mathcal{D}, \boldsymbol{\theta}_f, \boldsymbol{\theta}_g).$$



(a) Observed Data

(b) EP Approximation

(c) MAP Approximation

Figure 3. Figure 3(a) shows synthetic data generated from the GPPM with known settings and $\sigma = 0.05$. We applied the Expectation Propagation algorithm to the data and the Gaussian marginal posterior distributions over $\boldsymbol{f}$ and $\boldsymbol{g}$ are shown in Figure 3(b), along with the true $f(x)$ and $g(x)$ indicated as circles. Figure 3(c) shows the result of applying the MAP approximation to the data, despite the known observation noise. The true values are shown for comparison.

The EP scheme of Section 4.1 finds an approximate Gaussian distribution over $\boldsymbol{f}$ and $\boldsymbol{g}$, and this results in a convenient joint Gaussian distribution on $f^\star$ and $g^\star$, the values of the latent functions at $\boldsymbol{x}^\star$, with parameters

$$\boldsymbol{\mu}^\star = \boldsymbol{K}^\mathsf{T}\left(\boldsymbol{\Sigma}_{\mathsf{GP}} + \tilde{\boldsymbol{\Sigma}}\right)^{-1}\tilde{\boldsymbol{\mu}}, \quad \boldsymbol{\Sigma}^\star = \boldsymbol{\kappa} - \boldsymbol{K}^\mathsf{T}\left(\boldsymbol{\Sigma}_{\mathsf{GP}} + \tilde{\boldsymbol{\Sigma}}\right)^{-1}\boldsymbol{K},$$

where

$$\boldsymbol{K} = \begin{bmatrix} C(\boldsymbol{x}^\star, \boldsymbol{x}_1; \boldsymbol{\theta}_f) & 0 \\ C(\boldsymbol{x}^\star, \boldsymbol{x}_2; \boldsymbol{\theta}_f) & 0 \\ \vdots & \vdots \\ C(\boldsymbol{x}^\star, \boldsymbol{x}_N; \boldsymbol{\theta}_f) & 0 \\ 0 & C(\boldsymbol{x}^\star, \boldsymbol{x}_1; \boldsymbol{\theta}_g) \\ \vdots & \vdots \\ 0 & C(\boldsymbol{x}^\star, \boldsymbol{x}_N; \boldsymbol{\theta}_g) \end{bmatrix}$$

$$\boldsymbol{\kappa} = \begin{bmatrix} C(\boldsymbol{x}^\star, \boldsymbol{x}^\star; \boldsymbol{\theta}_f) & 0 \\ 0 & C(\boldsymbol{x}^\star, \boldsymbol{x}^\star; \boldsymbol{\theta}_g) \end{bmatrix}.$$

We expect that the resulting predictive distribution on $y^\star$ will be heavy-tailed and have similar properties to the noncentral Student's t distribution. To approximate the true distribution's heavy tails analytically, one approach is to generate several samples from $g^\star$ and use the conditional distribution on $f^\star$ to create a mixture of Gaussians:

$$p(y^\star \mid \boldsymbol{x}^\star, \mathcal{D}, \boldsymbol{\theta}_f, \boldsymbol{\theta}_g) \approx \sum_i \mathcal{N}(y^\star; \mu^\star_{f|g_i} e^{g^\star_i}, v^\star_{f|g_i} e^{2g^\star_i}).$$

We have used $\mu^\star_{f|g_i}$ and $v^\star_{f|g_i}$ to indicate the conditional Gaussian parameters on $f^\star$ given the ith marginal sample from $g^\star$.

If the heavy-tailed properties are not significant for the application, and a single Gaussian distribution is preferred, then a more tractable alternative is to linearize the model around the mean $\boldsymbol{\mu}^\star$. This is a similar approach to the Extended Kalman Filter (EKF) (Haykin, 2001), which uses the first terms of the Taylor series of a nonlinear function to maintain Gaussian uncertainty in latent state estimation. The resulting approximation is

$$f^\star e^{g^\star} \underset{\boldsymbol{\mu}^\star}{\approx} \mu^\star_f e^{\mu^\star_g} + \begin{bmatrix} e^{\mu^\star_g} \\ \mu^\star_f e^{\mu^\star_g} \end{bmatrix}^\mathsf{T} \begin{bmatrix} f^\star - \mu^\star_f \\ g^\star - \mu^\star_g \end{bmatrix}$$

which transforms the Gaussian on $f^\star$ and $g^\star$ into one on $y^\star$ with parameters

$$\mu^\star_y = \mu^\star_f e^{\mu^\star_g} \qquad v^\star_y = \begin{bmatrix} e^{\mu^\star_g} \\ \mu^\star_f e^{\mu^\star_g} \end{bmatrix}^\mathsf{T} \boldsymbol{\Sigma}^\star \begin{bmatrix} e^{\mu^\star_g} \\ \mu^\star_f e^{\mu^\star_g} \end{bmatrix} + \sigma^2.$$

6. Hyperparameter Learning

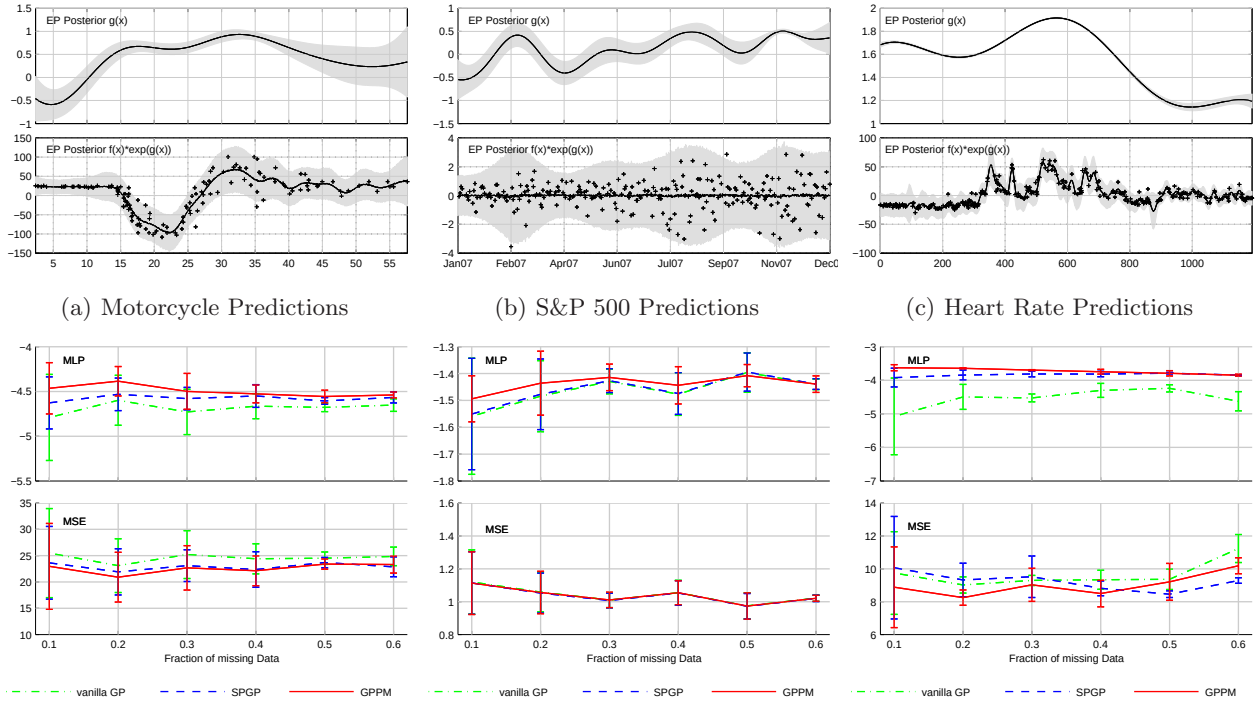
When performing Gaussian process regression, we are commonly interested in appropriate settings of the hyperparameters controlling the covariance function. These hyperparameters generally determine the length scale of correlations, the output variation (or amplitude) of the function, and the noise level. In the GPPM, we wish to find appropriate hyperparameter settings for *both* latent functions, given the data. While the vanilla Gaussian process offers the marginal likelihood analytically, it is not available directly in the GPPM. Fortunately, the EP algorithm of Section 4.1 provides a convenient estimate of the marginal likelihood, using the zeroth moments mentioned previously.

$$\ln Z_{\mathsf{EP}} = \frac{1}{2}\ln|\boldsymbol{\Sigma}| - \frac{1}{2}\ln|\boldsymbol{\Sigma}_{\mathsf{GP}}| - \frac{1}{2}\tilde{\boldsymbol{\mu}}^\mathsf{T}\tilde{\boldsymbol{\Sigma}}^{-1}\tilde{\boldsymbol{\mu}} + \frac{1}{2}\boldsymbol{\mu}^\mathsf{T}\boldsymbol{\Sigma}^{-1}\boldsymbol{\mu} + \sum_{n=1}^{N}\ln\tilde{Z}_n$$

In principle it is also possible to evaluate the gradients of $\ln Z_{\mathsf{EP}}$ with respect to hyperparameters following for instance (Seeger, 2005). In practice however, the quadrature-based moment calculation is numerically not stable enough to provide precise gradients. We hence reverted to gradient-free optimization methods to determine hyper parameter settings. We suggest setting hyperpriors to reflect the intuition described in Section 3 of $f(x)$ capturing local near-stationary variations and $g(x)$ capturing slowly varying nonstationarity on a larger lengthscale.

7. Results

We evaluated the GPPM model on three data sets. First, we examined the motorcycle data set (Parker & Rice, 1985), a well-studied example of a nonstationary regression task. The data are acceleration force in g's on a helmet during impact, as a function of time in milliseconds. Figure 4(a) in the upper plot shows the EP approximation found for the latent $g(x)$ function, and in the lower plot shows the Gaussian approximation to the predictive distribution, overlaid with the true data. The GPPM finds a good fit in most regions except where the $g(x)$ function becomes quite small. In these regions the uncertainty in the modulating function creates unrealistically large prediction error bars. We evaluated the accuracy of predictions using a fill-in test, where a fraction of the data are removed from the training set and compared to the model's predictions. Figure 4(d) depicts the mean log probability and the mean squared error for missing data as a function of the fraction of missing data. The GPPM outperforms both a vanilla GP and the sparse pseudo-input process (SPGP) (Snelson & Ghahramani, 2006) using either of the performance measures. We chose the SPGP for comparison to the GPPM, as it is one of the few



(a) Motorcycle Predictions (b) S&P 500 Predictions (c) Heart Rate Predictions

(d) Motorcycle Fill–in Performance (e) S&P Fill–in Performance (f) Heart Rate Fill–in Performance

Figure 4. Top panel: Predictive distribution of GPPM for three different data sets. The upper plot shows the EP approximation to the posterior of the log-modulating function $g(x)$ with 2σ error bars. The lower plot shows the raw data, along with the 2σ approximate predictive distribution. Lower panel: Fill-in test for corresponding data sets comparing three models. The upper plot shows the mean log probability of the missing data as a function of the fill-in rate. The lower plot shows the root mean squared error for these data. Both plots show mean values and 2σ error bars, calculated from four training/test splits.

methods capable of representing nonstationarity without requiring MCMC. Hyperparameters for the SPGP and the vanilla GP were set via ML-II optimization (Rasmussen & Williams, 2006). To set hyperparameters in the GPPM, a grid search was used, centered on the settings for the vanilla GP.

We also examined the performance of the GPPM for daily log returns of the S&P 500 stock index during 2007. We expect that these data will be well-modeled by a latent $f(x)$ comprised primarily of noise. The log modulating function $g(x)$ can be interpreted roughly as the log "volatility" of the stochastic process and is shown in the upper plot of Figure 4(b). The corresponding expected envelope is shown against the true data in the lower plot. Performance measures against the standard Gaussian process and the SPGP are shown in Figure 4(e). In this example mean predictions are equally good for three all models, but GPPM yields nonstationary uncertainty which results in an improved mean log probability.

As a last application we applied the GPPM to 23 hours of heart rate data, sampled at 5 minute intervals. Based on the physiological properties of heart rates, we expect correlations on a short time scale to be captured by $f(x)$. These local correlations will be modulated by an activity profile over a daily time scale. Figure 4(c) illustrates that these amplitude modulations are picked up by the latent $g(x)$ leading to improved predictive performance compared to the vanilla GP and SPGP, as shown in Figure 4(f).

8. Discussion

We have introduced the Gaussian process product model for modeling nonstationary amplitude in regression. We have presented an approximate inference algorithm using Expectation Propagation to infer the latent functions in this model and have exploited this approximation to make tractable predictions and enable hyperparameter learning. When examined on real-world data, the GPPM has yielded promising results, outperforming the vanilla Gaussian process. It has also outperformed an alternative approach to nonstationary regression in the SPGP, although it should be noted that the SPGP's focus is purely on efficient regression and not on modeling nonstationarity *per se*.

Computationally, the model we have presented, combined with the EP implementation has two appealing properties. First, as we expect the number of EP iterations to be independent of the number of data (Minka, 2001), and each local calculation is a $O(N^2)$ rank-one update of the inverse, the overall algorithm is $O(N^3)$. The GPPM is therefore only a constant multiple more expensive than performing standard Gaussian process regression. Second, in contrast to methods of modeling nonstationarity on the input side, the GPPM does not introduce additional latent spaces if the input dimensionality increases. The additional computational complexity of using the GPPM is essentially independent of input dimension.

In future work, a more comprehensive examination of inference of hyperparameters is warranted. We also expect that the basic idea of this model can be used to perform vector regression with correlation that varies across the input space.

Abstract

The problem of identifying the minimal gene set required to sustain life is of crucial importance in understanding cellular mechanisms and designing therapeutic drugs. This work describes several kernel-based solutions for predicting essential genes that outperform existing models while using less training data. Our first solution is based on a semi-manually designed kernel derived from the Pfam database, which includes several Pfam domains. We then present novel and general *domain-based* sequence kernels that capture sequence similarity with respect to several domains made of large sets of protein sequences. We show how to deal with the large size of the problem – several thousands of domains with individual domains sometimes containing thousands of sequences – by representing and efficiently computing these kernels using automata. We report results of extensive experiments demonstrating that they compare favorably with the Pfam kernel in predicting protein essentiality, while requiring no manual tuning.

1. Motivation

Identifying the minimal gene set required to sustain life is of crucial importance for understanding the fundamental requirements for cellular life and for selecting therapeutic drug targets. Gene knockout studies and RNA interference are experimental techniques for identifying an organism's "essential" genes, or the set of genes whose removal is lethal to the organism. However, these techniques are expensive and time-consuming. Recent work has attempted to extract from experimental knockout studies relevant features of essentiality, which aid in identifying essential genes in organisms lacking experimental results.

Several features have been proposed as indicators for essentiality, including evolutionary conservation, protein size, and number of paralogs (Chen & Xu, 2005). Using these basic features, Chen and Xu (2005) constructed a model of essentiality for *S. cerevisiae* (baker's yeast). Using Naive Bayes Classifiers (NBC), Gustafson et al. (2006) subsequently created a model of essentiality for *S. cerevisiae* and *E. coli* using an extended set of features generated from sequence data.

This work presents kernel methods to improve upon existing models. We first use several sequence kernels recently introduced by the computational biology community and show that the Pfam kernel (Ben-Hur & Noble, 2005) is most effective in selecting essential genes for *S. cerevisiae*. The Pfam kernel has recently been applied successfully in several biologically motivated learning tasks, and is generated from the Pfam database, the leading resource for storing protein family classification and protein domain data. However, the Pfam database is an ad-hoc solution relying on semi-manually tuned information.

In the second part of this work, we design general sequence kernels that produce effective similarity measures while bypassing the manual tuning of the Pfam database. We present two sequence kernels that are instances of rational kernels, a class of sequence kernels defined by weighted automata that are effective for analyzing variable-length sequences (Cortes et al., 2004). Using automata to represent and compute these ker-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

nels is crucial in order to handle the large number of Pfam domains and the size of each of domain – we work with 6190 domains with the largest domain containing over 3000 protein sequences. These novel kernels are designed from the same domain-specific data used by the Pfam library, and we show how they compare favorably to the Pfam kernel at predicting protein essentiality. They are general *domain-based* kernels that can be used in many problems in bioinformatics or other applications where similarity needs to be defined in terms of proximity to several large sets of sequences.

The remainder of the paper is organized as follows. Section 2 describes the various sequence kernels and outlines the model used to improve prediction accuracy of protein essentiality in *S. cerevisiae*. Section 3 describes and analyzes the novel rational kernels we present as alternatives to the Pfam kernel. Section 4 presents the results of extensive experiments comparing these domain-based kernels to the Pfam kernel.

2. Pfam-Based Solution

Our first model uses Support Vector Machines (SVMs) (Cortes & Vapnik, 1995) to predict protein essentiality with choices of kernels including the RBF kernel as well as three sequence kernels. In the following subsections, we define the sequence kernels, outline the experimental design, and present our first results.

2.1. Sequence Kernels

Pfam Kernel

The Pfam database is a collection of multiple sequence alignments and Hidden Markov Models (HMMs) representing many common protein domains and families. Pfam version 10.0 contains 6190 domains, and for each domain an HMM is constructed from a set of proteins experimentally determined to be part of the domain ('seed' proteins). Each HMM is trained using a manually-tuned multiple alignment of the seed proteins with gaps inserted to normalize sequence length. Once constructed, the HMM is evaluated in an ad-hoc fashion and the entire process is repeated if the alignment is deemed 'unsatisfactory.' See (Sonnhammer et al., 1997) for further details.

When applied to a test sequence, a Pfam domain HMM generates an E-value statistic that measures the likelihood of the test sequence containing the domain. Given a dataset of protein sequences, the Pfam sequence kernel matrix is constructed by representing each protein in the dataset as a vector of 6190 log E-values and computing explicit dot products from these feature vectors (Ben-Hur & Noble, 2005). The

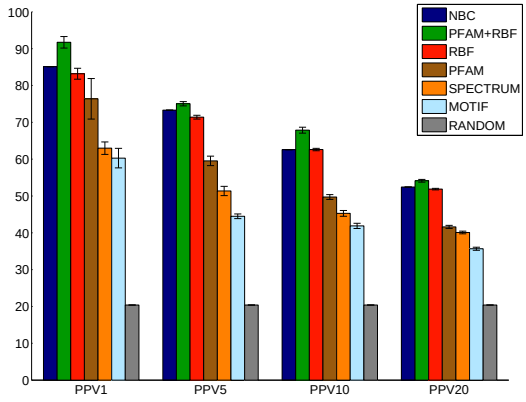

Figure 1. SVM's performance for RBF and Sequence Kernels using a reduced training set. Note that accuracy for NBC corresponds to a model trained on 50% of training data.

Pfam kernel has recently been applied successfully in learning tasks ranging from protein function (Lanckriet et al., 2004) to protein-protein interaction (Ben-Hur & Noble, 2005).

Spectrum and Motif Kernels

The Spectrum and Motif kernels are two recently proposed sequence kernels used in learning tasks to estimate protein similarity (Leslie & Kuang, 2004; Ben-Hur & Brutlag, 2003). Both kernels model a protein in a feature space of subsequences, with each feature measuring the extent to which the protein contains a specific subsequence. The Spectrum kernel models proteins in a feature space of all possible n-grams, representing each protein as a vector of n-gram counts (in our studies we set $n = 3$). Alternatively, the Motif kernel uses a feature space consisting of a set of discrete sequence motifs (we use a set of motifs extracted from the eMotif database (Ben-Hur & Noble, 2005)). For both kernels, the resulting kernel matrices are computed as an explicit dot product using these features.

2.2. Data

We used the dataset of *S. cerevisiae* proteins from Gustafson et al. (2006), consisting of 4728 yeast proteins of which 20.4% were essential. We constructed the RBF kernel matrix from a set of 16 features generated directly from protein sequences, corresponding to the 'easily attainable' features from Gustafson et al. (2006). We used data from Ben-Hur and Noble (2005) to construct the Pfam, Spectrum and Motif kernel matrices, each of which was constructed following the steps outlined in Section 2.1 and subsequently centered and normalized. In addition to the RBF and the three sequence kernels, we also used a combined Pfam/RBF

kernel, which we computed by additively combining the RBF kernel matrix with the normalized Pfam kernel matrix (RBF kernels are by definition normalized).

2.3. Experimental Design

We ran experiments with 100 trials. For each trial, we randomly chose 8.3% of the data as a training set and used the remaining points as a test set, subject to the constraint that an equal number of essential proteins were in each set.[1] We used the training set to train an SVM, and used the resulting model to make predictions on the test set in the form of probabilities of essentiality. We used libsvm's functionality (Chang & Lin, 2001) to estimate the outputs of an SVM as probabilities by fitting its results to a sigmoid function (Platt, 2000). To calculate the predicted probability of essentiality for each protein, we took the average over the predictions from each trial in which the protein appeared in the test set.

We measured the accuracy of the model for the proteins with the highest predicted probability of essentiality, using positive predictive value (PPV) as a performance indicator. Grid search was used to determine the optimal values for parameters C and gamma. Standard deviations were calculated from 10 'super-trials,' each corresponded to a 100-trial experiment described above. The Naive Bayes classifier (NBC) results were taken from Gustafson et al. (2006) and standard deviations were not reported.

2.4. First Results

Figure 1 shows SVM's performance using the set of kernels outlined above. The results show that the Pfam kernel is the most effective of the three sequence kernels at predicting essentiality. They also clearly show that the combined Pfam/RBF kernel outperforms all other models. The importance of the phyletic retention feature is a possible reason for the superior performance of the combined kernel compared with Pfam alone. As shown by Gustafson et al. (2006) and verified in our work, phyletic retention (a measure of gene conservation across species) is a powerful predictor of essentiality. This feature is used by RBF but not by Pfam (or by the domain-based kernels defined in Section 3) because it requires comparing sequences across organisms.

These results improve upon the leading model for prediction of protein essentiality while reducing the size of the training set more than five fold. Further, this is the first result showing the effectiveness of the Pfam kernel for this task, a fact that motivates the following sections of this paper, in which we seek a more general alternative to the Pfam kernel.

[1] Gustafson et al. (2006) used 50% of the data for training, but otherwise, our experimental designs are identical.

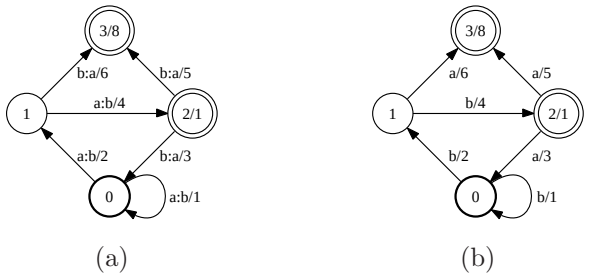

Figure 2. (a) Example of weighted transducer T. (b) Example of weighted automaton A. A can be obtained from T by projection on the output and $T(aab, bba) = A(bba) = 1 \times 2 \times 6 \times 8 + 2 \times 4 \times 5 \times 8$.

3. Domain-Based Sequence Kernels

In the previous section, we tested various sequence kernels, all introduced precisely to compute the similarity between protein sequences. Our results showed that the Pfam kernel was the most effective of these kernels, and we now aim to find a more general solution free of the manual tuning associated with the Pfam database.

Specifically, we wish to determine a method to extract similarities between protein sequences based on their similarities to several domains, each represented by a set of sequences, i.e., Pfam domains. Although several sequence kernels have been recently introduced in the machine learning community, e.g., mismatch, gappy, substitution and homology kernels (Leslie & Kuang, 2004; Eskin & Snir, 2005), none of these kernels provides a solution to our domain-based learning problem. Indeed, these kernels are not designed to efficiently compute the similarity between a string and a large set of strings, which in our case consists of 6190 Pfam domains each containing tens to thousands of sequences.

Alternatively, large sets of strings, such as the Pfam domains, can be efficiently represented by minimal deterministic automata. Hence, an efficient way to define a similarity measure between such sets is to use automata-based kernels. This leads us to consider the framework for automata-based kernels proposed by Cortes et al. (2004). An additional benefit of this framework is that most commonly used string kernels are special instances of this scheme.

3.1. Representation and Algorithms

We will follow the definitions and terminology given by Cortes et al. (2004). The representation and computation of the Domain-based kernels are based on *finite-state transducers*, which are finite automata in which each transition is augmented with an output label in addition to the familiar input label (Salomaa & Soittola, 1978). Input (output) labels are concatenated along a path to form an input (output) sequence. *Weighted transducers* are finite-state transducers in which each transition carries some weight in addition to the input and output labels. The weights of the transducers considered in this paper are real values.

Figure 2(a) shows an example of a weighted finite-state transducer. In this figure, the input and output labels of a transition are separated by a colon delimiter, and the weight is indicated after the slash separator. A weighted transducer has a set of initial states represented in the figure by a bold circle, and a set of final states, represented by double circles. A path from an initial state to a final state is an accepting path.

The weight of an accepting path is obtained by first multiplying the weights of its constituent transitions and multiplying this product by the weight of the initial state of the path (which equals one in our work) and the weight of the final state of the path (displayed after the slash in the figure). The weight associated by a weighted transducer T to a pair of strings $(x, y) \in \Sigma^* \times \Sigma^*$ is denoted by $T(x, y)$ and is obtained by summing the weights of all accepting paths with input label x and output label y. For example, the transducer of Figure 2(a) associates the weight 416 to the pair (aab, bba) since there are two accepting paths labeled with input aab and output bba: one with weight 96 and another one with weight 320.

The standard operations of sum $+$, product or concatenation $\cdot$, and Kleene-closure * can be defined for weighted transducers (Salomaa & Soittola, 1978). For any pair of strings (x, y),

$$\begin{aligned}(T_1 + T_2)(x, y) &= T_1(x, y) + T_2(x, y)\\ (T_1 \cdot T_2)(x, y) &= \sum_{\substack{x_1x_2=x\\ y_1y_2=y}} T_1(x_1, y_1) \cdot T_2(x_2, y_2). \end{aligned} \quad (1)$$

For any transducer T, T^{-1} denotes its *inverse*, that is the transducer obtained from T by swapping the input and output labels of each transition. For all $x, y \in \Sigma^*$, we have $T^{-1}(x, y) = T(y, x)$.

The *composition* of two weighted transducers T_1 and T_2 with matching input and output alphabets Σ, is a weighted transducer denoted by $T_1 \circ T_2$ when the sum:

$$(T_1 \circ T_2)(x, y) = \sum_{z \in \Sigma^*} T_1(x, z) \cdot T_2(z, y) \quad (2)$$

is well-defined and in $\mathbb{R}$ for all x, y (Salomaa & Soittola, 1978).

Weighted automata can be defined as weighted transducers A with identical input and output labels, for any transition. Since only pairs of the form (x, x) can have a non-zero weight associated to them by A, we denote the weight associated by A to (x, x) by $A(x)$ and call it the *weight associated by A to x*. Similarly, in the graph representation of weighted automata, the output (or input) label is omitted. Figure 2(b) shows an example of a weighted automaton. When A and B are weighted automata, $A \circ B$ is called the *intersection* of A and B. Omitting the input labels of a weighted transducer T results in a weighted automaton which is said to be the *output projection of T*.

3.2. Automata-Based Kernels

A string kernel $K : \Sigma^* \times \Sigma^* \to \mathbb{R}$ is *rational* if it coincides with the function defined by a weighted transducer U, that is for all $x, y \in \Sigma^*$, $K(x, y) = U(x, y)$. Not all rational kernels are *positive definite and symmetric* (PDS), or equivalently verify the Mercer condition, which is crucial for the convergence of training for discriminant classification algorithms such as SVMs. But, for any weighted transducer T, $U = T \circ T^{-1}$ is guaranteed to define a PDS kernel (Cortes et al., 2004).

Furthermore, most rational kernels used in computational biology and natural language processing are of this form (Haussler, 1999; Leslie & Kuang, 2004; Lodhi et al., 2002; Zien et al., 2000; Collins & Duffy, 2001; Cortes & Mohri, 2005). For instance, the n-gram kernel is a rational kernel. The n-gram kernel K_n is defined as

$$K_n(x, y) = \sum_{|z|=n} c_x(z)c_y(z), \quad (3)$$

where $c_x(z)$ is the number of occurrences of z in x. K_n is a PDS rational kernel since it corresponds to the weighted transducer $T_n \circ T_n^{-1}$ where the transducer T_n is defined such that $T_n(x, z) = c_x(z)$ for all $x, z \in \Sigma^*$ with $|z| = n$. The transducer T_2 for $\Sigma = \{a, b\}$ is shown in Figure 3.

We will now extend this formalism to measure the similarity between domains, or sets of strings represented by an automaton. Let us define the count of a string z in a weighted automaton A as:

$$c_A(z) = \sum_{u \in \Sigma^*} c_u(z)A(u). \quad (4)$$

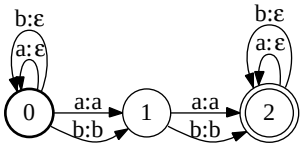

Figure 3. Counting transducer T_2 for $\Sigma = \{a, b\}$.

The similarity between two sets of strings represented by the weighted automata A and B according to n-gram kernel K_n can then be defined by:

$$\begin{aligned} K_n(A, B) &= \sum_{x,y \in \Sigma^*} (A \circ T_n \circ T_n^{-1} \circ B)(x, y) \\ &= \sum_{|z|=n} c_A(z) c_B(z). \end{aligned} \tag{5}$$

Other rational kernels can be extended into a similarity measure between sets of strings in the same way. We will now define two families of kernels that can be used in a variety of applications where similarity with respect to domains is needed.

3.3. Independent Domain Kernel

The Independent Domain kernel (IDK) measures the similarity between two sequences in our dataset $\mathcal{D}$ by comparing their similarities to each domain, e.g., Pfam domains.[2] For the i-th Pfam domain (with $1 \leq i \leq P = 6190$), let $\mathcal{P}_i$ be the set of all seed protein sequences for that domain. Each sequence in $\mathcal{P}_i$ is represented as a string in an alphabet, Σ, consisting of $|\Sigma| = 21$ characters, 20 for different amino acids plus an optional gap character used to represent gaps in the seed alignment. We denote by D_i the minimal deterministic automaton representing the set of strings $\mathcal{P}_i$. For a given sequence x in our dataset, we can use the n-gram kernel K_n to compute the similarity between x and the i-th Pfam domain $\mathcal{P}_i$: $K_n(x, D_i)$. This leads to an overall similarity measure vector $s(x) \in \mathbb{R}^P$ between x and the set of domains: $s(x) = (K_n(x, D_1), \ldots, K_n(x, D_P))$. We now define the IDK K_I as, for all x, y in Σ^*:

$$\begin{aligned} K_I(x, y) &= \sum_{i=1}^{P} K_n(x, D_i) K_n(y, D_i) \\ &= \sum_{i=1}^{P} \Big(\sum_{|z|=n} c_x(z) c_{D_i}(z) \Big) \Big(\sum_{|z|=n} c_y(z) c_{D_i}(z) \Big). \end{aligned} \tag{6}$$

K_I is PDS since it is constructed via an explicit dot-product. Any PDS kernel K with positive eigenvalues can be normalized to take values between 0 and 1 by defining K' as

$$K'(x, y) = \frac{K(x, y)}{\sqrt{K(x, x) K(y, y)}}. \tag{7}$$

We apply this normalization to K_I to account for the varying lengths of proteins in our dataset, since longer proteins will contain more n-grams and will thus tend to have more n-gram similarity with every domain.

The kernel K_I can be efficiently computed by computing $K_n(x, D_i)$ for all $1 \leq i \leq P$ as follows:

1. Compute D_i for each $\mathcal{P}_i$ by representing each sequence in $\mathcal{P}_i$ by an automaton and determinizing and minimizing the union of these automata.
2. For all $1 \leq i \leq P$ compute $T_n \circ D_i$, and for each sequence x in the dataset compute $T_n \circ X$, where X is the automaton representing x. Optimize the results by projecting onto outputs, applying epsilon-removal, determinizing and minimizing to obtain weighted automata A_i and Y_x.
3. Compute $K_n(x, D_i)$ by intersecting A_i and Y_x and using a generic single-source shortest-distance algorithm (Cortes et al., 2004) to compute the sum of all the paths in the resulting automaton.

The complexity of computing $K_n(x, D_i)$ for a fixed set of domains grows linearly in the length of x, hence the complexity of computing $K_I(x, y)$ grows linearly in the sum of the length of x and y, *i.e.* in $O(|x| + |y|)$. Thus, this kernel is efficient to compute. However, it does not capture the similarity of two sequences in as fine a way as the next kernel we present.

3.4. Joint Domain Kernel

Let us consider two sequences x and y and a given domain $\mathcal{P}_i$. Let $\mathcal{X}$ be the set of n-grams in common between x and $\mathcal{P}_i$, and $\mathcal{Y}$ the set of n-grams in common between y and $\mathcal{P}_i$. When computing the similarity between x and y according to $\mathcal{P}_i$, the IDK K_I takes into account all n-grams in common between x and $\mathcal{P}_i$ and between y and $\mathcal{P}_i$, i.e., all the n-grams in $\mathcal{X} \cup \mathcal{Y}$, regardless of whether these n-grams appear in both x and y. Thus, K_I may indicate that x and y are similar according to $\mathcal{P}_i$ even if $\mathcal{X}$ and $\mathcal{Y}$ differ significantly, or in other words, even if x and y are similar to $\mathcal{P}_i$ for different reasons. In contrast, the Joint Domain kernel (JDK) only takes into consideration the n-grams in common to x, y and $\mathcal{P}_i$, that is the n-grams in $\mathcal{X} \cap \mathcal{Y}$, when determining the similarity between x and y. It will thus declare x and y similar according to $\mathcal{P}_i$ iff x and y are similar to $\mathcal{P}_i$ for the same reason.

[2]Both the IDK and spectrum kernels represent sequences as vectors of n-gram counts but only the IDK accounts for the n-gram spectrums of the domains of interest.

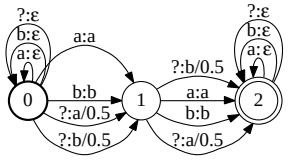

Figure 4. Counting transducer $\overline{T}_2$ with $\Sigma = \{a, b\}$, '?' representing the gap symbol and an expansion penalty weight of 0.5.

For each domain $\mathcal{P}_i$, the JDK defines a kernel K_i that measures the similarity between two sequences x and y according to $\mathcal{P}_i$, using as a similarity measure the count of the n-grams in common among x, y and $\mathcal{P}_i$. More precisely, we define $K_i : \Sigma^* \times \Sigma^* \to \mathbb{R}$ as follows:

$$K_i(x, y) = \sum_{|z|=n} c_x(z) c^2_{D_i}(z) c_y(z). \tag{8}$$

Each K_i is normalized as shown in Equation 7. We then combine these P kernels to obtain the kernel $K_J : \Sigma^* \times \Sigma^* \to \mathbb{R}$ defined as follows:

$$\begin{aligned} K_J(x, y) &= \sum_{i=1}^{P} K_i(x, y) \\ &= \sum_{i=1} \sum_{|z|=n} c_x(z) c^2_{D_i}(z) c_y(z). \end{aligned} \tag{9}$$

We will now show that each K_i and thus K_J is a PDS rational kernel. Let A_i be the weighted automata obtained by composing D_i with T_n and projecting the result onto its output: $A_i = \pi_2(D_i \circ T_n)$. From the definition of T_n, it follows that $A_i(z) = c_{D_i}(z)$ and $c_x(z) = T_n(x, z)$ for all $|z| = n$. Thus, for all (x, y), $K_i(x, y)$ can be rewritten as:

$$\begin{aligned} K_i(x, y) &= \sum_{|z|=n} T_n(x, z) A_i(z) A_i(z) T_n(y, z) \\ &= (T_n \circ A_i \circ A_i \circ (T_n)^{-1})(x, y). \end{aligned} \tag{10}$$

Observe that $(T_n \circ A_i)^{-1} = A_i^{-1} \circ T_n^{-1} = A_i \circ T_n^{-1}$ since for an automaton the inverse A_i^{-1} coincides with A_i. Thus, $K_i(x, y) = \big((T_n \circ A_i) \circ (T_n \circ A_i)^{-1}\big)(x, y)$, which is of the form $T \circ T^{-1}$ and thus K_i is PDS. Since PDS kernels are closed under sum, K_J is also PDS.

The computation of the kernel K_J is more costly than that of K_I since a full $D \times D$ kernel matrix needs to be computed for each Pfam domain. This leads to $D^2 \times P$ rational kernel computations to compute K_J, compared to only $D \times P$ rational kernel computations for K_I. This is significant when $P = 6190$. Thus, it is important to determine an efficient way to compute the kernels K_i. The following is an efficient method for computing K_J that we adopt in our experiments, in which the complexity of computing $K_J(x, y)$ for a fixed set of domains linearly depends on the product of the length of x and y, *i.e.* in $O(|x||y|)$:

1. Compute each A_i and optimize using epsilon-removal, determinization and minimization.
2. For each sequence x in the dataset, compute $Y_x = \pi_2(T_n \circ X)$ where X is the automaton representing x and optimize Y_x using epsilon-removal, determinization and minimization.
3. $K_i(x, y)$ is obtained by computing $A_i \circ Y_x$ and $A_i \circ Y_y$, computing the intersection of the resulting automata and using a generic single-source shortest-distance algorithm (Cortes et al., 2004) to compute the sum of all paths in the resulting automaton.

Gap Symbol Handling

The sequence alignments in the Pfam domain ($\mathcal{P}_i$) contain a gap symbol used to pad the alignments. In the previous two sections, we either ignored the gap symbol (when dealing with raw sequence data) or treated it as a regular symbol (when dealing with aligned sequences). In the latter case, since this symbol does not appear in the sequences in the dataset, the result is that all n-grams containing the gap symbol are ignored during the computation of K_I and K_J.

Alternatively, we can treat the gap symbol as a wildcard, allowing it to match any regular symbol. This can be achieved by modifying the transducer T_n to match any gap symbol on its input to any regular symbol on its output (these transitions can also be assigned a weight to penalize gap expansion). We denote by $\overline{T}_n$ the resulting transducer and replace T_n by $\overline{T}_n$ when composing with D_i. Figure 4 shows $\overline{T}_2$ for $|\Sigma| = \{a, b\}$ with the symbol '?' representing the gap symbol and an expansion penalty weight of 0.5.

3.5. Domain Kernels Based on Moments of Counts

Although counting common n-grams leads to informative kernels, this technique affords a further generalization that is particularly suitable when defining kernels for domains. We can view the sum of the counts of an n-gram in a domain as its average count after normalization. One could extend this idea to consider higher moments of the counts of an n-gram, as this could capture useful information about how similarity varies across the sequences within a single domain.

Remarkably, it is possible to design efficiently computable domain kernels based on these quantities by

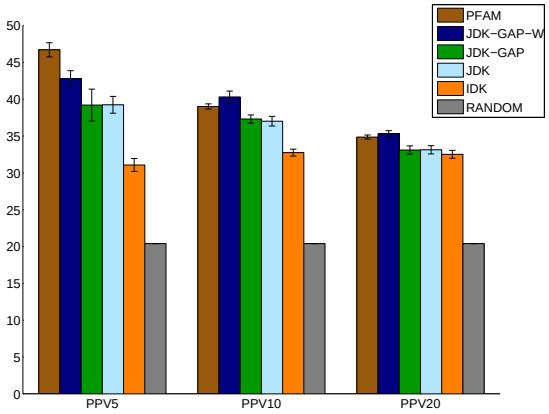

Figure 5. SVM's performance with various kernels averaged over all datasets.

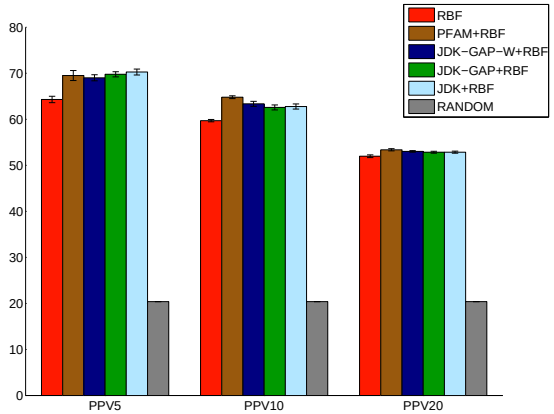

Figure 6. SVM's performance with various kernels combined with RBF kernel averaged over all datasets.

generalizing the domain kernels from Sections 3.3 and 3.4 in a way similar to what is described by Cortes and Mohri (2005). Let m be a positive integer. We can define the *m-th moment of the count* of the sequence z in a weighted automata A, denoted by $c_{A,m}(z)$, as:

$$c_{A,m}(z) = \sum_{u \in \Sigma^*} c_u^m(z) A(u). \tag{11}$$

Both of our kernel families can then be generalized to a similarity measure based on the m-th moment of the n-gram counts as follows:

$$K_m^I(x,y) = \sum_{i=1}^{P} \Big(\sum_{|z|=n} c_{x,m}(z) c_{D_i,m}(z) \Big) \Big(\sum_{|z|=n} c_{y,m}(z) c_{D_i,m}(z) \Big)$$

$$K_m^J(x,y) = \sum_{i=1} \sum_{|z|=n} c_{x,m}(z) c_{D_i,m}^2(z) c_{y,m}(z).$$

These kernels can be efficiently computed by using, in place of T_n, a transducer T_m^n that can be defined such that $T_m^n(x,z) = (c_x(z))^m = c_{x,m}(z)$ for all $x, z \in \Sigma^*$ with $|z| = n$.

4. Experimental Results

We evaluated the domain-based kernels described in Section 3 (with $n = 3$) using an experimental design similar to Section 2.3. In order to test these kernels under various conditions, we chose to work with datasets sampled from the yeast dataset used in Section 2. We constructed 10 datasets, each containing 500 sampled data points randomly chosen from the 4728 initial points, subject to the constraint that we maintained the same ratio of positively and negatively labeled points. We worked on a large cluster machines and used the OpenFst and OpenKernel libraries to construct similarity matrices for each sample dataset for varying kernels (Allauzen et al., 2007; Allauzen & Mohri, 2007). Generating similarity matrices took less than 30 minutes for IDK, 1 hour for JDK, and 2.5 hours for JDK with gaps treated as wildcards. We do not show results for the top 1% since it is an unreliable statistic when working with 500 points. In all reported results we exclude results from one sampled dataset that generated pathological results for all sequence kernels.

Figure 5 shows the average prediction performance over the sampled datasets for various kernels. The figure shows that the average performance of the JDK with gaps treated as wildcards (JDK-GAPS-W) is slightly better than the Pfam kernel, as it outperforms the Pfam kernel for the top 10% and 20% predictions. The figure also presents results for variants of the JDK that either ignore gaps in the seed alignment (JDK) or treat them as a distinct symbol (JDK-GAPS). The results show that, regardless of the treatment of gaps, the JDK drastically outperforms the IDK.

Based on these results, we next tested the effectiveness of the JDK combined with the RBF kernel. Similar to the results in Figure 1, average prediction performance over the sampled datasets was better using combination kernels in contrast to any kernel alone.[3] Figure 6 shows that the combined JDK is comparable to the combined Pfam kernel. Further, in contrast to the results in Figure 5, the treatment of gaps by the JDK does not significantly alter prediction efficiency. In other words, the JDK is able to match the best results of the Pfam kernel using only raw Pfam sequence data (JDK), while completely ignoring the hand-curated multiple sequence alignments that are vital to parameterizing the HMMs of the Pfam Library. We did not perform experiments using higher moments of the count, as described in Section 3.5, though we suspect

[3] As in Figure 1, RBF alone outperforms all sequence kernels alone, possibly due to the phyletic retention feature.

that these more refined kernels would lead to further improvements over the Pfam kernel.

5. Conclusion

We presented novel domain-based sequence kernels that require no hand-crafted information, in contrast to the Pfam kernel. The joint domain kernels we defined were shown to match or outperform the best previous results for predicting protein essentiality. These kernels and their generalization based on moments of counts can be used for any application requiring similarity between sequences that may be extracted from proximity to several large sequence domains. In bioinformatics, such applications may include remote homology prediction, subcellular localization, and prediction of protein-protein interaction.

Abstract

The kernel stick-breaking process (KSBP) is employed to segment general imagery, imposing the condition that patches (small blocks of pixels) that are spatially proximate are more likely to be associated with the same cluster (segment). The number of clusters is not set *a priori* and is inferred from the hierarchical Bayesian model. Further, KSBP is integrated with a shared Dirichlet process prior to simultaneously model multiple images, inferring their inter-relationships. This latter application may be useful for sorting and learning relationships between multiple images. The Bayesian inference algorithm is based on a hybrid of variational Bayesian analysis and local sampling. In addition to providing details on the model and associated inference framework, example results are presented for several image-analysis problems.

1. Introduction

The segmentation of general imagery is a problem of long-standing interest. There have been numerous techniques developed for this purpose, including K-means and associated vector quantization methods (Ding & He, 2004), statistical mixture models (McLachlan & Basford, 1988), as well as spectral clustering (Ng et al., 2001). This list of existing methods is not exhaustive, although these methods share attributes associated with most existing algorithms. First, the clustering is based on the features of the image, and when clustering these features one typically does not account for their physical location within the image (although the location may be appended as a feature component). Secondly, the segmentation or clustering of images is typically performed one image at a time, and therefore there is no attempt to relate the segments of one image to segments in other images (*i.e.*, to learn inter-relationships between multiple images). Finally, in many of the techniques cited above one must *a priori* set the number of anticipated segments or clusters. The techniques developed in this paper seek to perform clustering or segmentation in a manner that explicitly accounts for the physical locations of the features within the image, and multiple images are segmented simultaneously (termed "multi-task learning") to infer their inter-relationships. Moreover, the analysis is performed in a semi-parametric manner, in the sense that the number of segments or clusters is not set *a priori*, and is inferred from the data. There has been recent research wherein spatial information has been exploited when clustering (Figueiredo et al., 2007), but that segmentation has been performed one image at a time, and therefore not in a multi-task setting.

To address the goals elucidated above within a statistical setting, we employ a class of hierarchical models related to the Dirichlet process (DP) (Ferguson, 1973). The Dirichlet process is a statistical prior that may be summarized succinctly as follows. Assume that the n-th patch is represented by feature vector $\boldsymbol{x}_n$, and the total image is composed of N such feature vectors $\{\boldsymbol{x}_n\}_{n=1,N}$. The feature vector associated with each patch is assumed drawn from a parametric distribution $f(\phi_n)$, where ϕ_n represents the parameters associated with the n-th feature vector. A DP prior can be placed on ϕ_n, which is characterized by the non-negative parameter α and the "base" distribution G_o. We adopt the stick-breaking construction developed by Sethuraman (Sethuraman, 1994), and the hierarchical model may be expressed as

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

$$
\begin{aligned}
\boldsymbol{x}_n|\phi_n &\overset{ind}{\sim} f(\phi_n) \\
\phi_n|G &\overset{iid}{\sim} G \\
G &= \sum_{h=1}^{\infty} \pi_h \delta_{\theta_h} \\
\pi_h &= V_h \prod_{l=1}^{h-1} (1 - V_l) \\
V_h &\overset{iid}{\sim} Beta(1, \alpha) \\
\theta_h &\overset{iid}{\sim} G_o.
\end{aligned} \tag{1}
$$

This is termed a "stick-breaking" representation of DP because one sequentially breaks off "sticks" of length π_h from an original stick of unit length ($\sum_{h=1}^{\infty} \pi_h = 1$). As a consequence of the properties of the distribution $Beta(1, \alpha)$, for relatively small α it is likely that only a relatively small set of sticks π_h will have appreciable weight/size, and therefore when drawing parameters ϕ_n from the associated G it is probable multiple ϕ_n will share the same "atoms" θ_h (those associated with the large-amplitude sticks). The parameter α therefore plays an important role in defining the number of clusters that are constituted, and therefore in practice one typically places a non-informative Gamma prior on α (Xue et al., 2007).

The form of the model in (1) imposes the prior belief that the feature vectors $\{\boldsymbol{x}_n\}_{n=1,N}$ associated with an image should cluster, and the data are used to infer the most probable clustering distribution, via the posterior distribution on the parameters $\{\phi_n\}_{n=1,N}$. Such semi-parametric clustering has been studied successfully in many settings (Xue et al., 2007; Rasmussen, 2000). However, there are two limitations of such a model, with these defining the focus of this paper. First, while the model in (1) captures our belief that the feature vectors should cluster, it does not impose our additional belief that the probability that two feature vectors are in the same cluster should increase as their physical locations within the image become more proximate; this is an important factor when one is interested in segmenting an image into contiguous regions. Secondly, typical semi-parametric clustering has been performed one image or dataset at a time, and here we wish to cluster multiple images simultaneously, to infer the inter-relationships between clusters in different images, thereby inferring the inter-relationships between the associated multiple images themselves.

As an extension of the DP-based mixture model, we here consider the recently developed kernel stick-breaking process (KSBP) (Dunson & Park, 2008), introduced by Dunson and Park. As detailed below, this model is similar to that in (1), but now the stick-breaking process is augmented to employ a kernel function to quantify the prior belief associated with spatially proximate patches. In (Dunson & Park, 2008) a Markov chain Monte Carlo (MCMC) sampler was used to estimate the posterior on the model parameters. In the work considered here we are interested in relatively large data sets, and therefore we develop an inference engine that exploits ideas from variational Bayesian analysis (Beal, 2003).

There are problems for which one may wish to perform segmentation on multiple images simultaneously, with the goal of inferring the inter-relationships between the different images. This is referred to as multi-task learning (MTL) (Thrun & O'Sullivan, 1996; Xue et al., 2007), where here each "task" corresponds to clustering feature vectors from a particular image. As presented below, it is convenient to simultaneously cluster/segment multiple images by linking the multiple associated KSBP models with an overarching DP. There are at least three applications of MTL in the context of image analysis: (i) one may have a set of images, some of which are labeled, and others of which are unlabeled, and by performing an MTL analysis on all of the images one may infer labels for the unlabeled image segmentation, by drawing upon the relationships to the labeled imagery; (ii) by inferring the inter-relationships between the different images, one may sort the images as well as sort components within the images; (iii) one may identify abnormal images and locations within an image in an unsupervised manner, by flagging those locations that are allocated to a segmentation component that is locally rare. A similar scenario has been studied in (Sudderth et al., 2006), where the spatial translations are handled with transformed Dirichlet processes.

2. Kernel Stick-Breaking Process

2.1. KSBP prior for image processing

The stick-breaking representation of the Dirichlet process (DP) was summarized in (1), and this has served as the basis of a number of generalizations of the DP. The dependent DP (DDP) proposed by MacEachern (MacEachern, 1999) assumes a fixed set of weights, $\boldsymbol{\pi}$, while allowing the atoms $\theta = \{\theta_1, \cdots, \theta_N\}$ to vary with the predictor $\boldsymbol{x}$ according to a stochastic process. Dunson and Park (Dunson & Park, 2008) have proposed the kernel stick-breaking process (KSBP), which is particularly attractive for image-processing applications. Rather than simply considering the feature vector $\{\boldsymbol{x}_n\}_{n=1,N}$, we now consider $\{\boldsymbol{x}_n, \boldsymbol{r}_n\}_{n=1,N}$, where $\boldsymbol{r}_n$ is tied to the location of the pixel or block of pixels used to constitute feature vector $\boldsymbol{x}_n$. We let $K(\boldsymbol{r}, \boldsymbol{r}', \psi) \rightarrow [0, 1]$ define a bounded kernel function with parameter ψ, where $\boldsymbol{r}$ and $\boldsymbol{r}'$ represent general locations in the image of interest. One may choose to place a prior on the kernel parameter ψ; this issue is revisited be-

low. A draw $G_{\boldsymbol{r}}$ from a KSBP prior is a function of position $\boldsymbol{r}$, and is represented as

$$\begin{aligned} G_{\boldsymbol{r}} &= \sum_{h=1}^{\infty} \pi_h(\boldsymbol{r}; V_h, \Gamma_h, \psi)\delta_{\theta_h} \\ \pi_h(\boldsymbol{r}; V_h, \Gamma_h, \psi) &= V_h K(\boldsymbol{r}, \Gamma_h, \psi) \textstyle\prod_{l=1}^{h-1}[1 - V_l K(\boldsymbol{r}, \Gamma_l, \psi)] \\ V_h &\overset{iid}{\sim} Beta(a, b) \\ \Gamma_l &\overset{iid}{\sim} H \\ \theta_h &\overset{iid}{\sim} G_o. \end{aligned} \tag{2}$$

Dunson and Park (Dunson & Park, 2008) prove the validity of $G_{\boldsymbol{r}}$ as a probability measure. Comparing (1) and (2), both priors take the general form of a stick-breaking representation, while the KSBP prior possesses several interesting properties. For example, the stick weights $\pi_h(\boldsymbol{r}; V_h, \Gamma_h, \psi)$ are a function of $\boldsymbol{r}$. Therefore, although the atoms $\{\theta_h\}_{h=1,\infty}$ are the same for all $\boldsymbol{r}$, the weights effectively shift the probabilities of different θ_h based on $\boldsymbol{r}$. The basis functions Γ_h serve to localize in the space of $\boldsymbol{r}$ regions (clusters) in which the weights $\pi_h(\boldsymbol{r}; V_h, \Gamma_h, \psi)$ are relatively constant, with the size of these regions tied to the kernel parameter ψ.

If $f(\phi_n)$ is the parametric model (with parameter ϕ_n) responsible for the generation of $\boldsymbol{x}_n$, we now assume that the augmented data $\{\boldsymbol{x}_n, \boldsymbol{r}_n\}_{n=1,N}$ are generated as

$$\begin{aligned} \boldsymbol{x}_n &\overset{ind}{\sim} f(\phi_n) \\ \phi_n &\overset{ind}{\sim} G_{\boldsymbol{r}_n} \\ G_{\boldsymbol{r}} &\sim KSBP(a, b, \psi, G_o, H). \end{aligned} \tag{3}$$

The notation $G_{\boldsymbol{r}} \sim KSBP(a, b, \psi, G_o, H)$ is meant to convey that $G_{\boldsymbol{r}}$ is drawn *one* time from the KSBP, and is a parametric function of location $\boldsymbol{r}$, and it is evaluated at specific locations $\{\boldsymbol{r}_n\}_{n=1,N}$.

The generative model in (3) states that two feature vectors that come from the same region in the image (defined via $\boldsymbol{r}$) will have similar $\pi_h(\boldsymbol{r}; V_h, \Gamma_h, \psi)$, and therefore they are likely to share the same atoms θ_h. The settings of a and b control how much similarity there will be in drawn atoms for a given spatial cluster centered about a particular Γ_h. If we set $a = 1$ and $b = \alpha$, analogous to the DP, small concentration parameter α and/or small kernel parameter ψ will impose that π_h is likely to be near one, and therefore only a relatively small number of atoms θ_h are likely to be dominant for a given cluster spatial center Γ_h. On the other hand, if two features are generated from distant parts of a given image, the associated atoms θ_h that may be prominent for each feature vector are likely to be different, and therefore it is of relatively low probability that these feature vectors would have been generated via the same parameters ϕ. It is possible that the model may infer two distinct and widely separated clusters/segments with similar parameters (atoms); if the G_o within the KSBP is itself drawn from a DP, as it will be below when analyzing multiple images, widely separated clusters may share the exact same atoms.

For the case $a = 1$ and $b = \alpha$, which we consider below, we employ the notation $G_{\boldsymbol{r}} \sim KSBP(\alpha, \psi, G_o, H)$. Below we will also assume that $f(\phi)$ corresponds to a multivariate Gaussian distribution.

2.2. Spatial correlation properties

As indicated above, the functional form of the kernel function is important and needs to be chosen carefully. A commonly used kernel is given as $K(\boldsymbol{r}, \Gamma, \psi) = \exp(-\psi\|\boldsymbol{r} - \Gamma\|^2)$ for $\psi > 0$, which allows the associated stick weight to change continuously from $V_h \prod_{l=1}^{h-1}(1-V_l)$ to 0 conditional on the distance between $\boldsymbol{r}$ and Γ. By choosing a kernel we are also implicitly imposing the dependency between the priors of two samples, $G_{\boldsymbol{r}}$ and $G_{\boldsymbol{r}'}$. Specifically, both priors are encouraged to share the same atoms θ_h if $\boldsymbol{r}$ and $\boldsymbol{r}'$ are close, with this discouraged otherwise. Dunson and Park (Dunson & Park, 2008) derive the correlation coefficient between two probability measures $G_{\boldsymbol{r}}$ and $G_{\boldsymbol{r}'}$ to be

$$\begin{aligned} &corr\{G_{\boldsymbol{r}}, G_{\boldsymbol{r}'}\} \\ &= \frac{\sum_{h=1}^{\infty} \pi_h(\boldsymbol{r}; V_h, \Gamma_h, \psi)\pi_h(\boldsymbol{r}'; V_h, \Gamma_h, \psi)}{\sqrt{\sum_{h=1}^{\infty} \pi_h(\boldsymbol{r}; V_h, \Gamma_h, \psi)^2}\sqrt{\sum_{h=1}^{\infty} \pi_h(\boldsymbol{r}'; V_h, \Gamma_h, \psi)^2}}. \end{aligned}$$

The coefficient approaches unity in the limit as $\boldsymbol{r} \to \boldsymbol{r}'$. Since the correlation is a strong function of the kernel parameter ψ, below we will consider a distinct ψ_h for each stick. This implies that the spatial extent within the image over which a given stick is important will vary as a function of the stick (to accommodate textural regions of different sizes).

3. Multi-Task Image Segmentation with a Hierarchical KSBP

We now consider the problem for which we wish to jointly segment M images, where each image has an associated set of feature vectors with location information, in the sense discussed above. Aggregating the data across the M images, we have the set of feature vectors $\{\boldsymbol{x}_{nm}, \boldsymbol{r}_{nm}\}_{n=1,N_m;\ m=1,M}$. The image sizes may be different, and therefore the number of feature vectors N_m may vary between images. The premise of the model discussed below is that the cluster or segment characteristics may be

similar between multiple images, and the inference of these inter-relationships may be of value. Note that the assumption is that sharing of clusters may be of relevance for the feature vectors, but not for the associated locations.

3.1. Model

A relatively simple means of sharing feature-vector clusters between the different images is to let each image be processed with a separate $KSBP(\alpha_m, \psi_m, G_m, H_m)$. To achieve the desired sharing of feature-vector clusters between the different images, we impose that $G_m \equiv G$ and G is drawn $G \sim DP(\gamma, G_o)$. Recalling the stick-breaking form of a draw from $DP(\gamma, G_o)$, we have $G = \sum_{h=1}^{\infty} \pi_h \delta_{\theta_h}$, in the sense summarized in (1). The discrete form of G is very important, for it implies that the different $G_{\boldsymbol{r}}$ will share the same set of discrete atoms $\{\theta_h\}_{h=1,\infty}$. It is interesting to note that for the case in which the kernel parameter ψ is set such that $K(\boldsymbol{r}, \Gamma_h, \psi) \rightarrow 1$, the hierarchical KSBP (H-KSBP) model reduces to the hierarchical Dirichlet process (HDP) (Teh et al., 2005).

Therefore, the H-KSBP model is represented as

$$\begin{aligned} \boldsymbol{x}_{nm} &\overset{ind}{\sim} \mathcal{N}(\phi_{nm}) \\ \phi_{nm} &\overset{ind}{\sim} G_{\boldsymbol{r}_{nm}} \\ G_{\boldsymbol{r}} &\sim KSBP(\alpha_m, \psi_m, G, H_m) \\ G &\sim DP(\gamma, G_o), \end{aligned} \tag{4}$$

where $\mathcal{N}(\cdot)$ is a Gaussian distribution. Assume that G is composed of the atoms $\{\theta_h\}_{h=1,\infty}$, from the perspective of the stick-breaking representation in (1). These same atoms are shared across all $\{G_{\boldsymbol{r}_{nm}}\}_{n=1,N_m;m=1,M}$ drawn from the associated KSBPs, but with respective stick weights unique to the different images, and a function of position within a given image. The posterior inference allows one to infer which clusters of features are unique to a particular image, and which clusters are shared between multiple images. The density functions H_m are tied to the support of the m-th image, and in practice this is set as uniform across the image extent. The distinct α_m, for each of which a Gamma hyper-prior may be imposed, encourages that the number of clusters (segments) may vary between the different images, although one may simply wish to set $\alpha_m = \alpha$ for all M tasks.

For notational convenience, in (4) it was assumed that the kernel parameter ψ_m varied between tasks, but was fixed for all sticks within a given task; this is overly restrictive. In the implementation that follows the parameter ψ_{hm} may vary across tasks *and* across the task-specific KSBP sticks.

3.2. Posterior inference

For inference purposes, we truncate the number of sticks in the KSBP to T, and the number of sticks in the truncated DP to K (the truncation properties of the stick-breaking representation of DP are discussed in (Ishwaran & James, 2001), although we emphasize that when truncating KSBP one must take into account the draws from the Beta distribution *and* the properties of the kernel, to assure that the truncated set of sticks sum to one). Due to the discreteness of $G = \sum_{k=1}^{K} \beta_k \delta_{\theta_k}$, each draw of the KSBP, $G_{\boldsymbol{r}_{nm}} = \sum_{h=1}^{T} \pi_{hm} \delta_{\phi_{hm}}$, can only take atoms $\{\phi_{hm}\}_{h=1,T;\, m=1,M}$ from K unique possible values $\{\theta_k\}_{k=1,K}$; when drawing atoms ϕ_{hm} from G, the respective probabilities for $\{\theta_k\}_{k=1,K}$ are given by $\{\beta_k\}_{k=1,K}$, and for a given $\boldsymbol{r}_{nm}$ the respective probabilities for different $\{\phi_{hm}\}_{h=1,T;\, m=1,M}$ are defined by $\{\pi_{hm}\}_{h=1,T;\, m=1,M}$. In order to reflect the correspondences between the data and atoms explicitly, we further introduce two auxiliary indicator variables. One is z_{nm}, this indicating which stick of the KSBP the feature vector $\boldsymbol{x}_{nm}$ is associated, and the other is t_{hm}, this indicating which mixing component θ_k the atom ϕ_{hm} is associated with.

With this specification we can represent our H-KSBP mixture model via a stick-breaking characterization. A graphical representation of the proposed H-KSBP model is provided in Figure 1.

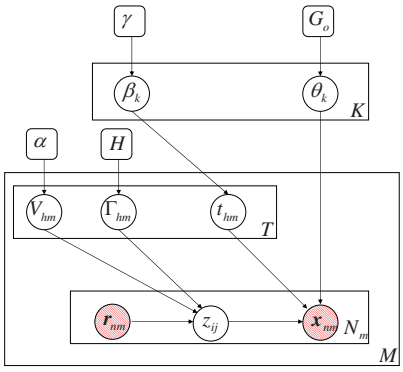

Figure 1. A graphical representation of the H-KSBP mixture model.

For the large-scale problems of interest here we employ variational Bayesian (VB) inference, which has proven to be a relatively fast (compared to MCMC) and accurate inference tool for many models and applications (Beal, 2003; Blei & Jordan, 2004). To employ VB, a conjugate prior is required for all variables in the model. In the proposed model, we however cannot obtain a closed form for the variational posterior distribution of the node V_{hm}, because of the the kernel function. Alternatively, motivated by

the Monte Carlo Expectation Maximization (MCEM) algorithm (Wei & Tanner, 1990), we develop a Monte Carlo Variational Bayesian (MCVB) inference algorithm, where the intractable nodes are approximated with Monte Carlo samples from their conditional posterior distributions. The resulting algorithm combines the benefits of both MCMC and VB, and has proven to be effective for the examples we have considered (some of which are presented here).

Given the H-KSBP mixture model detailed in Section 3.1, we can follow standard variational Bayesian inference (Beal, 2003) to infer the variables of interests. All the updates are analytical except for V_{hm}, which is estimated with the samples from its conditional posterior distributions. Due to the limited space, we only consider the update for V_{hm}. To obtain the conditional posterior distribution of V_{hm}, we rewrite $z_{nm} = min\{h : A_{nm,h} = B_{nm,h} = 1\}$, with two auxiliary variables defined as: $A_{nm,h} \sim Bernoulli(V_{hm})$ and $B_{nm,h} \sim Bernoulli(K(\boldsymbol{r}_{nm}, \Gamma_{hm}, \psi_m))$.

The conditional posterior distributions of V_{hm} are

$$Beta(1 + \sum_{n:z_{nm} \geq h} A_{nm,h}, \alpha + \sum_{n:z_{nm} \geq h} (1 - A_{nm,h})),$$

where

$$p(A_{nm,h} = B_{nm,h} = 0) = \frac{(1-V_{hm})(1-K(\boldsymbol{r}_{nm},\Gamma_{hm},\psi_m))}{1-V_{hm}K(\boldsymbol{r}_{nm},\Gamma_{hm},\psi_m)}$$
$$p(A_{nm,h} = 0, B_{nm,h} = 1) = \frac{(1-V_{hm})K(\boldsymbol{r}_{nm},\Gamma_{hm},\psi_m)}{1-V_{hm}K(\boldsymbol{r}_{nm},\Gamma_{hm},\psi_m)}$$
$$p(A_{nm,h} = 1, B_{nm,h} = 0) = \frac{V_{hm}(1-K(\boldsymbol{r}_{nm},\Gamma_{hm},\psi_m))}{1-V_{hm}K(\boldsymbol{r}_{nm},\Gamma_{hm},\psi_m)},$$

for $h = 1, 2, \cdots, z_{nm} - 1$, and $A_{nm,h} = B_{nm,h} = 1$ for $h = z_{nm}$.

The hyper-parameters α, γ, and $\boldsymbol{\psi}$ are assumed to be constant for inference of the other parameters. However, since the model performance may be sensitive to the settings of those hyper-parameters, we can relax this assumption by placing non-informative priors. The updates are straightforward (Beal, 2003) and therefore omitted here.

3.3. Convergence

To monitor the convergence of our MCVB algorithm, we compute the lower bound of the log model evidence at each iteration. Because of the sampling of some variables, the lower bound does not in general increase monotonically, but we observed in all experiments that the lower bound increases sequentially for the first several iterations, with generally small fluctuations after it has converged to the local optimal solution.

4. Experimental Results

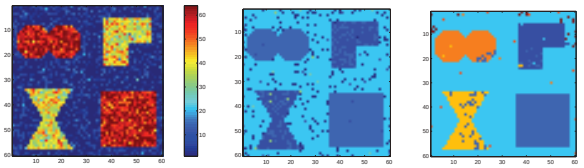
We have applied the H-KSBP multi-task image-segmentation algorithm to both synthetic and real images. We first present results on synthesized imagery, wherein we compare KSBP-based clustering of a single image with associated DP-based clustering. We then consider H-KSBP as applied to actual imagery, taken from a widely utilized database. The hyper-priors in the model for the examples are set as follows: Gamma priors, $G(\tau_{10}, \tau_{20})$ and $G(\tau_{30}, \tau_{40})$, for α and γ with parameter $\tau_{10} = 1e^{-2}$, $\tau_{20} = 1e^{-2}$, $\tau_{30} = 3e^{-2}$, $\tau_{40} = 3e^{-2}$, respectively; a normal-Wishart prior, $N(\boldsymbol{\mu}_k|\boldsymbol{\mu}_0, \eta_0\boldsymbol{\Sigma}_k)W(\boldsymbol{\Sigma}_k|w_*, \boldsymbol{\Sigma}_*)$, conjugate to the Gaussian distribution with $\boldsymbol{\mu}_0 = \mathbf{0}$, $\eta_0 = 1$, $w_* = d + 2$, $\boldsymbol{\Sigma}_* = 5 \times \boldsymbol{I}$; the discrete priors for $\boldsymbol{\Gamma}$ and $\boldsymbol{\psi}$ with uniform weights over all candidates. The stick-breaking truncations are $K = 40, T = 40$.

4.1. Single image segmentation

In this simple illustrative example, each feature vector is associated with a particular pixel, and the feature is simply a real number, corresponding to its intensity; the pixel location is the auxiliary information within the KSBP, while this information is not employed by the DP-based segmentation algorithm. Figure 2 shows the original image and the segmentation results of both algorithms. In Figure 2(a) we note that there are five contiguous regions for which the intensities are similar. There is a background region with a relatively fixed intensity, and within this are four distinct contiguous sub-regions, and of these there are pairs for which the intensities are comparable. The data in Figure 2(a) were generated as follows. Each pixel in each region is generated independently as a draw from a Gaussian distribution; the standard deviation of each of the Gaussians is 10, and the background has mean intensity 5, and the two pairs are generated with mean intensities of 40 and 60. The color bar in Figure 2(a) denotes the pixel amplitudes. The DP and KSBP segmentation results are shown in Figures 2(b) and 2(c), respectively. A distinct color is associated with distinct cluster parameters. In the DP results we note that the four subregions are generally properly segmented, but there is significant speckle in the background region. The KSBP segmentation algorithm is beset by far less speckle. Further, in the KSBP results there are five distinct clusters (dominant KSBP sticks), where in the DP results there are principally three distinct sticks (in the DP, the spatially separated segments with the same features are treated as one cluster, while in the KSBP each contiguous region is represented by its own stick).

In the next set of results, on real imagery, we employ the H-KSBP algorithm, and therefore at the task level segmentation is performed as in Figure 2(c). Alternatively, using the HDP model (Teh et al., 2005), at the task level one em-

ploys clustering of the form in Figure 2(b). The relative performance of H-KSBP and HDP is analyzed.



(a) (b) (c)

4.2. H-KSBP applied to a set of real images

Within the subsequent image analysis we employ features constituted by the independent feature subspace analysis (ISA) technique, developed by Hyvärinen and Hoyer (Hyvärinen & Hoyer, 2000). These features have proven to be relatively shift or translation invariant, which enables them to be widely applicable to many type of images.

We test the H-KSBP model on a subset of images from Microsoft Research Cambridge, available at http://research.microsoft.com/vision/cambridge/recognition/. There are seven types of images used in this database: buildings, clouds, countryside, faces, fireworks, offices and urban. Twenty images are randomly selected from the database for each type, yielding a total of 140 images. To capture textural information within the features, we first divided each image into a contiguous 24×24-pixel non-overlapping patches (more than 70,000 patches in total) and then extract ISA features from each patch; color images are considered, and the RGB colors are handled within ISA feature extraction as in (Hoyer & Hyvärinen, 2000). Concerning learning the ISA independent feature subspaces, we randomly select 150 patches out of each of the 140 images from the seven classes, and these 150 image patches are used for basis training. The posterior on the H-KSBP (and HDP) model parameters is inferred based on the proposed MCVB algorithm, processing all 140 images simultaneously; as discussed in Section 2, the HDP analysis is performed by a special setting of the H-KSBP parameters. To mitigate the influence of random samples and VB initialization, we perform the experiment ten times and report the average results.

Borrowing the successful "bag of words" assumption in text analysis (Blei & Lafferty, 2005), we assume each image is a bag of atoms, which results in a measurable quantity of inter-relationship between images, specifically similar images should share similar distribution over those mixture components. An important aspect of the H-KSBP algorithm is that while in text analysis the "bag of words" may be set *a priori*, here the "bag of atoms" is inferred from the data itself, within the clustering process. Related concepts have been employed previously in image analysis (Quelhas et al., 2007), but in that work one had to set the canonical set of image atoms (shapes) *a priori*, which is somewhat *ad hoc*.

As an example, for the data considered, we show one realization of H-KSBP in Figure 3. In the figure, we display canonical atom usage across all 140 images. Figure 3 is a count matrix, where each square represents the relative number of counts in a given image for a particular atom (atoms indexed along the vertical axis in Figure 3).

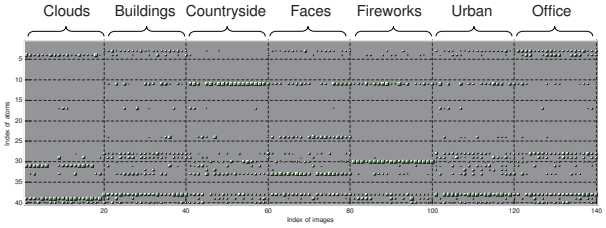

Figure 3. Matrix on the usage of atoms across the different images. The size of each box represents the relative frequency with which a particular atom is manifested in a given image. These results are computed via H-KSBP.

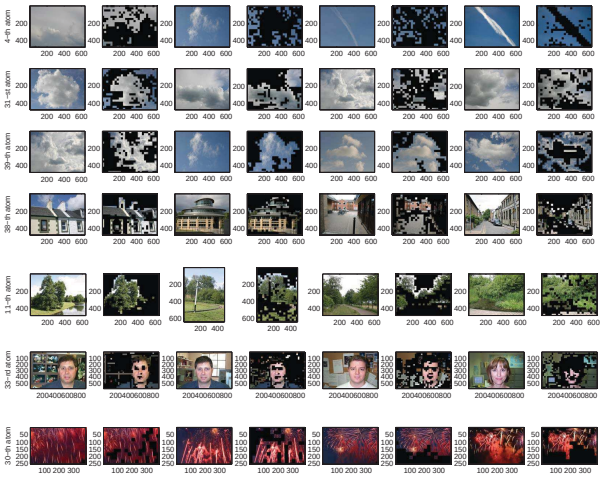

Figure 4. Demonstration of different atoms as inferred by an example run of the H-KSBP algorithm. Each row of the figure corresponds to one atom. Every two images form a set, with the original images at left and areas assigns to a particular atom shown at right.

Figure 4 gives a representation of most of the atoms. For example the 4-th, 31-st and 39-th atoms are associated with clouds and sky; the 38-th atom is principally modeling

buildings; and the 11-th atom is associated with trees and grasses. While performing the experiment, we also noticed it was relatively easy to segment clouds, fireworks, countryside, and urban images while harder to obtain contiguous segments within office images (these typically have far more details, and less large regions of smooth texture; this latter issue may be less an issue of the H-KSBP, but rather of the features employed). An example of this difficulty is observable in Figure 5, as office images are composed of many different atoms. Fortunately, the office images still tend to share similar usage of atoms so that they can be grouped together (sorted) when quantifying similarities between images based on the histogram over atoms (discussed next).

The results in Figure 5, in which both H-KSBP and HDP segmentation results are presented, demonstrate general properties observed when analyzing the images considered here: (i) the segmentation characteristics of HDP were generally good, but on some occasions they were markedly worse (less detailed) than those of H-KSBP; and (ii) the H-KSBP was generally more sensitive to detailed textural differences in the images, thereby generally inferring a larger number of principal atoms (increased number of large sticks).

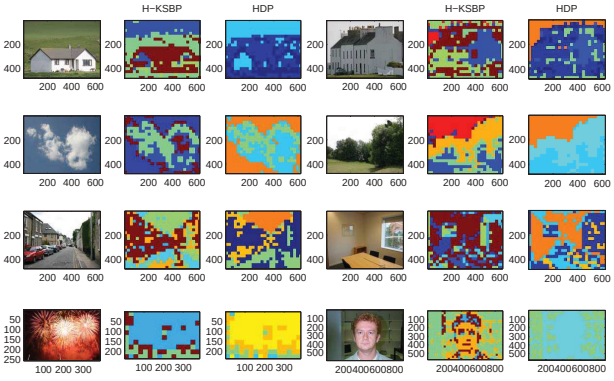

Figure 5. Representative set of segmentation results, comparing H-KSBP and HDP. While these two algorithms tend to generally yield comparable segmentations for the images considered, the H-KSBP is generally more sensitive to details, with this sometimes yielding better segmentations ($e.g.$, the top-level and bottom-right results).

To demonstrate the image-sorting potential of the H-KSBP, we compute the Kullback-Leibler (KL) divergence on the histogram over atoms between any two images, by averaging histograms of the form in Figure 3 over ten random MCVB initializations. For each image, we rank its similarity to all other images based on the associated KL divergence. Performance is addressed quantitatively as follows. For each of the 140 images, we quantify via KL divergence its similarity to all other 139 images, wherein we achieve in ordered list. In Figure 6 we present a confusion matrix, which represents the fraction of the top-ten members of this ordered list that are within the same class (among seven classes) as the image under test.

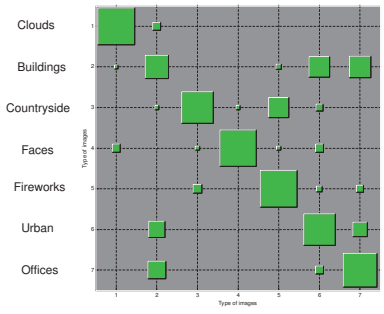

Figure 6. The confusion matrix over image types, generated using H-KSBP.

As demonstrated in Figure 6, the H-KSBP performs well in distinguishing clouds, faces and fireworks images. The buildings and urban images often share some similar atoms, mainly representing buildings, and therefore these are somewhat confused (reasonably, it is felt). The offices images are often related to other relatively complex scenes. Some typical image ranking results are given in Figure 7. It was found that the HDP produced similar sorting results as produced by H-KSBP ($e.g.$, the associated confusion matrix for HDP is similar to that in Figure 6), and therefore the HDP sorting results are omitted here for brevity. This indicates that while in some cases the HDP segmentation results are inferior to those of H-KSBP, in general the ability of HDP and H-KSBP to sort images is comparable (at least for the set of images considered).

The H-KSBP results on the 140-image database were performed in non-optimized $Matlab^{TM}$ software, on a PC with 3 GHz CPU and 2 GB memory. It required about 3 hours to compute one run of the MCVB code for 80 iterations, with typically 40-50 iterations required to achieve convergence. The H-KSBP and HDP algorithms were run with comparable computation times.

5. Conclusions

The kernel stick-breaking process has been extended for use in image segmentation. The algorithm explicitly imposes the belief that feature vectors that are generated from proximate locations in an image are more likely to be associated with the same image segment. We have also extended the KSBP algorithm to the MTL setting, exploring the inter-relationship of images by sharing the same mixing components. Generally superior segmentation performance of H-KSBP was observed relative to HDP, when

Figure 7. Sample image sorting results, as generated by H-KSBP. The top left image is the original image followed by the five most similar images and then the five most dissimilar images.

segmenting multiple images simultaneously. In addition to segmenting multiple images, the H-KSBP and HDP algorithms also yield information about the inter-relationships between the images, based on the underlying sharing mechanisms inferred among the associated clusters. For the images considered, it was found that the H-KSBP and HDP yielded very similar sorting results.

Graph Kernels between Point Clouds

Francis R. Bach FRANCIS.BACH@MINES.ORG
INRIA - WILLOW Project-Team, Laboratoire d'Informatique de l'Ecole Normale Supérieure, Paris, France

Abstract

Point clouds are sets of points in two or three dimensions. Most kernel methods for learning on sets of points have not yet dealt with the specific geometrical invariances and practical constraints associated with point clouds in computer vision and graphics. In this paper, we present extensions of graph kernels for point clouds, which allow one to use kernel methods for such objects as shapes, line drawings, or any three-dimensional point clouds. In order to design rich and numerically efficient kernels with as few free parameters as possible, we use kernels between covariance matrices and their factorizations on probabilistic graphical models. We derive polynomial time dynamic programming recursions and present applications to recognition of handwritten digits and Chinese characters from few training examples.

1. Introduction

In recent years, kernels for structured data have been designed in many domains, such as bioinformatics (Vert et al., 2004), text processing (Lodhi et al., 2002) and computer vision (Harchaoui & Bach, 2007; Parsana et al., 2008). They provide an elegant way of including known *a priori* information, by using directly the natural topological structure of objects. Using *a priori* knowledge through kernels on structured data have proved beneficial because it allows (a) to reduce the number of training examples, (b) to reuse existing data representations that are already well developed by experts of those domains and (c) to bring to bear the rapidly developing kernel machinery, and in particular semi-supervised learning—see, e.g., Chapelle et al. (2006)—and hyperparameter learning for supervised kernel methods—see, e.g., Bach et al. (2004).

In this paper, we propose a positive definite kernel between point clouds, with applications to classification of line drawings—such as handwritten digits (LeCun et al., 1998) or Chinese characters (Srihari et al., 2007)—or shapes (Belongie et al., 2002). The natural geometrical structure of point clouds is hard to represent in a few real-valued features (see, e.g., Forsyth and Ponce (2003)), in particular because of (a) the required local or global invariances by rotation, scaling, and/or translation, (b) the lack of preestablished registrations of the point clouds (i.e., points from one cloud are not given matched to points from another cloud), and (c) the noise and occlusion that impose that only portions of two point clouds ought to be compared.

One of the leading principles for designing kernels between structured objects is to decompose each object into parts and to compare all parts of one object to all parts of another object (Shawe-Taylor & Cristianini, 2004). Even if there is an exponential number of such decompositions, which is a common case, this is numerically possible under two conditions: (a) the object must lead itself to an efficient enumeration of subparts, and (b) the similarity function between subparts (i.e., the *local kernel*), beyond being a positive definite kernel, must be simple enough so that the sum over a potentially exponential number of terms can be recursively performed in polynomial time through factorization.

One of the most striking instantiations of this design principle are the *string kernels* (see, e.g., Shawe-Taylor and Cristianini (2004)), which consider all substrings of a given string but still allow efficient computation in polynomial time. The same principle can also be applied to graphs: intuitively, the *graph kernels* (Ramon & Gärtner, 2003; Kashima et al., 2004; Borgwardt et al., 2005) consider all possible subgraphs and compare and count matching subgraphs. However, the set of subgraphs (or even the set of paths) has exponential size and cannot be efficiently described recursively. By choosing appropriate substructures, such as *walks* or *tree-walks*, and fully factorized local kernels, matrix inversion formulations (Kashima et al., 2004) and efficient dynamic programming recursions (Harchaoui & Bach, 2007) allow one to sum over an exponential number of substructures in polynomial time (for more details

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

on graph kernels, see Section 2.1).

In this paper, we consider the application of graph kernels to point clouds. Indeed, we assume that each point cloud has a graph structure (most often a neighborhood graph); then, our graph kernels consider all partial matches between two neighborhood graphs and sum over those. However, the straightforward application of graph kernels poses a major problem: in the context of computer vision, substructures correspond to matched sets of points, and dealing with local invariances by rotation and/or translation imposes to use a local kernel that cannot be readily expressed as a product of separate terms for each pair of points, and the usual dynamic programming and matrix inversion approaches cannot then be directly applied. One of the main contributions of this paper is to design a local kernel that is not fully factorized but can be instead factorized according to the graph underlying the substructure. This is naturally done through probabilistic graphical models and the design of positive definite kernels for covariance matrices that factorize on graphical models (see Section 3). With this novel local kernel, we derive new polynomial time dynamic programming recursions in Section 4. In Section 5, we present simulations on handwritten character recognition.

2. Graph Kernels

In this section, we consider two labelled undirected graphs $G = (V, E, a, x)$ and $H = (W, F, b, y)$, where V, W are vertex sets, E, F are edge sets and a, b, x, y are vertex labelling functions (Diestel, 2005). Two types of labels are considered: *attributes*, which are denoted $a(v) \in \mathcal{A}$ for vertex $v \in V$ and $b(w) \in \mathcal{A}$ for vertex $w \in W$ and *positions*, which are denoted $x(v) \in \mathcal{X}$ and $y(w) \in \mathcal{X}$. We assume that the graphs have no self-loops. Our motivating examples are line drawings, where $\mathcal{X} = \mathcal{A} = \mathbb{R}^2$ (i.e., the position is itself also an attribute). In this case, the graph is naturally obtained from the drawings by considering 4-connectivity or 8-connectivity (Forsyth & Ponce, 2003). In other cases, graphs can be easily obtained from nearest-neighbor graphs.

2.1. Related work

Graph data occur in many application domains, and kernels for attributed graphs have received increased interest in the applied machine learning literature, in particular in bioinformatics (Kashima et al., 2004; Borgwardt et al., 2005) and computer vision (Harchaoui & Bach, 2007). Note that in this paper, we only consider kernels between graphs (each data point is a graph), as opposed to kernels for a single dataset with associated graph information between data points (see, e.g., Shawe-Taylor and Cristianini (2004)).

Current graph kernels can roughly be divided in two classes: the first class is composed of non positive definite similarity measures based on existing techniques from the graph matching literature, that can be made positive definite by *ad hoc* matrix transformations; this includes the edit-distance kernel (Neuhaus & Bunke, 2006) and the optimal assignment kernel (Fröhlich et al., 2005; Vert, 2008).

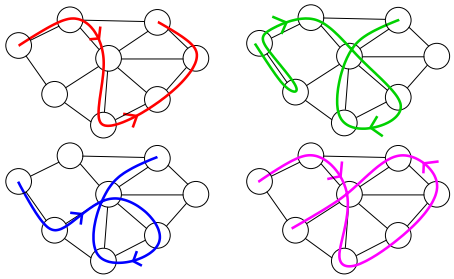

Figure 1. (top left) path, (top right) 1-walk which is not a 2-walk, (bottom left) 2-walk which is not a 3-walk, (bottom right) 4-walk.

Another class of graph kernels relies on a set of substructures of the graphs. The most natural ones are paths, subtrees and more generally subgraphs; however, they do not lead to positive definite kernels with polynomial time computation algorithms—see, in particular, NP-hardness results by Ramon and Gärtner (2003)—and recent work has focused on larger sets of substructures. In particular, *random walk* kernels consider all possible walks and sum a local kernel over all possible walks of the graphs (with all possible lengths). With a proper length-dependent factor, the computation can be achieved by solving a large sparse linear system (Kashima et al., 2004; Borgwardt et al., 2005), whose running time complexity has been recently reduced (Vishwanathan et al., 2007). When considering fixed-length walks, efficient dynamic programming recursions can de derived (Harchaoui & Bach, 2007) that drive down the computation time, at the cost of considering a smaller feature space. These however have the advantage of allowing extensions to other types of substructures, namely "tree-walks" (Ramon & Gärtner, 2003), that we now present.

2.2. Paths, Walks, Subtrees and Tree-walks

Given an undirected graph G with vertex set V, a *path* is a sequence of distinct connected vertices, while a *walk* is a sequence of possibly non distinct connected vertices. In order to prevent the walks from going back and forth too quickly (a phenomenon referred to as *tottering* by Mahé and Vert (2006)), we further restrain the set of walks; that is, for any positive integer β, we define β-walks as walks such that any $\beta+1$ successive vertices are distinct (1-walks are regular walks); see examples in Figure 1. Note that when the graph G is a tree (no cycles), then the set of 2-walks is equal to the set of paths. More generally, for any graph, β-walks of length $\beta + 1$ are exactly paths of length $\beta+1$. Note that the integer β corresponds to the "memory"

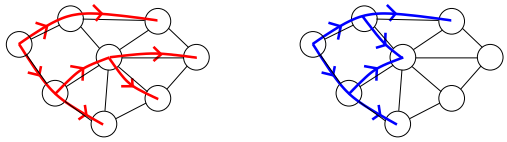

Figure 2. (left) binary 2-tree-walk, which in fact a subtree, (right) binary 1-tree-walk which is not a 2-tree-walk.

of the walk, i.e., the number of past vertices it needs to remember before going on.

A subtree of G is a subgraph of G with no cycles. A subtree of G can thus be seen as a connected subset of distinct nodes of G with an underlying tree structure. The notion of walk is extending the notion of path by allowing nodes to be equal; similarly, we can extend the notion of subtrees to *tree-walks*, which can have nodes that are equal. More precisely, we define an α-ary tree-walk of depth γ of G as a rooted labelled α-ary tree of depth γ with nodes labelled by vertices in G, and such that the labels of neighbors in the tree-walk must be neighbors in G (we refer to all allowed such set of labels as *consistent* labels). We assume that the tree-walks are not necessarily complete trees, i.e., each node may have less than α children. Tree-walks can be plotted on top of the original graph, as shown in Figure 2, and may be represented by a tree structure T over the vertex set $\{1, \dots, |T|\}$ and a tuple of consistent but possibly non distinct labels $I \in V^{|T|}$ (i.e., the labels of neighboring vertices in T must be neighboring vertices in G). Finally, in this paper, we consider only rooted subtrees, i.e., subtrees where a specific node is identified as the root; moreover, all the trees that we consider are unordered trees (i.e., no order is considered among siblings).

We can also define β-tree-walks, as tree-walks such that for each node in T, its label (which is an element of the original vertex set V) and the ones of all its descendants up to the β-th generation are all distinct. With that definition, 1-tree-walks are regular tree-walks (see Figure 2), and if $\alpha = 1$, we get back β-walks. From now on, we refer to the descendants up to the β-th generation as the β-descendants.

We let denote $\mathcal{T}_{\alpha,\gamma}$ the set of rooted tree structures of depth less than γ and with at most α children per node; for example, $\mathcal{T}_{1,\gamma}$ is exactly the set of chain graphs of length less than γ. For $T \in \mathcal{T}_{\alpha,\gamma}$, we denote $\mathcal{J}_\beta(T, G)$ the set of consistent labellings of T by vertices in V leading to β-tree-walks. With these definitions, a β-tree-walk of G is characterized by (a) a tree structure $T \in \mathcal{T}_{\alpha,\gamma}$ and (b) a labelling $I \in \mathcal{J}_\beta(T, G)$.

2.3. Graph Kernels

We assume that we are given a positive definite kernel between tree-walks that share the same tree structure, which we refer to as the *local kernel*. This kernel depends on the tree structure T and the set of attributes and positions associated with the nodes in the tree-walks (remember that each node of G and H has two labels, a position and an attribute). Given a tree structure T and consistent labellings $I \in \mathcal{J}_\beta(T, G)$ and $J \in \mathcal{J}_\beta(T, H)$, we let denote $q_{T,I,J}(G, H)$ the value of the local kernel between two tree-walks defined by the same structure T and labellings I and J.

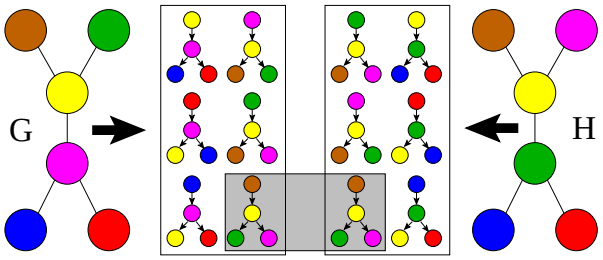

Figure 3. Graph kernels between two graphs (each color represents a different label). We display all binary 1-tree walks with a specific tree structure, extracted from two simple graphs; the graph kernels is computing and summing the local kernels between all those extracted tree-walks. In the case of the Dirac kernel (hard matching), only one pair of tree-walks is matched (for both labels and structures).

Following Ramon and Gärtner (2003), we can define the *tree-kernel* as the sum over all matching tree-walks of G and H of the local kernel, i.e.:

$$k^{\mathcal{T}}_{\alpha,\beta,\gamma}(G, H) = \sum_{T \in \mathcal{T}_{\alpha,\gamma}} f_{\lambda,\nu}(T) \times \sum_{I \in \mathcal{J}_\beta(T,G)} \sum_{J \in \mathcal{J}_\beta(T,H)} q_{T,I,J}(G, H). \quad (1)$$

When considering 1-walks (i.e., $\alpha = \beta = 1$), and letting the maximal walk length γ tend to $+\infty$, we get back the random walk kernel (Ramon & Gärtner, 2003; Kashima et al., 2004). If the kernel $q_{T,I,J}(G, H)$ has nonnegative values and is equal to 1 if the two tree-walks are equal, it can be seen as a soft matching indicator, and then the kernel in Eq. (1) simply counts the softly matched tree-walks in the two graphs (see Figure 3 for an illustration with hard matching).

We add a nonnegative penalization $f_{\lambda,\nu}(T)$ depending only on the tree-structure. Besides the usual penalization of the number of nodes $|T|$, we also add a penalization of the number of leaf nodes $\ell(T)$ (i.e., nodes with no children). More precisely, we use the penalization $f_{\lambda,\nu} = \lambda^{|T|}\nu^{\ell(T)}$. This penalization, suggested by Mahé and Vert (2006), is essential in our situation to avoid that trees with nodes of higher degrees dominate the sum.

If $q_{T,I,J}(G, H)$ is obtained from a positive definite kernel between (labelled) tree-walks, then $k^{\mathcal{T}}_{\alpha,\beta,\gamma}(G, H)$ also defines a positive definite kernel. The kernel $k^{\mathcal{T}}_{\alpha,\beta,\gamma}(G, H)$ sums the *local kernel* $q_{T,I,J}(G, H)$ over all tree-walks of G and H that share the same tree structure; the number

of such matching tree-walks is exponential in the depth γ, thus, in order to deal with potentially deep trees, a recursive definition is needed. As we now detail, it requires a specific type of local kernels, which can be decomposed according to tree structures.

2.4. Local Kernels

The local kernel is used between tree-walks which can have large depths (note that everything we propose will turn out to have linear time complexity in the depth γ). We use the product of a kernel for attributes and a kernel for positions. For attributes, we use the following usual factorized form $q_{\mathcal{A}}(a(I), b(J)) = \prod_{p=1}^{|I|} k_{\mathcal{A}}(a(I_p), b(J_p))$, where $k_{\mathcal{A}}$ is a positive definite kernel on $\mathcal{A} \times \mathcal{A}$. This allows the separate comparison of each matched pair of points and efficient dynamic programming recursions (Harchaoui & Bach, 2007). However, for our local kernel on positions, we need a kernel that *jointly* depends on the whole vectors $x(I) \in \mathcal{X}^{|I|}$ and $y(J) \in \mathcal{X}^{|J|}$, and not only on the p pairs $(x(I_p), y(J_p)) \in \mathcal{X} \times \mathcal{X}$. Indeed, we do not assume that the pairs are *registered*, i.e., we do not know the matching between points indexed by I in the first graph and the ones indexed by J in the second graph.

In this paper, we focus on $\mathcal{X} = \mathbb{R}^d$ and *translation invariant* local kernels, which implies that the local kernel for positions may only depend on differences $x(i) - x(i')$ and $y(j) - y(j')$ for $(i, i') \in I \times I$ and $(j, j') \in J \times J$. We further reduce these to kernel matrices corresponding to a translation invariant positive definite kernel $k_{\mathcal{X}}(x_1 - x_2)$. Depending on the application, $k_{\mathcal{X}}$ may or may not be rotation invariant. In simulations, we use the rotation invariant Gaussian kernel of the form $k_{\mathcal{X}}(x_1, x_2) = e^{-\upsilon \|x_1 - x_2\|^2}$.

Thus, we reduce the set of all positions in $\mathcal{X}^{|V|}$ and $\mathcal{X}^{|W|}$ to full kernel matrices $K \in \mathbb{R}^{|V| \times |V|}$ and $L \in \mathbb{R}^{|W| \times |W|}$ for each graph, defined as $K(v, v') = k_{\mathcal{X}}(x(v) - x(v'))$ (and similarly for L). These matrices are by construction symmetric positive semi-definite and, for simplicity, we assume that these matrices are positive definite (i.e., invertible), which can be enforced by adding a multiple of the identity matrix. The local kernel will thus only depend on the submatrices $K_I = K_{I,I}$ and $L_J = L_{J,J}$, which are positive definite matrices. Note that we use kernel matrices K and L to represent the geometry of each graph, and that we use a positive definite kernel on such kernel matrices.

We consider the following positive definite kernel on positive matrices K and L, the (squared) Bhattacharyya kernel $k_{\mathcal{B}}$, defined as (Kondor & Jebara, 2003):

$$k_{\mathcal{B}}(K, L) = |K|^{1/2} |L|^{1/2} \left| \tfrac{K+L}{2} \right|^{-1}, \qquad (2)$$

where $|K|$ denotes the determinant of K.

By taking the product of the attribute-based local kernel and the position-based local kernel, we get the following local kernel $q^0_{T,I,J}(G, H) = k_{\mathcal{B}}(K_I, L_J) q_{\mathcal{A}}(a(I), b(J))$. However, this local kernel $q^0_{T,I,J}(G, H)$ does not yet depend on the tree structure T and the recursion may be efficient only if $q^0_{T,I,J}(G, H)$ can be computed recursively. The factorized term $q_{\mathcal{A}}(a(I), b(J))$ does not cause any problems; however, for the term $k_{\mathcal{B}}(K_I, L_J)$, we need an approximation based on T. As we show in Section 3, this can be obtained by a factorization according to the appropriate graphical model, i.e., we will replace each kernel matrix of the form K_I by a projection onto a subset of kernel matrices which allow efficient recursions.

3. Positive Matrices and Graphical Models

The main idea underlying the factorization of the kernel is to consider symmetric positive definite matrices as covariance matrices and to look at probabilistic graphical models defined for Gaussian random vectors with those covariance matrices. The goal of this section is to show that by appropriate graphical model techniques, we can design properly factorized approximations of Eq. (2), namely through Eq. (6) and Eq. (7).

More precisely, we assume that we have n random variables $Z_1, \dots, Z_n$ with probability distribution $p(z) = p(z_1, \dots, z_n)$. Given a kernel matrix K (in our case defined as $K_{ij} = e^{-\upsilon \|x_i - x_j\|^2}$, for positions $x_1, \dots, x_n$), we consider jointly Gaussian distributed random variables $Z_1, \dots, Z_n$ such that $\operatorname{cov}(Z_i, Z_j) = K_{ij}$. In this section, with this identification, we consider covariance matrices as kernel matrices, and vice-versa.

3.1. Graphical Models and Junction Trees

Graphical models provide a flexible and intuitive way of defining factorized probability distributions. Given any undirected graph Q with vertices in $\{1, \dots, n\}$, the distribution $p(z)$ is said to factorize in Q if it can be written as a product of potentials over all cliques (completely connected subgraphs) of the graph Q. When the distribution is Gaussian with covariance matrix $K \in \mathbb{R}^{n \times n}$, the distribution factorizes if and only if $(K^{-1})_{ij} = 0$ for each (i, j) which is not an edge in Q (Lauritzen, 1996).

In this paper, we only consider *decomposable* graphical models, for which the graph Q is *triangulated* (i.e., there exists no chordless cycle of length strictly larger than 3). In this case, the joint distribution is uniquely defined from its marginals $p_C(z_C)$ on the cliques C of the graph Q. Namely, if $\mathcal{C}(Q)$ is the set of maximal cliques of Q, we can build a tree of cliques, a *junction tree*, such that $p(z) = \prod_{C \in \mathcal{C}(Q)} p_C(z_C) / \prod_{C, C' \in \mathcal{C}(Q), C \sim C'} p_{C \cap C'}(z_{C \cap C'})$ (see Figure 4 for an example of a graphical model and a junction tree). The sets $C \cap C'$ are usually referred to as *separators* and we let denote $\mathcal{S}(Q)$ the set of such separators. Note that for a zero mean normally distributed vector, the marginals

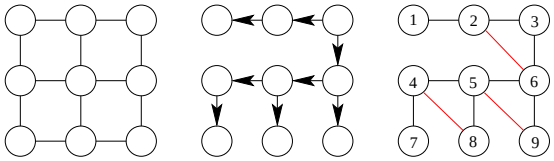

Figure 4. (left) original graph, (middle) a single extracted tre-walk, (right) decomposable graphical model $Q_1(T)$ with added edges in red, defined in Section 3.4. The junction tree is a chain composed of the cliques $\{1,2\},\{2,3,6\},\{5,6,9\},\{4,5,8\},\{4,7\}$.

$p_C(z_C)$ are characterized by the marginal covariance matrix $K_C = K_{C,C}$. Projecting onto a graphical model will preserve the marginal over all maximal cliques, and thus preserve the local kernel matrices, while imposing zeros in the inverse of K.

3.2. Graphical Models and Projections

We let denote $\Pi_Q(K)$ the covariance matrix that factorizes in Q which is closest to K for the Kullback-Leibler divergence between normal distributions. In this paper, we essentially replace K by $\Pi_Q(K)$; i.e., we project all our covariance matrices onto a graphical model, which is a classical tool in probabilistic modelling (Lauritzen, 1996). We leave the study of the approximation properties of such a projection (i.e., for a given K, how dense the graph should be to approximate the full local kernel correctly?) to future work—see, e.g., Caetano et al. (2006) for related results.

Practically, since our kernel on kernel matrices involves determinants, we simply need to compute $|\Pi_Q(K)|$ efficiently. For decomposable graphical models, $\Pi_Q(K)$ can be obtained in closed form (Lauritzen, 1996) and its determinant has the following simple expression:

$$\log|\Pi_Q(K)| = \sum_{C\in\mathcal{C}(Q)} \log|K_C| - \sum_{S\in\mathcal{S}(Q)} \log|K_S|. \quad (3)$$

The determinant $|\Pi_Q(K)|$ is thus a ratio of terms (determinants over cliques and separators), which will restrict the applicability of the projected kernels (see Proposition 1). In order to keep only products, we consider the following equivalent form: if the junction tree is rooted (by choosing any clique as the root), then for each clique but the root, a unique parent clique is defined, and we have:

$$\begin{aligned}\log|\Pi_Q(K)| &= \textstyle\sum_{C\in\mathcal{C}(Q)} \log\frac{|K_C|}{|K_{p_Q(C)}|} \\ &= \textstyle\sum_{C\in\mathcal{C}(Q)} \log|K_{C|p_Q(C)}|, \end{aligned} \quad (4)$$

where $p_Q(C)$ is the parent clique of Q (and $\varnothing$ for the root clique) and the conditional covariance matrix is defined, as usual, as $K_{C|p_Q(C)} = K_{C,C} - K_{C,p_Q(C)}K^{-1}_{p_Q(C),p_Q(C)}K_{p_Q(C),C}$ (Lauritzen, 1996).

3.3. Graphical Models and Kernels

We now propose several ways of defining a kernel adapted to graphical models. All of them are based on replacing determinants $|M|$ by $|\Pi_Q(M)|$, and their different decompositions in Eq. (3) and Eq. (4). Simply using Eq. (3), we obtain the similarity measure:

$$k^Q_{\mathcal{B},0}(K,L) = \prod_{C\in\mathcal{C}(Q)} k_{\mathcal{B}}(K_C,L_C) \prod_{S\in\mathcal{S}(Q)} k_{\mathcal{B}}(K_S,L_S)^{-1}. \quad (5)$$

which turns out not to be a positive definite kernel for general covariance matrices:

Proposition 1 *For any decomposable model Q, the kernel $k^Q_{\mathcal{B},0}$ defined in Eq. (5) is a positive definite kernel on the set of covariance matrices K such that for all separators $S\in\mathcal{S}(Q)$, $K_{S,S} = I$. In particular, when all separators have cardinal one, this is a kernel on correlation matrices.*

In order to remove the condition on separators (i.e., we want more sharing between cliques than through a single variable), we consider the rooted junction tree representation in Eq. (4). A straightforward kernel is to compute the product of the Bhattacharyya kernels $k_{\mathcal{B}}(K_{C|p_Q(C)}, L_{C|p_Q(C)})$ for each conditional covariance matrix. However, this does not lead to a true distance on covariance matrices that factorize on Q because the set of conditional covariance matrices do not characterize entirely those distributions. Rather, we consider the following kernel:

$$k^Q_{\mathcal{B}}(K,L) = \textstyle\prod_{C\in\mathcal{C}(Q)} k^{C|p_Q(C)}_{\mathcal{B}}(K,L); \quad (6)$$

for the root clique, we define $k^{R|\varnothing}_{\mathcal{B}}(K,L) = k_{\mathcal{B}}(K_R,L_R)$ and the kernels $k^{C|p_Q(C)}_{\mathcal{B}}(K,L)$ are defined as kernels between conditional Gaussian distributions of Z_C given $Z_{p_Q(C)}$. We use

$$k^{C|p_Q(C)}_{\mathcal{B}}(K,L) = \frac{|K_{C|p_Q(C)}|^{1/2}|L_{C|p_Q(C)}|^{1/2}}{\left|\frac{1}{2}K_{C|p_Q(C)}+\frac{1}{2}L_{C|p_Q(C)}+MM^\top\right|}, \quad (7)$$

where the additional term M is equal to $\frac{1}{2}(K_{C,p_Q(C)}K^{-1}_{p_Q(C)} - L_{C,p_Q(C)}L^{-1}_{p_Q(C)})$. This exactly corresponds to putting a prior with identity covariance matrix on variables $Z_{p_Q(C)}$ and considering the kernel between the resulting joint covariance matrices on variables indexed by $(C,p_Q(C))$. We now have a positive definite kernel on all covariance matrices:

Proposition 2 *For any decomposable model Q, the kernel $k^Q_{\mathcal{B}}(K,L)$ defined in Eq. (6) and Eq. (7) is a positive definite kernel on the set of covariance matrices.*

Note that the kernel is not invariant by the choice of the particular root of the junction tree. However, in our setting, this is not an issue because we have a natural way of rooting the junction trees (i.e, following the rooted tree-walk, see Section 3.4). Note that these kernels could be useful in other domains than point clouds and computer vision.

In Section 4, we will use the notation $k_{\mathcal{B}}^{I_1|I_2,J_1|J_2}(K,L)$ for $|I_1| = |I_2|$ and $|J_1| = |J_2|$ to denote the kernel between covariance matrices $K_{I_1\cup I_2}$ and $L_{I_1\cup I_2}$ adapted to the conditional distributions $I_1|I_2$ and $J_1|J_2$, defined through Eq. (7).

3.4. Choice of Graphical Models

Given the rooted tree structure T of a β-tree-walk, we now need to define the graphical model $Q_\beta(T)$ that we use to project our kernel matrices. A natural candidate is T itself; however, as shown in Section 4, in order to compute efficiently the kernel we simply need that the local kernel is a product of terms that only involve a node and its β-descendants. The densest graph (remember that denser graphs lead to better approximations when projecting onto the graphical model) we may use is exactly the following: we define $Q_\beta(T)$ such that for all nodes in T, the node together with all its β-descendants form a clique, i.e., a node is connected to its β-descendants and all β-descendants are also mutually connected (see Figure 4 for example for $\beta = 1$): the set of cliques are thus the set of *families* of depth $\beta+1$ (i.e., with $\beta+1$ generations). Thus, our final kernel is:

$$k_{\alpha,\beta,\gamma}^{\mathcal{T}}(G,H) = \sum_{T\in\mathcal{T}_{\alpha,\gamma}} f_{\lambda,\nu}(T)\times$$
$$\sum_{I\in\mathcal{J}_\beta(T,G)}\ \sum_{J\in\mathcal{J}_\beta(T,H)} k_{\mathcal{B}}^{Q_\beta(T)}(K_I,L_J)q_{\mathcal{A}}(a(I),b(J)). \quad (8)$$

The main intuition behind this definition is to sum local similarities over all matching subgraphs. In order to obtain a tractable formulation, we simply needed (a) to extend the set of subgraphs (to tree-walks of depth γ) and (b) to factorize the local similarities along the graphs. We now show how these elements can be combined to derive efficient recursions.

4. Dynamic Programming Recursions

In order to derive dynamic programming recursions, we follow Mahé and Vert (2006) and rely on the fact that α-ary β-tree-walks of G can essentially be defined through 1-tree-walks on the augmented graph of all rooted subtrees of G of depth at most β and arity less than α. We thus consider the set $V_{\alpha,\beta}$ of non complete rooted (unordered) subtrees of $G = (V,E)$, of depths less than β and arity less than α. Given two different rooted unordered labelled trees, they are said *equivalent* (or isomorphic) if they share the same tree structure, and this is denoted $\sim_t$.

On this set $V_{\alpha,\beta}$, we define a *directed* graph with edge set $E_{\alpha,\beta}$ as follows: $R_0 \in V_{\alpha,\beta}$ is connected to $R_1 \in V_{\alpha,\beta}$ if "the tree R_1 extends the tree R_0 one generation further", i.e., if and only if (a) the first $\beta-1$ generations of R_1 are exactly equal to one of the complete subtree of R_0 rooted at a child of the root of R_0, and (b) the nodes of depth β of R_1 are distinct from the nodes in R_0. This defines a graph $G_{\alpha,\beta} = (V_{\alpha,\beta}, E_{\alpha,\beta})$ and a neighborhood $\mathcal{N}_{G_{\alpha,\beta}}(R)$ for $R \in V_{\alpha,\beta}$ (see Figure 5 for an example). Similarly we define a graph $H_{\alpha,\beta} = (W_{\alpha,\beta}, F_{\alpha,\beta})$ for the graph H. Note that when $\alpha = 1$, $V_{1,\beta}$ is the set of paths of length less than or equal to β.

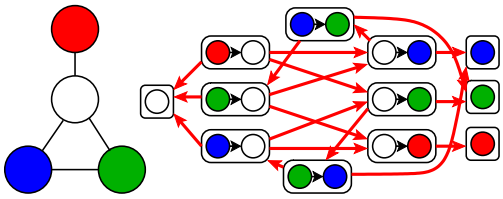

Figure 5. (left) undirected graph G, (right) graph $G_{1,2}$.

For a β-tree-walk, the root with its β-descendants must have distinct vertices and thus corresponds exactly to an element of $V_{\alpha,\beta}$. We denote $k_{\alpha,\beta,\gamma}^{\mathcal{T}}(G,H,R_0,S_0)$ the same kernel as defined in Eq. (8), but restricted to tree-walks that start respectively with R_0 and S_0. Note that if R_0 and S_0 are not equivalent, then $k_{\alpha,\beta,\gamma}^{\mathcal{T}}(G,H,R_0,S_0) = 0$.

We obtain the following recursion between depths γ and depth $\gamma-1$, for all $R_0 \in V_{\alpha,\beta}$ and and $S_0 \in W_{\alpha,\beta}$ such that $R_0 \sim_t S_0$:

$$k_{\alpha,\beta,\gamma}^{\mathcal{T}}(G,H,R_0,S_0) = k_{\alpha,\beta,\gamma-1}^{\mathcal{T}}(G,H,R_0,S_0)$$
$$+\sum_{p=1}^{\alpha} \sum_{\substack{R_1,\dots,R_p \in \mathcal{N}_{G_{\alpha,\beta}}(R_0) \\ R_1,\dots,R_p \text{ disjoint}}} \sum_{\substack{S_1,\dots,S_p \in \mathcal{N}_{H_{\alpha,\beta}}(S_0) \\ S_1,\dots,S_p \text{ disjoint}}}$$
$$\left[\lambda \prod_{i=1}^{p} k_{\mathcal{A}}(a(\mathrm{root}(R_i)),b(\mathrm{root}(S_i)))\times \right.$$
$$\left. \frac{k_{\mathcal{B}}^{\cup_{i=1}^p R_i|R_0,\cup_{i=1}^p S_i|S_0}(K,L)}{\prod_{i=1}^p k_{\mathcal{B}}^{R_i,S_i}(K,L)} \left(\prod_{i=1}^{p} k_{\alpha,\beta,\gamma-1}^{\mathcal{T}}(G,H,R_i,S_i)\right)\right].$$

Note that if any of the trees R_i is not equivalent to S_i, it does not contribute to the sum. The recursion is initialized with $k_{\alpha,\beta,\gamma}^{\mathcal{T}}(G,H,R_0,S_0) = \lambda^{|R_0|}\nu^{\ell(R_0)}q_{\mathcal{A}}(a(R_0),b(S_0))k_{\mathcal{B}}(K_{R_0},L_{S_0})$ while the final kernel is obtained by summing over all R_0 and S_0, i.e, $k_{\alpha,\beta,\gamma}^{\mathcal{T}}(G,H) = \sum_{R_0\sim_t S_0} k_{\alpha,\beta,\gamma}^{\mathcal{T}}(G,H,R_0,S_0)$.

Computational Complexity The complexity of computing one kernel between two graphs is linear in γ (the depth of the tree-walks), and quadratic in the size of $V_{\alpha,\beta}$ and $W_{\alpha,\beta}$. However, those sets may have exponential size in β and α in general (in particular if graphs are densely connected). And thus, we are limited to small values (typically $\alpha \leqslant 3$ and $\beta \leqslant 6$) which are sufficient for good classification performance (in particular, higher β or α do not necessarily mean better performance, see Section 5). Overall, one can deal with any graph size, as long as the "sufficient statistics" (i.e., the unique local neighorhoods in $V_{\alpha,\beta}$) are not too numerous.

Figure 6. For digits and Chinese characters: (left) original characters, (right) thinned and subsampled characters.

For example, for the handwritten digits we use in simulations, the average number of nodes in the graphs is 18 ± 4, while the average cardinal of $V_{\alpha,\beta}$ and running times[1] for one kernel evaluation are, for walk kernels of depth 24: $|V_{\alpha,\beta}| = 36$, $T = 2$ ms ($\alpha = 1$, $\beta = 2$), $|V_{\alpha,\beta}| = 37$, $T = 3$ ms ($\alpha = 1$, $\beta = 4$); and for tree-kernels: $|V_{\alpha,\beta}| = 56$, $T = 25$ ms ($\alpha = 2$, $\beta = 2$), $|V_{\alpha,\beta}| = 70$, $T = 32$ ms ($\alpha = 2$, $\beta = 4$).

Finally, we may reduce the computational load by considering a set of trees of smaller arity in the previous recursions; i.e., we can consider $V_{1,\beta}$ instead of $V_{\alpha,\beta}$ with tree-kernels of arity $\alpha > 1$.

5. Application to Character Recognition

We have tested our new kernels on the task of isolated handwritten character recognition, handwritten arabic numerals (MNIST dataset) and Chinese characters (ETL9B dataset). We selected the first 100 examples for the ten classes in the MNIST dataset, while for the ETL9B dataset, we selected the five hardest classes to discriminate among 3,000 classes (by computing distances between class means) and then selected the first 50 examples per class. Our learning task it to classify those characters; we use a one-vs-rest multiclass scheme with 1-norm support vector machines (see, e.g., Shawe-Taylor and Cristianini (2004)).

We consider characters as drawings in $\mathbb{R}^2$, which are sets of possibly intersecting contours. Those are naturally represented as undirected planar graphs. We have thinned and subsampled uniformly each character to reduce the sizes of the graphs (see two examples in Figure 6).

The kernel on positions is $k_{\mathcal{X}}(x, y) = \exp(-\tau\|x-y\|^2) + \kappa\delta(x, y)$, but could take into account different weights on horizontal and vertical directions. We add the positions from the center of the bounding box as features, to take into account the global positions, i.e., we use $k_{\mathcal{A}}(x, y) = \exp(-\upsilon\|x-y\|^2)$. This is necessary because the problem of handwritten character recognition is not globally translation invariant.

[1]Those do not take into account preprocessing and were evaluated on an Intel Xeon 2.33 GHz processor from MATLAB/C code, and are to be compared to the simplest recursions which correspond to the usual random walk kernel ($\alpha = 1$, $\beta = 1$), where $T = 1$ ms.

In this paper, we have defined a family of kernels, corresponding to different values of the following free parameters (shown with their possible values): arity of tree-walks ($\alpha = 1, 2$), order of tree-walks ($\beta = 1, 2, 4, 6$), depth of tree-walks ($\gamma = 1, 2, 4, 8, 16, 24$), penalization on number of nodes ($\lambda = 1$), penalization on number of leaf nodes ($\nu = .1, .01$), bandwidth for kernel on positions ($\tau = .05, .01, .1$), ridge parameter ($\kappa = .001$), bandwidth for kernel on attributes ($\upsilon = .05, .01, .1$).

The first two sets of parameters $(\alpha, \beta, \gamma, \lambda, \nu)$ are parameters of the graph kernel, independent of the application, while the last set (τ, κ, ν) are parameters of the kernels for attributes and positions. Note that with only a few important scale parameters (τ and ν), we are able to characterize complex interactions between the vertices and edges of the graphs. In practice, this is important to avoid considering many more distinct parameters for all sizes and topologies of subtrees.

In simulations, we performed two loops of 5-fold cross-validation: in the outer loop, we consider 5 different training folds with their corresponding testing folds. On each training fold, we consider all possible values of α and β. For all of those values, we select all other parameters (including the regularization parameters of the SVM) by 5-fold cross-validation (the inner folds). Once the best parameters are found only by looking only at the training fold, we train on the whole training fold, and test on the testing fold. We output the means and standard deviations of the testing errors for each testing fold. We show in Figure 7 the performance for various values of α and β. We compare those favorably to three baseline kernels with hyperparameters learned by cross-validation in the same way: (a) the *Gaussian-RBF kernel* on the vectorized original images, which leads to testing errors of $11.6 \pm 5.4\%$ (MNIST) and $50.4 \pm 6.2\%$ (ETL9B); (b) the regular *random walk kernel* which sums over all walk lengths, which leads to testing errors of $8.6 \pm 1.3\%$ (MNIST) and $34.8 \pm 8.4\%$ (ETL9B); and (c) the *pyramid match kernel* (Grauman & Darrell, 2007), which is commonly used for image classification and leads here to testing errors of $10.8 \pm 3.6\%$ (MNIST) and $45.2 \pm 3.4\%$ (ETL9B).

These results show that our new family of kernels that use the natural structure of line drawings are outperforming other kernels on structured data (regular random walk kernel and pyramid match kernel) as well as the "blind" Gaussian-RBF kernel which does not take into account explicitly the structure of images but still leads to very good performance with more training data (LeCun et al., 1998). Note that for arabic numerals, higher arity does not help, which is not surprising since most digits have a linear structure (i.e, graphs are chains). On the contrary, for Chinese characters, which exhibit higher connectivity, best performance is achieved for binary tree-walks.

	MNIST $\alpha = 1$	MNIST $\alpha = 2$	ETL9B $\alpha = 1$	ETL9B $\alpha = 2$
$\beta = 1$	11.6 ± 4.6	9.2 ± 3.9	36.8 ± 4.6	32 ± 8.4
$\beta = 2$	5.6 ± 3.1	5.6 ± 3.0	29.2 ± 8.8	$\mathbf{25.2 \pm 2.7}$
$\beta = 4$	$\mathbf{5.4 \pm 3.6}$	$\mathbf{5.4 \pm 3.1}$	32.4 ± 3.9	29.6 ± 4.3
$\beta = 6$	5.6 ± 3.3	6 ± 3.5	29.6 ± 4.6	28.4 ± 4.3

Figure 7. Error rates (multiplied by 100) on handwritten character classification tasks.

6. Conclusion

We have presented a new kernel for point clouds which is based on comparisons of local subsets of the point clouds. Those comparisons are made tractable by (a) considering subsets based on tree-walks and walks, and (b) using a specific factorized form for the local kernels between tree-walks, namely a factorization on a properly defined probabilistic graphical model.

Moreover, we have reported applications to handwritten character recognition where we showed that the kernels were able to capture the relevant information to allow good predictions from few training examples. We are currently investigating other domains of applications of points clouds, such as shape mining in computer vision (Belongie et al., 2002), and prediction of protein functions from their three-dimensional structures (Qiu et al., 2007).

Bolasso: Model Consistent Lasso Estimation through the Bootstrap

Francis R. Bach FRANCIS.BACH@MINES.ORG
INRIA - WILLOW Project-Team, Laboratoire d'Informatique de l'Ecole Normale Supérieure, Paris, France

Abstract

We consider the least-square linear regression problem with regularization by the ℓ_1-norm, a problem usually referred to as the Lasso. In this paper, we present a detailed asymptotic analysis of model consistency of the Lasso. For various decays of the regularization parameter, we compute asymptotic equivalents of the probability of correct model selection (i.e., variable selection). For a specific rate decay, we show that the Lasso selects all the variables that should enter the model with probability tending to one exponentially fast, while it selects all other variables with strictly positive probability. We show that this property implies that if we run the Lasso for several bootstrapped replications of a given sample, then intersecting the supports of the Lasso bootstrap estimates leads to consistent model selection. This novel variable selection algorithm, referred to as the Bolasso, is compared favorably to other linear regression methods on synthetic data and datasets from the UCI machine learning repository.

1. Introduction

Regularization by the ℓ_1-norm has attracted a lot of interest in recent years in machine learning, statistics and signal processing. In the context of least-square linear regression, the problem is usually referred to as the *Lasso* (Tibshirani, 1994). Much of the early effort has been dedicated to algorithms to solve the optimization problem efficiently. In particular, the *Lars* algorithm of Efron et al. (2004) allows to find the entire regularization path (i.e., the set of solutions for all values of the regularization parameters) at the cost of a single matrix inversion.

Moreover, a well-known justification of the regularization by the ℓ_1-norm is that it leads to *sparse* solutions, i.e., loading vectors with many zeros, and thus performs model selection. Recent works (Zhao & Yu, 2006; Yuan & Lin, 2007; Zou, 2006; Wainwright, 2006) have looked precisely at the model consistency of the Lasso, i.e., if we know that the data were generated from a sparse loading vector, does the Lasso actually recover the sparsity pattern when the number of observed data points grows? In the case of a fixed number of covariates, the Lasso does recover the sparsity pattern if and only if a certain simple condition on the generating covariance matrices is verified (Yuan & Lin, 2007). In particular, in low correlation settings, the Lasso is indeed consistent. However, in presence of strong correlations between relevant variables and irrelevant variables, the Lasso cannot be consistent, shedding light on potential problems of such procedures for variable selection. Adaptive versions where data-dependent weights are added to the ℓ_1-norm then allow to keep the consistency in all situations (Zou, 2006).

In this paper, we first derive a detailed asymptotic analysis of sparsity pattern selection of the Lasso estimation procedure, that extends previous analysis (Zhao & Yu, 2006; Yuan & Lin, 2007; Zou, 2006), by focusing on a specific decay of the regularization parameter. Namely, we show that when the decay is proportional to $n^{-1/2}$, where n is the number of observations, then the Lasso will select all the variables that should enter the model (the *relevant* variables) with probability tending to one exponentially fast with n, while it selects all other variables (the *irrelevant* variables) with strictly positive probability. If several datasets generated from the same distribution were available, then the latter property would suggest to consider the intersection of the supports of the Lasso estimates for each dataset: all relevant variables would always be selected for all datasets, while irrelevant variables would enter the models randomly, and intersecting the supports from sufficiently many different datasets would simply eliminate them. However, in practice, only one dataset is given; but resampling methods such as the *bootstrap* are exactly dedicated to mimic the availability of several datasets by resampling from the same unique dataset (Efron & Tibshirani, 1998). In this paper, we show that when using the bootstrap and intersecting the supports, we actually get a consistent

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

model estimate, *without* the consistency condition required by the regular Lasso. We refer to this new procedure as the *Bolasso* (**bo**otstrap-enhanced **l**east **a**bs**o**lute **s**hrinkage **o**perator). Finally, our Bolasso framework could be seen as a voting scheme applied to the supports of the bootstrap Lasso estimates; however, our procedure may rather be considered as a consensus combination scheme, as we keep the (largest) subset of variables on which *all* regressors agree in terms of variable selection, which is in our case provably consistent and also allows to get rid of a potential additional hyperparameter.

The paper is organized as follows: in Section 2, we present the asymptotic analysis of model selection for the Lasso; in Section 3, we describe the Bolasso framework, while in Section 4, we illustrate our results on synthetic data, where the true sparse generating model is known, and data from the UCI machine learning repository. Sketches of proofs can be found in Appendix A.

Notations For a vector $v \in \mathbb{R}^p$, we denote $\|v\|_2 = (v^\top v)^{1/2}$ its ℓ_2-norm, $\|v\|_\infty = \max_{i\in\{1,\dots,p\}} |v_i|$ its ℓ_∞-norm and $\|v\|_1 = \sum_{i=1}^p |v_i|$ its ℓ_1-norm. For $a \in \mathbb{R}$, $\operatorname{sign}(a)$ denotes the sign of a, defined as $\operatorname{sign}(a) = 1$ if $a > 0$, -1 if $a < 0$, and 0 if $a = 0$. For a vector $v \in \mathbb{R}^p$, $\operatorname{sign}(v) \in \mathbb{R}^p$ denotes the the vector of signs of elements of v.

Moreover, given a vector $v \in \mathbb{R}^p$ and a subset I of $\{1,\dots,p\}$, v_I denotes the vector in $\mathbb{R}^{\operatorname{Card}(I)}$ of elements of v indexed by I. Similarly, for a matrix $A \in \mathbb{R}^{p\times p}$, $A_{I,J}$ denotes the submatrix of A composed of elements of A whose rows are in I and columns are in J.

2. Asymptotic Analysis of Model Selection for the Lasso

In this section, we describe existing and new asymptotic results regarding the model selection capabilities of the Lasso.

2.1. Assumptions

We consider the problem of predicting a response $Y \in \mathbb{R}$ from covariates $X = (X_1,\dots,X_p)^\top \in \mathbb{R}^p$. The only assumptions that we make on the joint distribution P_{XY} of (X,Y) are the following:

(**A1**) The cumulant generating functions $\mathbb{E}\exp(s\|X\|_2^2)$ and $\mathbb{E}\exp(sY^2)$ are finite for some $s > 0$.

(**A2**) The joint matrix of second order moments $\mathbf{Q} = \mathbb{E}XX^\top \in \mathbb{R}^{p\times p}$ is invertible.

(**A3**) $\mathbb{E}(Y|X) = X^\top\mathbf{w}$ and $\operatorname{var}(Y|X) = \sigma^2$ a.s. for some $\mathbf{w} \in \mathbb{R}^p$ and $\sigma \in \mathbb{R}_+^*$.

We let denote $\mathbf{J} = \{j, \mathbf{w}_j \neq 0\}$ the sparsity pattern of $\mathbf{w}$, $\mathbf{s} = \operatorname{sign}(\mathbf{w})$ the sign pattern of $\mathbf{w}$, and $\varepsilon = Y - X^\top\mathbf{w}$ the additive noise.[1] Note that our assumption regarding cumulant generating functions is satisfied when X and ε have compact supports, and also when the densities of X and ε have light tails.

We consider *independent and identically distributed* (i.i.d.) data $(x_i, y_i) \in \mathbb{R}^p \times \mathbb{R}$, $i = 1,\dots,n$, sampled from P_{XY}; the data are given in the form of matrices $\overline{Y} \in \mathbb{R}^n$ and $\overline{X} \in \mathbb{R}^{n\times p}$.

Note that the i.i.d. assumption, together with (**A1-3**), are the simplest assumptions for studying the asymptotic behavior of the Lasso; and it is of course of interest to allow more general assumptions, in particular growing number of variables p, more general random variables, etc., which are outside the scope of this paper—see, e.g., Meinshausen and Yu (2008); Zhao and Yu (2006); Lounici (2008).

2.2. Lasso Estimation

We consider the square loss function $\frac{1}{2n}\sum_{i=1}^n (y_i - w^\top x_i)^2 = \frac{1}{2n}\|\overline{Y} - \overline{X}w\|_2^2$ and the regularization by the ℓ_1-norm defined as $\|w\|_1 = \sum_{i=1}^p |w_i|$. That is, we look at the following Lasso optimization problem (Tibshirani, 1994):

$$\min_{w\in\mathbb{R}^p} \tfrac{1}{2n}\|\overline{Y} - \overline{X}w\|_2^2 + \mu_n\|w\|_1, \qquad (1)$$

where $\mu_n \geqslant 0$ is the regularization parameter. We denote $\hat{w}$ any global minimum of Eq. (1)—it may not be unique in general, but will with probability tending to one exponentially fast under assumption (**A2**).

2.3. Model Consistency - General Results

In this section, we detail the asymptotic behavior of the Lasso estimate $\hat{w}$, both in terms of the difference in norm with the population value $\mathbf{w}$ (i.e., regular consistency) and of the *sign pattern* $\operatorname{sign}(\hat{w})$, for all asymptotic behaviors of the regularization parameter μ_n. Note that information about the sign pattern includes information about the *support*, i.e., the indices i for which $\hat{w}_i$ is different from zero; moreover, when $\hat{w}$ is consistent, consistency of the sign pattern is in fact equivalent to the consistency of the support.

We now consider five mutually exclusive possible situations which explain various portions of the regularization path (we assume (**A1-3**)); many of these results appear elsewhere (Yuan & Lin, 2007; Zhao & Yu, 2006; Fu & Knight, 2000; Zou, 2006; Bach, 2008; Lounici, 2008) but some of the finer results presented below are new (see Section 2.4).

[1] Throughout this paper, we use boldface fonts for population quantities.

1. If μ_n tends to infinity, then $\hat{w} = 0$ with probability tending to one.

2. If μ_n tends to a finite strictly positive constant μ_0, then $\hat{w}$ converges in probability to the unique global minimum of $\frac{1}{2}(w - \mathbf{w})^\top \mathbf{Q}(w - \mathbf{w}) + \mu_0 \|w\|_1$. Thus, the estimate $\hat{w}$ never converges in probability to $\mathbf{w}$, while the sign pattern tends to the one of the previous global minimum, which may or may not be the same as the one of $\mathbf{w}$.[2]

3. If μ_n tends to zero slower than $n^{-1/2}$, then $\hat{w}$ converges in probability to $\mathbf{w}$ (regular consistency) and the sign pattern converges to the sign pattern of the global minimum of $\frac{1}{2} v^\top \mathbf{Q} v + v_{\mathbf{J}}^\top \operatorname{sign}(\mathbf{w}_{\mathbf{J}}) + \|v_{\mathbf{J}^c}\|_1$. This sign pattern is equal to the population sign vector $\mathbf{s} = \operatorname{sign}(\mathbf{w})$ if and only if the following consistency condition is satisfied:

$$\|\mathbf{Q}_{\mathbf{J}^c\mathbf{J}} \mathbf{Q}_{\mathbf{J}\mathbf{J}}^{-1} \operatorname{sign}(\mathbf{w}_{\mathbf{J}})\|_\infty \leqslant 1. \tag{2}$$

   Thus, if Eq. (2) is satisfied, the probability of correct sign estimation is tending to one, and to zero otherwise (Yuan & Lin, 2007).

4. If $\mu_n = \mu_0 n^{-1/2}$ for $\mu_0 \in (0, \infty)$, then the sign pattern of $\hat{w}$ agrees on $\mathbf{J}$ with the one of $\mathbf{w}$ with probability tending to one, while for all sign patterns consistent on $\mathbf{J}$ with the one of $\mathbf{w}$, the probability of obtaining this pattern is tending to a limit in $(0, 1)$ (in particular strictly positive); that is, all patterns consistent on $\mathbf{J}$ are possible with positive probability. See Section 2.4 for more details.

5. If μ_n tends to zero faster than $n^{-1/2}$, then $\hat{w}$ is consistent (i.e., converges in probability to $\mathbf{w}$) but the support of $\hat{w}$ is equal to $\{1, \dots, p\}$ with probability tending to one (the signs of variables in $\mathbf{J}^c$ may be negative or positive). That is, the ℓ_1-norm has no sparsifying effect.

Among the five previous regimes, the only ones with consistent estimates (in norm) and a sparsity-inducing effect are μ_n tending to zero and $\mu_n n^{1/2}$ tending to a limit $\mu_0 \in (0, \infty]$ (i.e., potentially infinite). When $\mu_0 = +\infty$, then we can only hope for model consistent estimates if the consistency condition in Eq. (2) is satisfied. This somewhat disappointing result for the Lasso has led to various improvements on the Lasso to ensure model consistency even when Eq. (2) is not satisfied (Yuan & Lin, 2007; Zou, 2006). Those are based on adaptive weights based on the non regularized least-square estimate. We propose in Section 3 an alternative way which is based on resampling.

[2] Here and in the third regime, we do not take into account the pathological cases where the sign pattern of the limit in unstable, i.e., the limit is exactly at a hinge point of the regularization path.

In this paper, we now consider the specific case where $\mu_n = \mu_0 n^{-1/2}$ for $\mu_0 \in (0, \infty)$, where we derive new asymptotic results. Indeed, in this situation, we get the correct signs of the relevant variables (those in $\mathbf{J}$) with probability tending to one, but we also get all possible sign patterns consistent with this, i.e., all other variables (those not in $\mathbf{J}$) may be non zero with asymptotically strictly positive probability. However, if we were to repeat the Lasso estimation for many datasets obtained from the same distribution, we would obtain for each μ_0, a set of active variables, all of which include $\mathbf{J}$ with probability tending to one, but potentially containing all other subsets. By intersecting those, we would get exactly $\mathbf{J}$.

However, this requires multiple copies of the samples, which are not usually available. Instead, we consider bootstrapped samples which exactly mimic the behavior of having multiple copies. See Section 3 for more details.

2.4. Model Consistency with Exact Root-n Regularization Decay

In this section we present detailed new results regarding the pattern consistency for μ_n tending to zero exactly at rate $n^{-1/2}$ (see proofs in Appendix A):

Proposition 1 *Assume (**A1-3**) and $\mu_n = \mu_0 n^{-1/2}$, with $\mu_0 > 0$. Then for any sign pattern $s \in \{-1, 0, 1\}^p$ such that $s_{\mathbf{J}} = \operatorname{sign}(\mathbf{w}_{\mathbf{J}})$, $\mathbb{P}(\operatorname{sign}(\hat{w}) = s)$ tends to a limit $\rho(s, \mu_0) \in (0, 1)$, and we have:*

$$\mathbb{P}(\operatorname{sign}(\hat{w}) = s) - \rho(s, \mu_0) = O(n^{-1/2} \log n).$$

Proposition 2 *Assume (**A1-3**) and $\mu_n = \mu_0 n^{-1/2}$, with $\mu_0 > 0$. Then, for any pattern $s \in \{-1, 0, 1\}^p$ such that $s_{\mathbf{J}} \neq \operatorname{sign}(\mathbf{w}_{\mathbf{J}})$, there exist a constant $A(\mu_0) > 0$ such that*

$$\log \mathbb{P}(\operatorname{sign}(\hat{w}) = s) \leqslant -nA(\mu_0) + O(n^{-1/2}).$$

The last two propositions state that we get all relevant variables with probability tending to one *exponentially fast*, while we get exactly get all other patterns with probability tending to a limit *strictly* between zero and one. Note that the results that we give in this paper are valid for *finite* n, i.e., we can derive actual bounds on probability of sign pattern selections with known constants that explictly depend on $\mathbf{w}$, $\mathbf{Q}$ and the joint distribution P_{XY}.

3. Bolasso: Bootstrapped Lasso

Given the n i.i.d. observations $(x_i, y_i) \in \mathbb{R}^d \times \mathbb{R}$, $i = 1, \dots, n$, put together into matrices $\overline{X} \in \mathbb{R}^{n \times p}$ and $\overline{Y} \in \mathbb{R}^n$, we consider m *bootstrap* replications of the n data points (Efron & Tibshirani, 1998); that is, for $k = 1, \dots, m$, we consider a *ghost sample* $(x_i^k, y_i^k) \in \mathbb{R}^p \times \mathbb{R}$, $i = 1, \dots, n$, given by matrices $\overline{X}^k \in \mathbb{R}^{n \times p}$ and $\overline{Y}^k \in \mathbb{R}^n$.

The n pairs (x_i^k, y_i^k), $i = 1, \dots, n$, are sampled uniformly at random *with replacement* from the n original pairs in $(\overline{X}, \overline{Y})$. The sampling of the nm pairs of observations is independent. In other words, we defined the distribution of the ghost sample $(\overline{X}^*, \overline{Y}^*)$ by sampling n points with replacement from $(\overline{X}, \overline{Y})$, and, given $(\overline{X}, \overline{Y})$, the m ghost samples are independently sampled i.i.d. from the distribution of $(\overline{X}^*, \overline{Y}^*)$.

The asymptotic analysis from Section 2 suggests to estimate the supports $J_k = \{j,\ \hat{w}_j^k \neq 0\}$ of the Lasso estimates $\hat{w}^k$ for the bootstrap samples, $k = 1, \dots, m$, and to intersect them to define the Bolasso model estimate of the support: $J = \bigcap_{k=1}^m J_k$. Once J is selected, we estimate w by the unregularized least-square fit restricted to variables in J. The detailed algorithm is given in Algorithm 1. The algorithm has only one extra parameter (the number of bootstrap samples m). Following Proposition 3, $\log(m)$ should be chosen growing with n asymptotically slower than n. In simulations, we always use $m = 128$ (except in Figure 3, where we study the influence of m).

Algorithm 1 Bolasso

Input: data $(\overline{X}, \overline{Y}) \in \mathbb{R}^{n \times (p+1)}$
number of bootstrap replicates m
regularization parameter μ
for $k = 1$ **to** m **do**
  Generate bootstrap samples $(\overline{X}^k, \overline{Y}^k) \in \mathbb{R}^{n \times (p+1)}$
  Compute Lasso estimate $\hat{w}^k$ from $(\overline{X}^k, \overline{Y}^k)$
  Compute support $J_k = \{j,\ \hat{w}_j^k \neq 0\}$
end for
Compute $J = \bigcap_{k=1}^m J_k$
Compute $\hat{w}_J$ from $(\overline{X}_J, \overline{Y})$

Note that in practice, the Bolasso estimate can be computed simultaneously for a large number of regularization parameters because of the efficiency of the Lars algorithm (which we use in simulations), that allows to find the entire regularization path for the Lasso at the (empirical) cost of a single matrix inversion (Efron et al., 2004). Thus the computational complexity of the Bolasso is $O(m(p^3 + p^2 n))$.

The following proposition (proved in Appendix A) shows that the previous algorithm leads to consistent model selection.

Proposition 3 *Assume (**A1-3**) and $\mu_n = \mu_0 n^{-1/2}$, with $\mu_0 > 0$. Then, for all $m > 1$, the probability that the Bolasso does not exactly select the correct model, i.e., $\mathbb{P}(J \neq \mathbf{J})$, has the following upper bound:*

$$\mathbb{P}(J \neq \mathbf{J}) \leqslant m A_1 e^{-A_2 n} + A_3 \frac{\log(n)}{n^{1/2}} + A_4 \frac{\log(m)}{m},$$

where A_1, A_2, A_3, A_4 are strictly positive constants.

Therefore, if $\log(m)$ tends to infinity slower than n when n tends to infinity, the Bolasso asymptotically selects with overwhelming probability the correct active variable, and by regular consistency of the restricted least-square estimate, the correct sign pattern as well. Note that the previous bound is true whether the condition in Eq. (2) is satisfied or not, but could be improved on if we suppose that Eq. (2) is satisfied. See Section 4.1 for a detailed comparison with the Lasso on synthetic examples.

4. Simulations

In this section, we illustrate the consistency results obtained in this paper with a few simple simulations on synthetic examples and some medium scale datasets from the UCI machine learning repository (Asuncion & Newman, 2007).

4.1. Synthetic examples

For a given dimension p, we sampled $X \in \mathbb{R}^p$ from a normal distribution with zero mean and covariance matrix generated as follows: (a) sample a $p \times p$ matrix G with independent standard normal distributions, (b) form $\mathbf{Q} = GG^\top$, (c) scale $\mathbf{Q}$ to unit diagonal. We then selected the first $\mathrm{Card}(\mathbf{J}) = r$ variables and sampled non zero loading vectors as follows: (a) sample each loading signs in $\{-1, 1\}$ uniformly at random and (b) rescale those by a scaling which is uniform at random between $\frac{1}{3}$ and 1 (to ensure $\min_{j \in \mathbf{J}} |\mathbf{w}_j| \geqslant 1/3$). Finally, we chose a constant noise level σ equal to 0.1 times $(\mathbb{E}(\mathbf{w}^\top X)^2)^{1/2}$, and the additive noise ε is normally distributed with zero mean and variance σ^2. Note that the joint distribution on (X, Y) thus defined satisfies with probability one (with respect to the sampling of the covariance matrix) assumptions (**A1-3**).

In Figure 1, we sampled two distributions P_{XY} with $p = 16$ and $r = 8$ relevant variables, one for which the consistency condition in Eq. (2) is satisfied (left), one for which it was not satisfied (right). For a fixed number of sample $n = 1000$, we generated 256 replications and computed the empirical frequencies of selecting any given variable for the Lasso as the regularization parameter μ varies. Those plots show the various asymptotic regimes of the Lasso detailed in Section 2. In particular, on the right plot, although no μ leads to perfect selection (i.e., exactly variables with indices less than $r = 8$ are selected), there is a range where all relevant variables are always selected, while all others are selected with probability within $(0, 1)$.

In Figure 2, we plot the results under the same conditions for the Bolasso (with a fixed number of bootstrap replications $m = 128$). We can see that in the Lasso-consistent case (left), the Bolasso widens the consistency region, while in the Lasso-inconsistent case (right), the Bolasso "creates" a consistency region.

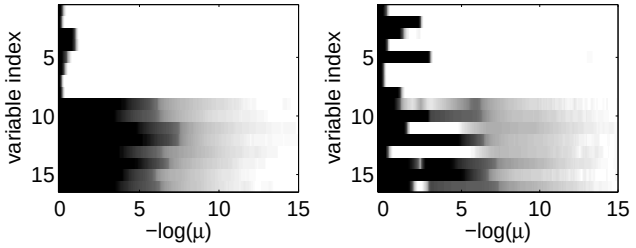

Figure 1. **Lasso**: log-odd ratios of the probabilities of selection of each variable (white = large probabilities, black = small probabilities) vs. regularization parameter. Consistency condition in Eq. (2) satisfied (left) and not satisfied (right).

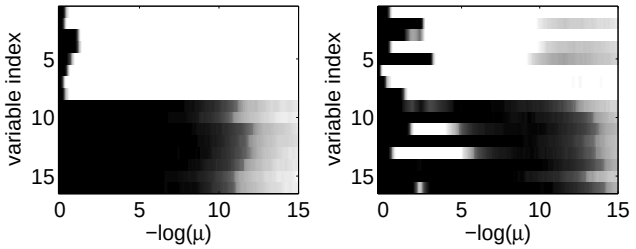

Figure 2. **Bolasso**: log-odd ratios of the probabilities of selection of each variable (white = large probabilities, black = small probabilities) vs. regularization parameter. Consistency condition in Eq. (2) satisfied (left) and not satisfied (right).

In Figure 3, we selected the same two distributions and compared the probability of exactly selecting the correct support pattern, for the Lasso, and for the Bolasso with varying numbers of bootstrap replications (those probabilities are computed by averaging over 256 experiments with the same distribution). In Figure 3, we can see that in the Lasso-inconsistent case (right), the Bolasso indeed allows to fix the unability of the Lasso to find the correct pattern. Moreover, increasing m looks always beneficial; note that although it seems to contradict the asymptotic analysis in Section 3 (which imposes an upper bound for consistency), this is due to the fact that not selecting (at least) the relevant variables has very low probability and is not observed with only 256 replications.

Finally, in Figure 4, we compare various variable selection procedures for linear regression, to the Bolasso, with two distributions where $p = 64$, $r = 8$ and varying n. For all the methods we consider, there is a natural way to select exactly r variables with no free parameters (for the Bolasso, we select the most stable pattern with r elements, i.e., the pattern which corresponds to most values of μ). We can see that the Bolasso outperforms all other variable selection methods, even in settings where the number of samples becomes of the order of the number of variables, which requires additional theoretical analysis, subject of ongoing

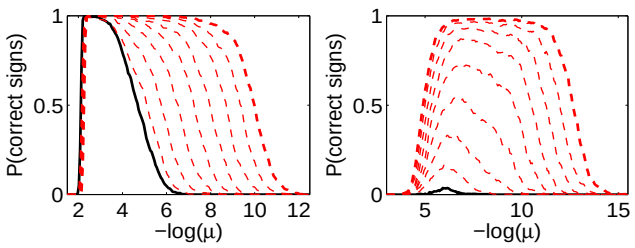

Figure 3. Bolasso (red, dashed) and Lasso (black, plain): probability of correct sign estimation vs. regularization parameter. Consistency condition in Eq. (2) satisfied (left) and not satisfied (right). The number of bootstrap replications m is in $\{2, 4, 8, 16, 32, 64, 128, 256\}$.

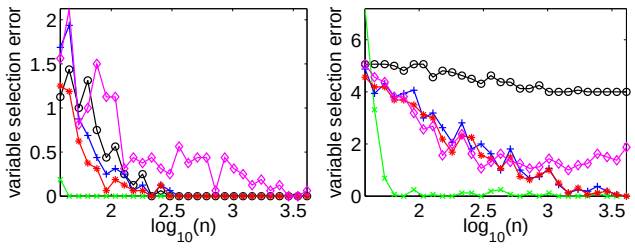

Figure 4. Comparison of several variable selection methods: Lasso (black circles), Bolasso (green crosses), forward greedy (magenta diamonds), thresholded LS estimate (red stars), adaptive Lasso (blue pluses). Consistency condition in Eq. (2) satisfied (left) and not satisfied (right). The averaged (over 32 replications) variable selection error is computed as the square distance between sparsity pattern indicator vectors.

research. Note in particular that we compare with bagging of least-square regressions (Breiman, 1996a) followed by a thresholding of the loading vector, which is another simple way of using bootstrap samples: the Bolasso provides a more efficient way to use the extra information, not for usual stabilization purposes (Breiman, 1996b), but directly for model selection. Note finally, that the bagging of Lasso estimates requires an additional parameter and is thus not tested.

4.2. UCI datasets

The previous simulations have shown that the Bolasso is succesful at performing model selection in synthetic examples. We now apply it to several linear regression problems and compare it to alternative methods for linear regression, namely, ridge regression, Lasso, bagging of Lasso estimates (Breiman, 1996a), and a soft version of the Bolasso (referred to as Bolasso-S), where instead of intersecting the supports for each bootstrap replications, we select those which are present in at least 90% of the bootstrap replications. In Table 1, we consider data randomly generated as in Section 4.1 (with $p = 32$, $r = 8$, $n = 64$), where

the true model is known to be composed of a sparse loading vector, while in Table 2, we consider regression datasets from the UCI machine learning repository, for which we have no indication regarding the sparsity of the best linear predictor. For all of those, we perform 10 replications of 10-fold cross validation and for all methods (which all have one free regularization parameter), we select the best regularization parameter on the 100 folds and plot the mean square *prediction* error and its standard deviation.

Note that when the generating model is actually sparse (Table 1), the Bolasso outperforms all other models, while in other cases (Table 2) the Bolasso is sometimes too strict in intersecting models, i.e., the softened version works better and is more competitive with other methods. Studying the effects of this softened scheme (which is more similar to usual voting schemes), in particular in terms of the potential trade-off between good model selection and low prediction error, and under conditions where p is large, is the subject of ongoing work.

Table 1. Comparison of least-square estimation methods, data generated as described in Section 4.1, with $\kappa = \|\mathbf{Q}_{J^cJ}\mathbf{Q}_{JJ}^{-1}\mathbf{s}_J\|_\infty$ (cf. Eq. (2)). Performance is measured through mean squared prediction error (multiplied by 100).

5. Conclusion

We have presented a detailed analysis of the variable selection properties of a boostrapped version of the Lasso. The model estimation procedure, referred to as the Bolasso, is provably consistent under general assumptions. This work brings to light that poor variable selection results of the Lasso may be easily enhanced thanks to a simple parameter-free resampling procedure. Our contribution also suggests that the use of bootstrap samples by L. Breiman in Bagging/Arcing/Random Forests (Breiman, 1998) may have been so far slightly overlooked and considered a minor feature, while using boostrap samples may actually be a key computational feature in such algorithms for good model selection performances, and eventually good prediction performances on real datasets.

The current work could be extended in various ways: first, we have focused on a fixed total number of variables, and allowing the numbers of variables to grow is important in theory and in practice (Meinshausen & Yu, 2008). Second, the same technique can be applied to similar settings than least-square regression with the ℓ_1-norm, namely regularization by block ℓ_1-norms (Bach, 2008) and other losses such as general convex classification losses. Finally, theoretical and practical connections could be made with other work on resampling methods and boosting (Bühlmann, 2006).

A. Proof of Model Consistency Results

In this appendix, we give sketches of proofs for the asymptotic results presented in Section 2 and Section 3. The proofs rely on the well-known property of the Lasso optimization problems, namely that if the sign pattern of the solution is known, then we can get the solution in closed form.

A.1. Optimality Conditions

We let denote $\overline{\varepsilon} = \overline{Y} - \overline{X}\mathbf{w} \in \mathbb{R}^n$, $Q = \overline{X}^\top \overline{X}/n \in \mathbb{R}^{p\times p}$ and $q = \overline{X}^\top \overline{\varepsilon}/n \in \mathbb{R}^p$. First, we can equivalently rewrite Eq. (1) as:

$$\min_{w\in\mathbb{R}^p} \tfrac{1}{2}(w-\mathbf{w})^\top Q(w-\mathbf{w}) - q^\top(w-\mathbf{w}) + \mu_n\|w\|_1. \quad (3)$$

The optimality conditions for Eq. (3) can be written in terms of the sign pattern $s = s(w) = \operatorname{sign}(w)$ and the sparsity pattern $J = J(w) = \{j,\ w_j \neq 0\}$ (Yuan & Lin, 2007):

$$\|(Q_{J^cJ}Q_{JJ}^{-1}Q_{J\mathbf{J}} - Q_{J^c\mathbf{J}})\mathbf{w}_\mathbf{J} + (Q_{J^cJ}Q_{JJ}^{-1}q_J - q_{J^c}) + \mu_n Q_{J^cJ}Q_{JJ}^{-1}s_J\|_\infty \leqslant \mu_n, \quad (4)$$

$$\operatorname{sign}(Q_{JJ}^{-1}Q_{J\mathbf{J}}\mathbf{w}_\mathbf{J} + Q_{JJ}^{-1}q_J - \mu_n Q_{JJ}^{-1}s_J) = s_J. \quad (5)$$

In this paper, we focus on regularization parameters μ_n of the form $\mu_n = \mu_0 n^{-1/2}$. The main idea behind the results is to consider that (Q, q) are distributed according to their limiting distributions, obtained from the law of large numbers and the central limit theorem, i.e., Q converges to $\mathbf{Q}$ a.s. and $n^{1/2}q$ is asymptotically normally distributed with mean zero and covariance matrix $\sigma^2\mathbf{Q}$. When assuming this, Propositions 1 and 2 are straightforward. The main effort is to make sure that we can safely replace (Q, q) by

their limiting distributions. The following lemmas give sufficient conditions for correct estimation of the signs of variables in $\mathbf{J}$ and for selecting a given pattern s (note that all constants could be expressed in terms of $\mathbf{Q}$ and $\mathbf{w}$, details are omitted here):

Lemma 1 *Assume (**A2**) and* $\|Q-\mathbf{Q}\|_2 \leqslant \lambda_{\min}(\mathbf{Q})/2$. *Then* $\operatorname{sign}(\hat{w}_{\mathbf{J}}) \neq \operatorname{sign}(\mathbf{w}_{\mathbf{J}})$ *implies* $\|\mathbf{Q}^{-1/2}q\|_2 \geqslant C_1 - \mu_n C_2$, *where* $C_1, C_2 > 0$.

Lemma 2 *Assume (**A2**) and let* $s \in \{-1,0,1\}^p$ *such that* $s_{\mathbf{J}} = \operatorname{sign}(\mathbf{w}_{\mathbf{J}})$. *Let* $J = \{j, s_j \neq 0\} \supset \mathbf{J}$. *Assume*

$$\|\mathbf{Q}-Q\|_2 \leqslant \min\{\eta_1, \lambda_{\min}(\mathbf{Q})/2\}, \tag{6}$$

$$\|\mathbf{Q}^{-1/2}q\|_2 \leqslant \min\{\eta_2, C_1 - \mu_n C_4\}, \tag{7}$$

$$\|\mathbf{Q}_{J^cJ}\mathbf{Q}_{JJ}^{-1}q_J - q_{J^c} - \mu_n \mathbf{Q}_{J^cJ}\mathbf{Q}_{JJ}^{-1}s_J\|_\infty \leqslant \mu_n - C_5\eta_1\mu_n - C_6\eta_1\eta_2, \tag{8}$$

$$\forall i \in J\backslash\mathbf{J}, s_i\left[Q_{JJ}^{-1}(q_J - \mu_n s_J)\right]_i \geqslant \mu_n C_7\eta_1 + C_8\eta_1\eta_2, \tag{9}$$

with C_4, C_5, C_6, C_7, C_8 *are positive constants. Then* $\operatorname{sign}(\hat{w}) = \operatorname{sign}(\mathbf{w})$.

Those two lemmas are useful because they relate optimality of certain sign patterns to quantities from which we can derive concentration inequalities.

A.2. Concentration Inequalities

Throughout the proofs, we need to provide upper bounds on the following quantities $\mathbb{P}(\|\mathbf{Q}^{-1/2}q\|_2 > \alpha)$ and $\mathbb{P}(\|Q-\mathbf{Q}\|_2 > \eta)$. We obtain, following standard arguments (Boucheron et al., 2004): if $\alpha < C_9$ and $\eta < C_{10}$ (where $C_9, C_{10} > 0$ are constants),

$$\mathbb{P}(\|\mathbf{Q}^{-1/2}q\|_2 > \alpha) \leqslant 4p\exp\left(-\tfrac{n\alpha^2}{2pC_9}\right).$$

$$\mathbb{P}(\|Q-\mathbf{Q}\|_2 > \eta) \leqslant 4p^2\exp\left(-\tfrac{n\eta^2}{2p^2C_{10}}\right).$$

We also consider multivariate *Berry-Esseen inequalities* (Bentkus, 2003); the probability $\mathbb{P}(n^{1/2}q \in \mathcal{C})$ can be estimated as $\mathbb{P}(t \in \mathcal{C})$ where t is normal with mean zero and covariance matrix $\sigma^2\mathbf{Q}$. The error $|\mathbb{P}(n^{1/2}q \in \mathcal{C}) - \mathbb{P}(t \in \mathcal{C})|$ is then *uniformly* (for all convex sets $\mathcal{C}$) upperbounded by:

$$400p^{1/4}n^{-1/2}\lambda_{\min}(\mathbf{Q})^{-3/2}\mathbb{E}|\varepsilon|^3\|X\|_2^3 = C_{11}n^{-1/2}.$$

A.3. Proof of Proposition 1

By Lemma 2, for any A and n large enough, the probability that the sign is different from s is upperbounded by

$$\mathbb{P}\left(\|\mathbf{Q}^{-1/2}q\|_2 > \tfrac{A(\log n)^{1/2}}{n^{1/2}}\right) + \mathbb{P}\left(\|\mathbf{Q}-Q\|_2 > \tfrac{A(\log n)^{1/2}}{n^{1/2}}\right) + \mathbb{P}\{t \notin \mathcal{C}(s, \mu_0(1-\alpha))\} + 2C_{11}n^{-1/2},$$

where $\mathcal{C}(s,\beta)$ is the set of t such that (a) $\|\mathbf{Q}_{J^cJ}\mathbf{Q}_{JJ}^{-1}t_J - t_{J^c} - \beta\mathbf{Q}_{J^cJ}\mathbf{Q}_{JJ}^{-1}s_J\|_\infty \leqslant \beta$ and (b) for all $i \in J\backslash\mathbf{J}, s_i\left[Q_{JJ}^{-1}(t_J - \beta s_J)\right]_i \geqslant 0$. Note that with $\alpha = O((\log n)n^{-1/2})$, which tends to zero, we have: $\mathbb{P}\{t \notin \mathcal{C}(s,\mu_0(1-\alpha))\} \leqslant \mathbb{P}\{t \notin \mathcal{C}(s,\mu_0)\} + O(\alpha)$. All terms (if A is large enough) are thus $O((\log n)n^{-1/2})$.

This shows that $\mathbb{P}(\operatorname{sign}(\hat{w}) = \operatorname{sign}(\mathbf{w})) \geqslant \rho(s,\mu_0) + O((\log n)n^{-1/2})$ where $\rho(s,\mu_0) = \mathbb{P}\{t \in \mathcal{C}(s,\mu_0)\} \in (0,1)$–the probability is strictly between 0 and 1 because the set and its complement have non empty interiors and the normal distribution has a positive definite covariance matrix $\sigma^2\mathbf{Q}$. The other inequality can be proved similarly. Note that the constant in $O((\log n)n^{-1/2})$ depends on μ_0 but by carefully considering this dependence on μ_0, we can make the inequality uniform in μ_0 as long as μ_0 tends to zero or infinity at most at a logarithmic speed (i.e., μ_n deviates from $n^{-1/2}$ by at most a logarithmic factor). Also, it would be interesting to consider uniform bounds on portions of the regularization path.

A.4. Proof of Proposition 2

From Lemma 1, the probability of not selecting any of the variables in $\mathbf{J}$ is upperbounded by

$$\mathbb{P}(\|\mathbf{Q}^{-1/2}q\|_2 > C_1 - \mu_n C_2) + \mathbb{P}(\|\mathbf{Q}-Q\|_2 > \lambda_{\min}(\mathbf{Q})/2),$$

which is straightforwardly upper bounded (using Section A.2) by a term of the required form.

A.5. Proof of Proposition 3

In order to simplify the proof, we made the simplifying assumption that the random variables X and ε have compact supports. Extending the proofs to take into account the looser condition that $\|X\|^2$ and ε^2 have non uniformly infinite cumulant generating functions (i.e., assumption (**A1**)) can be done with minor changes. The probability that $\bigcap_{k=1}^m J_k$ is different from $\mathbf{J}$ is upper bounded by the sum of the following probabilities:

(a) Probability of missing at least one variable in J in any of the m replications: by Lemma 1, the probability that for the k-th replication, one index in $\mathbf{J}$ is not selected, is upper bounded by

$$\mathbb{P}(\|\mathbf{Q}^{-1/2}q^*\|_2 > C_1/2) + \mathbb{P}(\|\mathbf{Q}-Q^*\|_2 > \lambda_{\min}(\mathbf{Q})/2),$$

where q^* corresponds to the ghost sample; as common in theoretical analysis of the bootstrap, we relate q^* to q as follows: $\mathbb{P}(\|\mathbf{Q}^{-1/2}q^*\|_2 > C_1/2) \leqslant \mathbb{P}(\|\mathbf{Q}^{-1/2}(q^*-q)\|_2 > C_1/4) + \mathbb{P}(\|\mathbf{Q}^{-1/2}q\|_2 > C_1/4)$ (and similarly for $\mathbb{P}(\|\mathbf{Q}-Q^*\|_2 > \lambda_{\min}(\mathbf{Q})/2)$). Because we have assumed that X and ε have compact supports, the bootstrapped variables have also compact support and we can use concentration inequalities (given the original variables $\overline{X}$, and also

after expectation with respect to $\overline{X}$). Thus the probability for one bootstrap replication is upperbounded by Be^{-Cn} where B and C are strictly positive constants. Thus the overall contribution of this part is less than mBe^{-Cn}.

(b) Probability of not selecting exactly J in all replications: note that this is not tight at all since on top of the relevant variables which are selected with overwhelming probability, different additional variables may be selected for different replications and cancel out when intersecting.

Our goal is thus to bound $\mathbb{E}\left\{\mathbb{P}(\mathbf{J}^* \neq \mathbf{J}|\overline{X})^m\right\}$. By Lemma 2, we have that $\mathbb{P}(\mathbf{J}^* \neq \mathbf{J}|\overline{X})$ is upper bounded by

$$\mathbb{P}\left(\|\mathbf{Q}^{-1/2}q^*\|_2 > \tfrac{A(\log n)^{1/2}}{n^{1/2}}|\overline{X}\right)$$

$$+\mathbb{P}\left(\|\mathbf{Q} - Q^*\|_2 > \frac{A(\log n)^{1/2}}{n^{1/2}}|\overline{X}\right)$$

$$+\mathbb{P}(t^* \notin \mathcal{C}(\mu_0)|\overline{X}) + 2C_{11}n^{-1/2} + O(\tfrac{\log n}{n^{1/2}}),$$

where now, given $\overline{X}, \overline{Y}$, t^* is normally distributed with mean $n^{1/2}q$ and covariance matrix $\frac{1}{n}\sum_{i=1}^n \varepsilon_i^2 x_i x_i^\top$.

As in (a), the first two terms and the last two ones are uniformly $O(\frac{\log n}{n^{1/2}})$ (if A is large enough). We then have to consider the remaining term. We have $\mathcal{C}(\mu_0) = \{t^* \in \mathbb{R}^p, \|\mathbf{Q}_{\mathbf{J}^c\mathbf{J}}\mathbf{Q}_{\mathbf{J}\mathbf{J}}^{-1}t^*_{\mathbf{J}} - t^*_{\mathbf{J}^c} - \mu_0\mathbf{Q}_{\mathbf{J}^c\mathbf{J}}\mathbf{Q}_{\mathbf{J}\mathbf{J}}^{-1}\mathbf{s}_{\mathbf{J}}\|_\infty \leqslant \mu_0\}$. By Hoeffding's inequality, we can replace the covariance matrix that depends on $\overline{X}$ and $\overline{Y}$ by $\sigma^2\mathbf{Q}$, at cost $O(n^{-1/2})$. We thus have to bound $\mathbb{P}(n^{1/2}q + y \notin \mathcal{C}(\mu_0)|q)$ for y normally distributed and $\mathcal{C}(\mu_0)$ a fixed compact set. Because the set is compact, there exist constants $A, B > 0$ such that, if $\|n^{1/2}q\|_2 \leqslant \alpha$ for α large enough, then $\mathbb{P}(n^{1/2}q + y \notin \mathcal{C}(\mu_0)|q) \leqslant 1 - Ae^{-B\alpha^2}$. Thus, by truncation, we obtain a bound of the form:

$$\mathbb{E}\left\{\mathbb{P}(\mathbf{J}^* \neq \mathbf{J}|\overline{X})^m\right\} \leqslant (1 - Ae^{-B\alpha^2} + F\frac{\log n}{n^{1/2}})^m + Ce^{-B\alpha^2}$$

$$\leqslant \exp(-mAe^{-B\alpha^2} + mF\frac{\log n}{n^{1/2}}) + Ce^{-B\alpha^2},$$

where we have used Hoeffding's inequality to upper bound $\mathbb{P}(\|n^{1/2}q\|_2 > \alpha)$. By minimizing in closed form with respect to $e^{-B\alpha^2}$, i.e., with $e^{-B\alpha^2} = \frac{F\log n}{An^{1/2}} + \frac{\log(mA/C)}{mA}$, we obtain the desired inequality.

Learning All Optimal Policies with Multiple Criteria

1947 Center St. Ste. 600, Berkeley, CA 94704

Abstract

We describe an algorithm for learning in the presence of multiple criteria. Our technique generalizes previous approaches in that it can learn optimal policies for all linear preference assignments over the multiple reward criteria at once. The algorithm can be viewed as an extension to standard reinforcement learning for MDPs where instead of repeatedly backing up maximal expected rewards, we back up the set of expected rewards that are maximal for some set of linear preferences (given by a weight vector, $\overrightarrow{w}$). We present the algorithm along with a proof of correctness showing that our solution gives the optimal policy for any linear preference function. The solution reduces to the standard value iteration algorithm for a specific weight vector, $\overrightarrow{w}$.

1. Introduction

In Reinforcement Learning (RL), an agent interacts with the environment to learn optimal behavior. (Sutton & Barto, 1998) Most RL techniques are based on a scalar reward, i.e., they aim to optimize an objective that is expressed as a function of a scalar reinforcement. A natural extension to traditional RL techniques is thus the case where there are multiple rewards. In many realistic domains, actions depend on satisfying multiple objectives simultaneously (such as achieving performance while keeping costs low, a robot moving efficiently toward a goal while being close to a recharging station, or a government funding both military and social programs). Learning optimal policies in many real-world domains thus depends on the ability to learn in the presence of multiple rewards. However, the resulting policies depend heavily on the preferences over these rewards, and they may change swiftly as preferences vary. We present both an algorithm for the general case of learning all optimal policies under all assignments of linear priorities for the reward components, and a proof showing the correctness of our algorithm.

We start with a motivating example of a simple task with multiple rewards in Section 2. The paper then proceeds to the main algorithm in Section 3. We address related work in Section 4, and then Section 5 discusses the complexity of our algorithm including realistic and tractable specializations of our algorithm. Section 6 describes the application of this algorithm to an example domain, and Section 7 discusses extensions to this technique, such as implementations using other RL methods (such as temporal difference methods) and applications of our algorithm to infer another agent's preferences based on observing their behavior. Section 8 outlines the proof of the algorithm's correctness.

2. Explanation and Motivating Example

We assume that instead of getting a single reward signal, the agent gets a reward divided up into several components, a reward vector. That is, we decompose the reward signal $r(s,a)$ (where s is a state and a is an action) into a vector $\overrightarrow{r}(s,a) = [r_1(s,a), r_2(s,a), \ldots, r_n(s,a)]$. An agent could potentially optimize many different functions of these rewards, but the simplest function is a weighted sum: for every fixed weight vector $\overrightarrow{w}$ we obtain a total reward scalar $r_{\overrightarrow{w}}(s,a) = \overrightarrow{w} \cdot \overrightarrow{r}(s,a)$. There is thus an optimal policy $\pi^*_{\overrightarrow{w}}$ for *each* weight vector $\overrightarrow{w}$.

Consider, for example, a lab guinea pig running a familiar maze, shown in Figure 1. The guinea pig runs through the maze to one of four stashes of food. Once it has reached a stash and eaten the food, the experimenter takes it out of the maze and returns it to its cage, so it can only hope to eat one of the stashes per run of the maze. Assume that there are

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

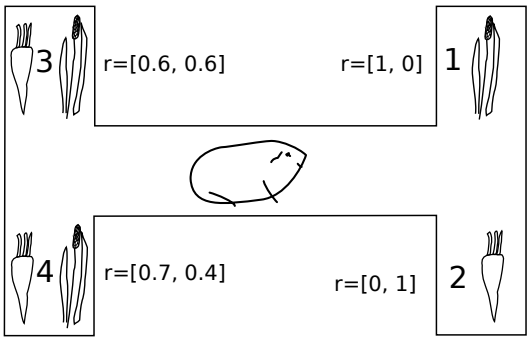

Figure 1. An example maze with rewards, split into 2 components, at 3 different locations

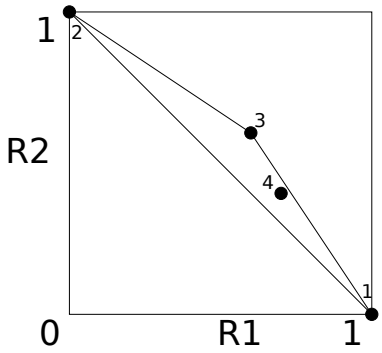

Figure 2. The potential reward vectors in the guinea pig example

only 2 types of food provided (hay and carrot), so reward vectors take the form [hay,carrot]. Location 1 contains hay ($\overrightarrow{r} = [1, 0]$), location 2 contains carrot ($\overrightarrow{r} = [0, 1]$), and locations 3 and 4 contain a little of both ($\overrightarrow{r} = [0.6, 0.6]$ and $[0.7, 0.4]$, respectively). Because the maze is familiar, the animal knows where the food is placed and what sort of food is in each location.

The experimenter has several different guinea pigs and has discovered that each has different tastes. For instance, Chester likes only hay ($\overrightarrow{w} = [1, 0]$), and Milo likes only carrot ($\overrightarrow{w} = [0, 1]$), but greedy Louis likes both equally ($\overrightarrow{w} = [0.5, 0.5]$). (Without loss of generality, assume that all animals' weight vectors satisfy $\sum_i w_i = 1$: they describe relative preferences, not absolute utilities.) So, if Chester goes to location 4 ($\overrightarrow{r} = [0.7, 0.4]$), then he gets reward $r = \overrightarrow{w} \cdot \overrightarrow{r} = 0.7$. Milo would get 0.4, and Louis would get a reward of 0.55.

Looking at the maze, we see that although there are 4 possible strategies (with rewards shown in Figure 2, only 3 of them are optimal for any values of $\overrightarrow{w}$. One strategy occurs when the weight vector has $w_0 > 0.6$ (and hence $w_1 = 1 - w_0 < 0.4$): then the guinea pig should head straight for location 1, because the reward elsewhere will be no more than 0.6. By the exact same logic, when the weight vector has $w_1 > 0.6$ (and $w_0 < 0.4$), then the animal should go to location 2. In all other cases ($0.4 \leq w_0 \leq 0.6$), it will optimize its reward by going to location 3. Under no circumstances would an optimal agent go to location 4! No matter what its weight vector, some other location dominates location 4. We would like to determine exactly this: which policies are viable and which are not (even without knowing $\overrightarrow{w}$).

Our method learns the set of optimal policies for *all* $\overrightarrow{w}$ at the same time. Once the agent has learned all these policies, it can change reward weights at runtime to get a new optimal behavior, without having to do any relearning. For a fixed priority scheme (fixed weight vector $\overrightarrow{w}$) over the multiple reward components, our algorithm results in the standard recurrence for Q-values that is analogous to the equation for the average weighted reward case as in (Natarajan & Tadepalli, 2005):

$$Q^*_{\overrightarrow{w}}(s, a) = \mathbb{E}\left[\overrightarrow{w} \cdot \overrightarrow{r}(s, a) + \gamma \max_{a'} Q^*_{\overrightarrow{w}}(s', a') | s, a\right]$$

In the general case, where we do not know the relative priorities over the reward components, our algorithm exploits the fact that the extrema of the set of Q-values vectors (Q vectors that are maximal for some weight setting) is the same as the *convex hull* of the Q-value vectors. (The convex hull is defined as the smallest convex set that contains all of a set of points. In this case, we mean the points that lie on the boundary of this convex set, which are of course the extreme points–the ones that are maximal in some direction. This is somewhat similar to the Pareto curve, since both are maxima over trade-offs in linear domains.) Now we can rewrite the general RL recurrence in terms of operations on the convex hull of Q-values, and we show this recurrence to be correct and convergent to the value iteration algorithm in the fixed weight vector case. Many standard RL algorithms in the literature can be seen as limiting cases of our more general algorithm. While the worst-case complexity of our general algorithm is exponentially higher than that of fixed-$\overrightarrow{w}$ cases, it not only solves all the fixed-$\overrightarrow{w}$ cases but also determines which cases are worth solving. We also give some constraints and techniques that can help reduce the complexity.

3. Convex Hull Value Iteration

In this section, we introduce the problem definition in the context of a traditional MDP setting and our approach and algorithm.

3.1. Preliminaries and Notation

Our approach is based on an MDP which is a tuple $(S, A, T, \gamma, \overrightarrow{r})$, where S is a finite set of N states, $A = \{a_1, \ldots, a_k\}$ is a set of k actions, $T = \{\mathrm{P}_{sa}(s')\}$ is the set of state transition probabilities ($\mathrm{P}_{sa}(s')$ is the transition probability of going to state $s' \in S$ by taking action $a \in A$ from state $s \in S$), $\gamma \in [0, 1)$ is the discount factor, and $\overrightarrow{r} : S \times A \mapsto \mathbb{R}^d$ is the reward function giving d-component reward vector $\overrightarrow{r}(s, a)$. This differs from the standard formulation only in that reward now comes as a vector.

A policy, π, is the map $S \mapsto A$, and the value function for any policy π, evaluated at some state s_i is the vector

$$\overrightarrow{V}^{\pi}(s_i) = \mathbb{E}[\overrightarrow{r}(s_i, a_i) + \gamma \overrightarrow{r}(s_{i+1}, a_{i+1}) + \ldots | \pi] \quad (1)$$

where the expectation is over the distribution of the state and reward sequence $(s_i, \overrightarrow{r}_i, s_{i+1}, \overrightarrow{r}_{i+1}, \ldots)$, that is obtained on executing the policy π starting from the state s_i. The Q-function is the vector

$$\overrightarrow{Q}^{\pi}(s, a) = \mathbb{E}_{\overrightarrow{r}(s,a), s' \sim P_{sa}} \left[\overrightarrow{r}(s, a) + \gamma \overrightarrow{V}^{\pi}(s') \right] \quad (2)$$

where $\overrightarrow{r}(s, a), s' \sim P_{sa}$ means that the expectation with respect to s' and $\overrightarrow{r}(s, a)$ distributed according to P_{sa}. The optimal Q function for a weight $\overrightarrow{w}$ is $Q^*_{\overrightarrow{w}}(s, a) = sup_{\pi} \overrightarrow{w} \cdot \overrightarrow{Q}^{\pi}(s, a)$.

3.2. Approach: Convex Hulls

Given some $\overrightarrow{w}$, the resulting reward for taking an action is $r(s, a) = \overrightarrow{w} \cdot \overrightarrow{r}(s, a)$. This gives us the following recurrence for optimal Q-values, which is exactly equivalent to the equation for a single reward component:

$$Q_{\overrightarrow{w}}(s, a) = \mathbb{E}\left[\overrightarrow{w} \cdot \overrightarrow{r}(s, a) + \gamma \max_{a'} Q_{\overrightarrow{w}}(s', a') | s, a \right]$$

We can solve this recurrence directly, or we can use it to get converging approximations to the optimal value function—this gives rise to the value iteration method, Q-learning, and so on.

An alternative view is that each possible policy gives a different expected reward $\overrightarrow{Q}(s, a)$, and we simply want to select a policy by maximizing the dot product of this with $\overrightarrow{w}$. For a fixed $\overrightarrow{w}$, only one such $\overrightarrow{Q}(s, a)$ can be optimal, but in general we might care about any $\overrightarrow{Q}$s that are maximal for some $\overrightarrow{w}$. But this set of Q-values that are extrema is exactly the convex hull of the Q-values! This allows us to use standard convex hull operations to pare down the set of points we consider and gives rise to the following proposition.

Proposition 1. *The convex hull over Q-values contains the optimal policy over the average expected reward $r(s, a) = \overrightarrow{w} \cdot \overrightarrow{r}(s, a)$ for any $\overrightarrow{w}$.*

To make this operational and derive an algorithm that maintains all optimal policies for any weight vector $\overrightarrow{w}$, we need a few definitions for relevant operations on the convex hull.

We write $\overset{\circ}{Q}(s, a)$ to represent the vertices of the convex hull of possible Q-value vectors for taking action a at state s. We then define the following operations on convex hulls which will be used to construct our learning algorithm.

Definition 1. Translation and scaling operations

$$\overrightarrow{u} + b\overset{\circ}{Q} \equiv \{\overrightarrow{u} + b\overrightarrow{q} : \overrightarrow{q} \in \overset{\circ}{Q}\} \quad (3)$$

Definition 2. Summing two convex hulls

$$\overset{\circ}{Q} + \overset{\circ}{U} \equiv \text{hull}\{\overrightarrow{q} + \overrightarrow{u} : \overrightarrow{q} \in \overset{\circ}{Q}, \overrightarrow{u} \in \overset{\circ}{U}\} \quad (4)$$

Definition 3. Extracting the Q-value *To extract the best Q-value for a given $\overrightarrow{w}$, we perform a simple maximum:*

$$Q_{\overrightarrow{w}}(s, a) \equiv \max_{\overrightarrow{q} \in \overset{\circ}{Q}(s,a)} \overrightarrow{w} \cdot \overrightarrow{q} \quad (5)$$

Given these definitions, we are now ready to illustrate the basic algorithm.

3.3. Convex Hull Value Iteration Algorithm

Our algorithm extends the single-$\overrightarrow{w}$ case (which is the standard expected discounted reward framework (Bellman, 1957)) into the following recurrence:

$$\overset{\circ}{Q}(s, a) = \mathbb{E}\left[\overrightarrow{r}(s, a) + \gamma \,\text{hull} \bigcup_{a'} \overset{\circ}{Q}(s', a') | s, a \right] \quad (6)$$

That is, instead of repeatedly backing up maximal expected rewards, we back up the set of expected rewards that are maximal for some $\overrightarrow{w}$. While the expectation over hulls looks awkward, it is the natural equivalent of an expectation of maxima, and it arises for the same reason. We must take an expectation over s', but once in s', we can choose the best action, no matter what our $\overrightarrow{w}$. The expectation's computation can be broken down, in the usual way, into the scalings and sums we have already defined.

This leads us to define Algorithm 1, which extends the value iteration algorithm (Bellman, 1957) to learn optimal Q-values for all possible $\overrightarrow{w}$. A proof of its correctness is given in Section 8.

Algorithm 1 Value iteration algorithm modified from that of Bellman (1957)

Initialize $\overset{\circ}{Q}(s,a)$ arbitrarily $\forall s, a$
while not converged **do**
  for all $s \in S$, $a \in A$ **do**
    $\overset{\circ}{Q}(s,a) \leftarrow \mathbb{E}[\overrightarrow{r}(s,a)$
      $+\gamma \,\mathrm{hull} \bigcup_{a'} \overset{\circ}{Q}(s',a')|s,a]$
  end for
end while

return $\overset{\circ}{Q}$

4. Related Work

There is now a body of work addressing multi-reward reinforcement learning. There have been algorithms that assume a fixed ordering between different rewards, such as staying alive and not losing food (Gabor et al., 1998), techniques based on formulating the multiple reward problem as optimizing a weighted sum of the discounted total rewards for multiple reward types (Feinberg & Schwartz, 1995), and techniques that decompose the reward function into multiple components which are learned independently (with a single policy) (Russell & Zimdars, 2003). In all these cases, the preference over rewards is assumed to be fixed and time-invariant. In a slightly more flexible formulation, Mannor and Shimkin (2004) take multiple reward components and perform learning that results in expected rewards lying in a particular region of reward space.

More recently, (Natarajan & Tadepalli, 2005) formulate the multiple reward RL problem as we do, using a weighted expected discounted reward framework, and they store both the currently best policy and its Q-values as vectors. When priorities change dynamically (as reflected in changes in the weight vector), the agent can calculate new reward scalars from the vectors and thus start from the Q-values of the best policy learned so far rather than resetting entirely. As far as we are aware, none of the techniques proposed tackle the general case of learning optimal policies for all linear preference assignments over the multiple reward components.

4.1. Relation to POMDPs

Our problem, and hence its solution, is closely related to the standard partially observable Markov decision process (POMDP) formulation. In a POMDP, we have a model of both observed and unobserved variables and use Bayesian reasoning to infer a joint distribution over the hidden variables. Then, we must choose an optimal action based on both the observed state and the continuous beliefs. (Kaelbling et al., 1998)

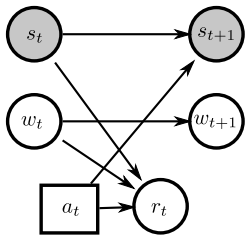

Figure 3. A POMDP formulation of multiple reward components

Consider the POMDP shown in Figure 3; here, the reward depends on an unobserved multinomial random variable, so $\mathbb{E}[r] = \sum_i \mathrm{P}(w = i) r_i$. If we define $\mathrm{P}(w_t|w_{t-1})$ to be the identity, the distribution of w will not change with t. Then, the expected reward depends linearly on our prior distribution over w, and the dual of the usual POMDP maximum-hyperplane algorithm corresponds to a convex hull operation over reward components. It is thus possible to write our multiple-reward problem as a POMDP problem. This suggests a natural route to extend our algorithm to operate on POMDPs. It remains future work, however, to see if the approximation algorithms used for solving POMDPs can yield useful results in our domain.

5. Complexity

This algorithm relies on four convex hull operations, whose complexity we will analyze in terms of the number of points on the hull, n; in the limit, this number converges to the number of optimal policies in the environment. We must both scale (by probabilities and discounts) and translate (by rewards) our convex hulls; these operations only require touching every point once, resulting in a complexity of $O(n)$. We must also merge two or more convex hulls. This takes time at most $O((kn)^{\lfloor d/2 \rfloor})$ if $d > 3$, where k is the number of hulls involved, n is the number of points in each hull, and d is the dimension (number of reward components) (Clarkson & Shor, 1989). Finally, we must add two convex hulls. If done naively by adding all pairs of points and taking a hull, this takes time at most $O(n^{2\lfloor d/2 \rfloor})$. All these operations must be performed whenever we back up Q-values, so we multiply the complexity of ordinary reinforcement learning by $O(n^{2\lfloor d/2 \rfloor})$. (However, in the $d = 2$ and $d = 3$ cases, there are efficient ways to perform these operations.)

In the long run, the number of points on each convex hull, n, must converge to a limit as the Q-values con-

		R1	E2	
		E1		R2
		H		

Figure 4. A resource-collection domain

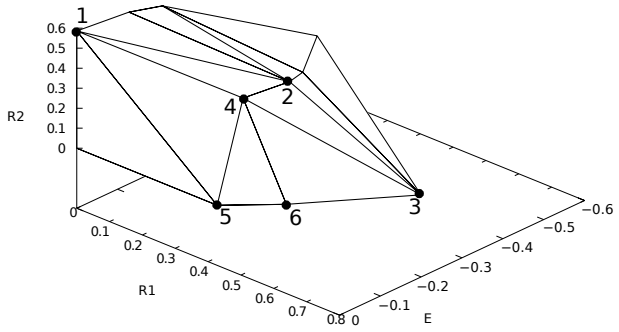

Figure 5. Optimal rewards in the resource-collection domain

verge to their optimal values. Eventually, there will be exactly one point on each convex hull for each optimal policy. However, in the short term, the number of short-range policies we might have to track might be much lower or even higher. Also, the number of optimal policies n depends on the environment in a complicated way, with the worst case being that all policies ($|A|^{|S|}$ of them) may be optimal for some weight vector.

5.1. Reducing the Complexity

The complexity result of our algorithmic modifications is an exponential blowup with the number of reward components. There are a few main ways of tackling this. The first is to simply restrict the number of reward components; with only, say, 5 or fewer, this additional computation is likely not to be an undue burden. In practice, there are currently very few problems studied with more reward components than this.

When we must handle a high-dimensional problem, we can reduce the complexity by applying constraints on the weight vectors that we might optimize for. Given the geometric nature of our approach, if we have knowledge about the directions of allowable vectors, such as $\overrightarrow{a} \cdot \overrightarrow{w} > 0$, then we can simply take a partial convex hull. This will, on average, reduce the complexity of the convex hull computation by half. So, if we know that all d elements of $\overrightarrow{w}$ must be positive, then we can write that as d such constraints to divide the convex hull complexity by 2^d.

In addition, the convergence of Q-values means that we are essentially performing the same convex hull operations again and again; this means that we might be able to reuse the information from the last iteration. The idea is to annotate each point with a "witness", or proof of its status: if a point is not on the convex hull, then we note down a set of faces that enclose it, and if it is on the hull, we note down a direction in which it is the extremum. Then, on the next iteration, when these points have moved slightly and we must compute a convex hull again, we can simply check these proofs

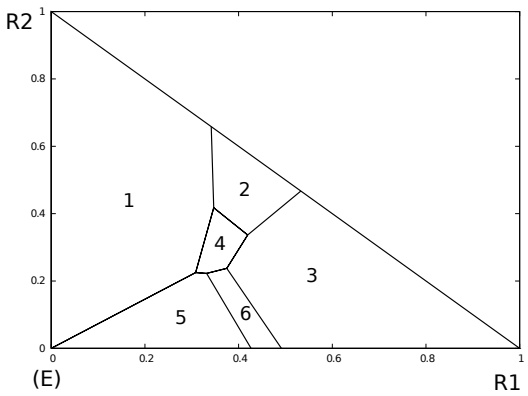

Figure 6. Regions of preference space in which policies are optimal. Axes are reward components $R1$ and $R2$; the enemy weight is $E = 1 - R1 - R2$.

(in at most $O(n^2)$ time). If all the proofs are correct, then our convex hull remains correct and the locations of the points have moved only slightly. On the other hand, if any proof is violated, we can simply rebuild the convex hull in the ordinary, expensive way. In the limit as the Q-values and policy converge, the policy must stop changing, so this trick may greatly reduce the complexity of refining Q-values.

#	**policy**

2	Go to both Rs, through both Es
3	Go to R1, through E1 both ways
4	Go to both Rs, dodging E1 but through E2
5	Go to R1, dodging all Es
6	Go to R1, going through E1 only once

Table 1. The optimal policies for the example domain

6. Example Application: Resource Gathering

In order to demonstrate the application of this method, we have tested it on a resource-collecting problem similar to that of many strategy games. We model this as a resource-collecting agent moving (in the 4 cardinal directions) around in a grid environment shown in Figure 4, starting from the home base, labelled H. Its goal is to gather resources and take them back to the home base. If it reaches location R1, it then picks up resource 1, and at R2 it gets resource 2; it can carry both at the same time. When the agent returns to H, it receives a reward for each resource it brings back. Also, if it steps on one of the two enemy spaces, labeled E1 and E2, with a 10% probability it will be attacked, receiving a penalty and resetting to the home space, losing all it carries. Its reward space is then [enemy, resource1, resource2], so it can get a penalty of [-1,0,0] for being attacked, or a reward of [0,1,0], [0,0,1], or [0,1,1] for bringing back one or both resources. We use a discounting rate of $\gamma = 0.9$.

Depending on the relative values of the resources and attack, the agent may find different policies to be valuable. The convex hull of values starting at H, $\overset{\circ}{V}(H)$, is shown in Figure 5. The points on the hull correspond to optimal policies, described in Table 1; each policy is valid for some range of preferences $\overrightarrow{w}$, which are shown in Figure 6.[1]

7. Extensions and Current Work

This same convex-hull technique can be used with other RL algorithms, such as the temporal difference learning algorithm. The critical thing to recall is that because we are learning more than one policy at once, we can use only off-policy learning algorithms.

Our solution can also be used for inferring the preference function from observation data. This is closely related to the inverse reinforcement learning problem (Ng & Russell, 2000; Abeel & Ng, 2004). The basic idea behind inverse reinforcement learning is to use observed behavior to infer weights from a user that can then be used to find optimal policies. In our case, the method for learning all policies at once can also be used in reverse to learn the range of reward weights that an agent must have. If we assume that an agent we observe is rational and uses a policy that is optimal for its reward weights, then we can use our observations of the agent to infer its reward weights. We simply repeatedly observe its choice of action a and use our knowledge of $\overset{\circ}{Q}(s,a)$ to identify which values of $\overrightarrow{w}$ are consistent with that action. Then, we take the intersection of the constraints.

The multi-criterion RL approach also allows us to examine reward at different time scales. Instead of having a single discounting factor γ, we could have a discounting factor γ_i for each component. This allows us to use a sum of exponentials with different time constants to approximate non-exponential discounting rates, which are helpful in explaining the preferences of humans (Ainslie, 2001). With our convex hull method, we can find what policies are optimal for a whole range of discounting rates.

[1] We do not show the ranges of policies optimal where the values of the rewards are less than 0 ($w_i < 0$); these policies, while sometimes interesting, are not valuable for the task.

8. Appendix: Proof of Correctness

We prove that $\forall \overrightarrow{w}$ Algorithm 1 gives the optimal policy by reducing the recurrence to the standard value iteration recurrence for any $\overrightarrow{w}$. First, recall the basic recurrence of our algorithm, Equation 6.

$$\overset{\circ}{Q}(s,a) \leftarrow \mathbb{E}\left[\overrightarrow{r}(s,a) + \gamma \,\mathrm{hull} \bigcup_{a'} \overset{\circ}{Q}(s',a') | s,a\right]$$

Now apply Equation 5 to the both sides (to extract the optimal value for $\overrightarrow{w}$):

$$\begin{aligned} Q_{\overrightarrow{w}}(s,a) \quad \leftarrow \quad & \max\{\overrightarrow{w}\cdot\overrightarrow{q} : \overrightarrow{q} \in \mathbb{E}\Big[\overrightarrow{r}(s,a) \\ & +\gamma \,\mathrm{hull} \bigcup_{a'} \overset{\circ}{Q}(s',a') | s,a\Big]\}. \end{aligned}$$

Next, apply the definition of an expectation

$$\begin{aligned} \leftarrow \max \quad & \{\overrightarrow{w}\cdot\overrightarrow{q} : \overrightarrow{q} \in \textstyle\sum_{s',\overrightarrow{r}(s,a)} \mathrm{P}(s',\overrightarrow{r}(s,a)|s,a) \\ & \cdot \left(\overrightarrow{r}(s,a) + \gamma \,\mathrm{hull} \textstyle\bigcup_{a'} \overset{\circ}{Q}(s',a')\right)\}, \end{aligned}$$

then use Equations 3 and 4 and rewrite

$$\begin{aligned} \leftarrow \quad & \max\{\overrightarrow{w}\cdot\overrightarrow{q} : \overrightarrow{q} \in \mathrm{hull}\Big\{ \\ & \sum_{i,\overrightarrow{r}(s,a)} \mathrm{P}(s'_i,\overrightarrow{r}(s,a)|s,a)\left(\overrightarrow{r}(s,a) + \gamma \overrightarrow{q}'_{s'_i}\right) \\ & : \overrightarrow{q}'_{s'_1} \in \mathrm{hull} \bigcup_{a'} \overset{\circ}{Q}(s'_1,a'), \ldots\Big\}\}. \end{aligned}$$

$$\leftarrow \max\Bigg\{\overrightarrow{w}\cdot\sum_{i,\overrightarrow{r}(s,a)}\mathrm{P}(s'_i,\overrightarrow{r}(s,a)|s,a)\cdot\Big(\overrightarrow{r}(s,a)+\gamma\,\overrightarrow{q}'_{s'_i}\Big):\ \overrightarrow{q}'_{s'_1}\in\mathrm{hull}\bigcup_{a'}\overset{\circ}{Q}(s'_1,a'),\ldots\Bigg\}$$

$$\leftarrow \max\Bigg\{\mathbb{E}\Big[\overrightarrow{w}\cdot\overrightarrow{r}(s,a)\Big|s,a\Big]+\gamma\sum_i\mathrm{P}(s'_i|s,a)\overrightarrow{w}\cdot\overrightarrow{q}'_{s'_i}:\ \overrightarrow{q}'_{s'_1}\in\mathrm{hull}\bigcup_{a'}\overset{\circ}{Q}(s'_1,a'),\ldots\Bigg\}.$$

Pull $\overrightarrow{r}(s,a)$ (added independently to the entire set) and γ (non-negative) out of the maximum.

$$\leftarrow \mathbb{E}[\overrightarrow{w}\cdot\overrightarrow{r}(s,a)|s,a]+\gamma\max\Bigg\{\sum_i\mathrm{P}(s'_i|s,a)\overrightarrow{w}\cdot\overrightarrow{q}'_{s'_i}:\ \overrightarrow{q}'_{s'_1}\in\mathrm{hull}\bigcup_{a'}\overset{\circ}{Q}(s'_1,a'),\ldots\Bigg\}$$

But the max of a sum over different sets is the sum of the sets' maxima, which we simplify.

$$\leftarrow \mathbb{E}[\overrightarrow{w}\cdot\overrightarrow{r}(s,a)|s,a]+\gamma\sum_i\mathrm{P}(s'_i|s,a)\max\Bigg\{\overrightarrow{w}\cdot\overrightarrow{q}'_{s'_i}:\ \overrightarrow{q}'_{s'_i}\in\mathrm{hull}\bigcup_{a'}\overset{\circ}{Q}(s'_i,a')\Bigg\}$$

$$\leftarrow \mathbb{E}[\overrightarrow{w}\cdot\overrightarrow{r}(s,a)|s,a]+\gamma\sum_i\mathrm{P}(s'_i|s,a)\max\Bigg\{\overrightarrow{w}\cdot\overrightarrow{q}'_{s'_i}:\ \overrightarrow{q}'_{s'_i}\in\overset{\circ}{Q}(s'_i,a'),a'\in A(s'_i)\Bigg\}$$

$$\leftarrow \mathbb{E}[\overrightarrow{w}\cdot\overrightarrow{r}(s,a)|s,a]+\gamma\sum_i\mathrm{P}(s'_i|s,a)\max_{a'}\max_{q'_{s'_i}\in\overset{\circ}{Q}(s'_i,a')}\overrightarrow{w}\cdot\overrightarrow{q}'_{s'_i}$$

But we re-order the maxima and rewrite an expectation, and so we recover our recurrence for a single $\overrightarrow{w}$.

$$Q_{\overrightarrow{w}}(s,a)\leftarrow\mathbb{E}\Big[\overrightarrow{w}\cdot\overrightarrow{r}(s,a)+\gamma\max_{a'}\overset{\circ}{Q}_{\overrightarrow{w}}(s',a')\Big|s,a\Big].$$

Given a $\overrightarrow{w}$, at any point in the algorithm, this gives the same Q-value as ordinary value iteration. Therefore, the proof of convergence for the value iteration algorithm applies to our method, and our method converges exactly as quickly as ordinary value iteration (for every $\overrightarrow{w}$).

Abstract

This paper introduces a novel machine learning model called multiple instance ranking (MIRank) that enables ranking to be performed in a multiple instance learning setting. The motivation for MIRank stems from the hydrogen abstraction problem in computational chemistry, that of predicting the group of hydrogen atoms from which a hydrogen is abstracted (removed) during metabolism. The model predicts the preferred hydrogen group within a molecule by ranking the groups, with the ambiguity of not knowing which hydrogen atom within the preferred group is actually abstracted. This paper formulates MIRank in its general context and proposes an algorithm for solving MIRank problems using successive linear programming. The method outperforms multiple instance classification models on several real and synthetic datasets.

1. Introduction

This paper introduces a new machine learning paradigm called multiple instance ranking (MIRank), bringing the concept of ranking to the framework of multiple instance learning. Some problems that MIRank could potentially solve based on prior data are:

1. For a given country, predict the city that contains the most profitable store.
2. For a given state, predict the congressional district that contains the politician that delivers the most subsidies.
3. For a given document, predict the paragraph/passage that contains the most pertinent sentence/phrase/word.
4. For a given molecular class, predict the molecule with the conformation having the highest human immunodeficiency virus (HIV) inhibition efficacy.
5. For a given state, predict the division that contains the town with the highest median housing unit price.
6. For a given molecule, predict the site of metabolism from which a hydrogen atom is abstracted (removed).

It is this last application, that of hydrogen abstraction from the field of computational chemistry, that motivated this work. The fifth application, which involves making predictions from the census, is also explored here. Later in this paper, a general formulation for multiple instance ranking is provided, an algorithm for MIRank is proposed, and this algorithm is tested on datasets that stem from both applications as well as synthetic data.

As introduced by Dietterich et al. (1997), the setup for multiple instance learning differs somewhat from the standard learning framework. In standard classification, the task is to predict the class of each item. Each item has a corresponding binary classification label, and features defined for each item are used to build the model. In multiple instance classification (MIC), each item belongs to a bag. The task is to predict the class of each bag of items. Features are defined for

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

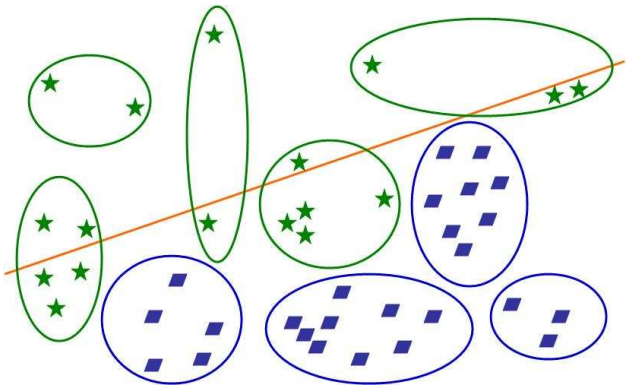

Figure 1. Schematic of multiple instance classification. Bags are ellipses, active bags contain stars and inactive bags contain parallelograms.

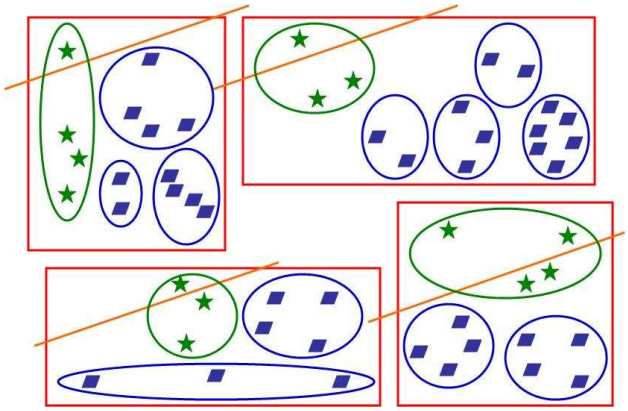

Figure 2. Schematic of multiple instance ranking. Boxes are rectangles, bags are ellipses, preferred bags contain stars, and other bags contain parallelograms.

each item, but the class label is assigned to each bag. For simplicity of presentation, assume there are two classes: active and inactive. By definition, an active bag must contain at least one active item, while an inactive bag contains exclusively inactive items. It is not known which item is active.

Figure 1 illustrates MIC, in which bags are ellipses, items in active bags are represented as stars, and items in inactive bags are marked as parallelograms. The straight line is the separating line representing the classification function. Notice that at least one item from each active bag is found above the line, while all items in inactive bags are located below the line.

The difficulty is that there exists an ambiguity as to which items in an active bag are actually active. For example, consider the drug discovery application (Dietterich et al., 1997), with molecules as bags and conformations (three-dimensional molecular shapes that differ from each other by the rotation of atom groups about one or more bonds) as items. If a molecule possesses one—or possibly several—conformations that are active, then it is known that the molecule is active. However, it is not known which conformation is active. On the other hand, if none of a molecule's conformations are active, then the molecule is deemed inactive, and in this case, it is inferred that all of that molecule's conformations are inactive.

Other applications of MIC include automatic image annotation (Andrews et al., 2003), context-based image indexing (Maron & Ratan, 1998), text categorization (Andrews et al., 2003) and hard-drive failure prediction (Murray et al., 2005). Algorithms for MIC stem from diverse density (Maron & Ratan, 1998; Zhang & Goldman, 2001), neural networks (Ramon & Raedt, 2000), and generalisations of support vector machines (Andrews et al., 2003; Mangasarian & Wild, 2008). The drug discovery application later inspired Ray & Davis (2001) to formulate multiple instance regression, where this time the response assigned to each bag is a real number quantifying the activity of the molecules.

Multiple instance ranking differs in that a classification label is not known for each bag. Rather, some preference information is available for pairs of bags. For example, it may be known that bag A ranks higher than both bags B and C, while the relative ranking of bags B and C may not be known. In many applications, even more structure exists. In these cases, it is convenient to think of every bag as belonging to a box. Within each box, exactly one bag ranks higher than the other ones in the box, and this bag is designated the preferred bag. It is not known how the other bags in the box rank with respect to each other. Further, it is not known how bags rank with respect to each other across boxes. Additionally, there remains the ambiguity of which items in the preferred bags are preferred and which ones are not preferred. Figure 2 illustrates the situation. Large rectangles represent boxes. As was the case in Figure 1, bags are ellipses, items in preferred bags are represented as stars and items in the other bags are marked as parallelograms. Instead of being fixed, the separating line (representing the ranking function) slides from one box to the next. For each box, the ranking function separates at least one item of the preferred bag from the remaining items of the box.

The hydrogen abstraction application fits perfectly into this framework. For each molecule (box), the task

is to find the group (bag) from which a hydrogen atom (item) is abstracted. It is not known which hydrogen atom is abstracted, only to which group it belongs.

The organization of this paper is as follows. Section 2 defines some mathematical notation. Section 3 motivates multiple instance ranking through the computational chemistry problem of hydrogen abstraction. Multiple instance ranking is formulated, and an algorithm for MIRank is proposed, in Section 4. The model and algorithm are generalized to nonlinear MIRank problems in Section 5. Section 6 describes the datasets used in this paper, and Section 7 specifies the modeling results. Finally, Sections 8 and 9 constitute a discussion and outlook, respectively.

2. Notation

Let $\boldsymbol{x}$ denote a vector in R^n and let $\boldsymbol{x}^T$ mark the transpose of $\boldsymbol{x}$. Let $\mathbf{0}$ denote the vector of all zeros and $\boldsymbol{e}$ denote the vector of all ones. Let $|\boldsymbol{x}|$ denote the cardinality of $\boldsymbol{x}$, that is, the number of entries in the vector. Let $\|\boldsymbol{x}\|_1$ denote the 1-norm of $\boldsymbol{x}$, equal to the sum of the absolute values of the entries of the vector. If $\boldsymbol{x}$ has nonnegative entries, then this equals $\boldsymbol{e}^T\boldsymbol{x}$. Let $X \in R^{k\times n}$ and $H \in R^{m\times n}$ denote matrices. I and J indicate index sets. The cardinality of the set I is indicated by $|I|$. The matrix X_I indicates the matrix in $R^{|I|\times n}$ with rows restricted to the index set I. A kernel matrix $K(X, H')$ maps $R^{k\times n}$ and $R^{n\times m}$ into $R^{k\times m}$. Each entry of the mapping results from a function (such as the radial basis function) applied to one row of X applied to one row of H.

3. Motivating application

Bioavailability of a drug, or its ability to be administered orally, is a major concern to the pharmaceutical industry. This characteristic depends on a drug's capability to withstand degradation by intestinal and hepatic enzymes during first-pass metabolism in order to cross the intestinal lining and make it into the bloodstream so that its medicinal effect may be felt (Thummel et al., 1997). Hence, this process of drug metabolism needs to be better understood. More specifically, it is important to discover the attributes of molecules that identify sites which are vulnerable to enzymatic degradation.

Cytochrome CYP3A4 is but one of many metabolising enzymes found in the human liver and small intestine, yet this enzyme metabolises nearly 50% of marketed drugs (Guengerich, 1999; Rendic, 1997). For CYP3A4 substrates, approximately half of the known metabolism reactions occur via hydroxylation, the rate limiting step of which is hydrogen atom abstraction (Sheridan et al., 2007). Knowing where a molecule is preferentially oxidized by this cytochrome would aid the modification of compounds to improve their kinetic or pharmacological profiles (Afzelius et al., 2007).

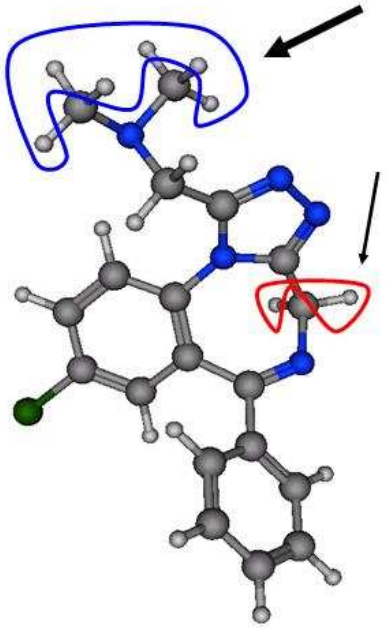

Figure 3. Stick model of an Adinazolam molecule. Large spheres represent nonhydrogen atoms while small spheres represent hydrogen atoms. Two groups of hydrogens are evidenced. The top group, indicated by a thick arrow, has a hydrogen abstracted during metabolism. The lower group, indicated by a thin arrow, does not.

Normally, experimental techniques are used to identify the molecular sites susceptible to metabolism. This is a time- and labor-intensive process. While *in vitro* studies are increasingly high throughput, the *in silico* identification of metabolic liability early on in the drug discovery process will help prevent taking forward poor drug candidates. In addition, the constraints of the biological problem fit perfectly into the framework of a MIRank application, leading to a potential *in silico* solution.

The goal is to build a model that predicts, for each molecule, the site of abstraction of a hydrogen atom during metabolism. In order to accomplish this, individual hydrogen atoms are first grouped together according to molecular equivalence: hydrogens are placed within the same group if and only if the abstraction of any hydrogen from within the group would result in the same metabolised molecule. In this way, groups are equivalent representations of potential sites

of metabolism. Note that experimental data do not show which individual hydrogen is abstracted during metabolism, but rather to which group this hydrogen atom belongs. This setup perfectly fits that of multiple instance ranking. Molecules can be viewed as boxes, groups as bags, and individual hydrogens as items. Figure 3 illustrates these using a stick representation of a molecule.

Two prior modeling attempts are described. Firstly, Singh et al. (2003) chose the hydrogen atom that has the minimum estimated abstraction energy, with a sufficiently large surface area (of 8 squared Angstroms), as the abstracted hydrogen. Allowing 1 guess per molecule, their rule-based model performed correctly in 44% of molecules. Sheridan et al. (2007) later reported that this model has a prediction rate of 51%, allowing for 2 guesses per molecule. Secondly, Sheridan et al. (2007) assembled a database of 316 molecules (including the 50 molecules used by Singh et al. (2003)). They used a random forest applied to molecular descriptors, and found a model that correctly predicted the site of abstraction for 77% of molecules, allowing for 2 guesses per molecule.

4. Formulation

Let (I, J) denote an ordered pair of bags where I and J are lists of indices referring to their items. Let $\boldsymbol{x}_i$ denote a vector of n features for an item i, and let matrix X_I's rows contain the features for each index in I. Further let f denote the ranking function. Then the statement *bag I is preferred over bag J* is expressed mathematically as

$$\max_{i \in I} f(\boldsymbol{x}_i) > \max_{j \in J} f(\boldsymbol{x}_j).$$

The maximum operator on the right hand side can be replaced with all of the items it operates over, hence the inequality is rewritten as

$$\max_{i \in I} f(\boldsymbol{x}_i) > f(\boldsymbol{x}_j) \ \ \forall \ \ j \in J.$$

The maximum operator on the left hand side is also replaced. A convex combination of the items in bag I is taken, following the lead of Mangasarian & Wild (2008) in their formulation of MIC. This convex combination is achieved through vector $\boldsymbol{v_{I,J}}$ whose cardinality is that of I. In a slight abuse of notation, $\boldsymbol{v_{I,J}}$ means the vector corresponding to the pair of bags (I, J). This vector is nonnegative $\boldsymbol{v_{I,J}} \geq 0$, and its entries sum to one: $\boldsymbol{e}^T \boldsymbol{v_{I,J}} = 1$. This vector multiplies matrix X_I:

$$f(X_I^T \boldsymbol{v_{I,J}}) > f(\boldsymbol{x}_j) \ \ \forall \ \ j \in J.$$

Let the model be linear defined by vector $\boldsymbol{w}$, i.e.

$$f(\boldsymbol{x}) = \boldsymbol{x}^T \boldsymbol{w}. \tag{1}$$

In this case, we have

$$\boldsymbol{v_{I,J}}^T X_I \boldsymbol{w} > \boldsymbol{x}_j^T \boldsymbol{w}.$$

This paper focuses on linear models, because chemists are interested model interpretation. However, this formulation is readily kernelized, as discussed in Section 5.

Now introduce an empirical risk scalar $\xi_{I,j}$ based on the hinge-loss, allowing for errors in training the model:

$$\boldsymbol{v_{I,J}}^T X_I \boldsymbol{w} - \boldsymbol{x}_j^T \boldsymbol{w} \geq 1 - \xi_{I,j}.$$

This inequality resembles the main constraint in Joachims' ranking support vector machine (2002). It is also the key constraint in an optimization problem whose objective function is to minimize

$$\nu \mathcal{L}_{emp}(\boldsymbol{\xi}) + \mathcal{L}_{reg}(\boldsymbol{w})$$

where $\nu > 0$ is the tradeoff parameter and $\mathcal{L}_{emp}$ and $\mathcal{L}_{reg}$ are arbitrary loss functions.

Choosing the 1-norm for both loss functions makes the objective linear in the variables, a choice that was also made by Mangasarian & Wild (2008). Furthermore, using the 1-norm on $\boldsymbol{w}$ makes for sparse models, facilitating the interpretability of linear models. Thereupon, the 1-norm MIRank optimization problem is

$$\min_{\boldsymbol{\xi}, \boldsymbol{w}, \boldsymbol{v_{I,J}}} \quad \nu \boldsymbol{e}^T \boldsymbol{\xi} + \|\boldsymbol{w}\|_1 \tag{2}$$

subject to

$$\boldsymbol{v_{I,J}}^T X_I \boldsymbol{w} - \boldsymbol{x}_j^T \boldsymbol{w} \geq 1 - \xi_{I,j} \ \ \forall \ \ (I, J, j) \tag{3}$$

$$\boldsymbol{e}^T \boldsymbol{v_{I,J}} = 1 \ \ \forall \ \ (I, J) \tag{4}$$

$$\boldsymbol{v_{I,J}} \geq \boldsymbol{0} \ \ \forall \ \ (I, J) \tag{5}$$

$$\boldsymbol{\xi} \geq \boldsymbol{0}. \tag{6}$$

The entries of empirical risk vector $\boldsymbol{\xi}$ are $\xi_{I,j}$ as they appear in the first constraint. This notation signifies that, for each pair (I, J), there is an empirical risk contribution from each item $j \in J$. These are nonnegative quantities, as per 6. Note that there are as many vectors $\boldsymbol{v_{I,J}}$ as there are pairs (I, J). These vectors are forced to be nonnegative and to sum to one in constraints 4 and 5.

Since the first constraint is linear and the remaining terms are linear, this is a bilinear optimization problem. We use the successive linear programming algorithm given in Algorithm 1 to find a locally optimal

Algorithm 1 Multiple instance ranking algorithm

Select tolerance τ and tradeoff parameter ν.
Initialise $\boldsymbol{u_{I,J}} = \frac{\boldsymbol{e}}{|I|} \ \forall \ (I, J)$.
repeat
  Set $\boldsymbol{v_{I,J}} = \boldsymbol{u_{I,J}} \ \forall \ (I, J)$.
  Fix the $\boldsymbol{v_{I,J}}$'s and solve the linear program 2-6 for $\boldsymbol{\xi}$ and $\boldsymbol{w}$.
  Fix $\boldsymbol{w}$ and solve the linear program 2-6 for $\boldsymbol{\xi}$ and the $\boldsymbol{u_{I,J}}$'s.
until $\|\boldsymbol{v_I} - \boldsymbol{u_I}\|_1 \leq \tau \ \forall \ (I, J)$

solution of the bilinear problem. This proposed MI-Rank algorithm belongs to a family of algorithms that has proven to find good local solutions on a variety of bilinear machine learning problems. The subproblem solutions are not necessarily unique, but this has no impact on algorithm convergence.

The convergence proof for the MIC algorithm in Mangasarian & Wild (2008) can be readily adapted to Algorithm 1. Specifically, the algorithm converges because the sequence of objective function values

$$\{\nu \boldsymbol{e}^T \boldsymbol{\xi} + \|\boldsymbol{w}\|_1\}$$

at each iteration is nonincreasing and bounded below by zero, and every accumulation point satisfies a local minima property. The formal proof is omitted for brevity; see Mangasarian & Wild (2008).

Algorithm 1, as well the Mangasarian & Wild (2008) algorithm for MIC, were implemented in Matlab using the linear programming solver MOSEK (`www.mosek.com`).

5. Nonlinear Formulation

A nonlinear MIRank function can be generated by kernel transformations (Shawe-Taylor & Cristianini, 2004). We adopt the notation and direct kernel approach used for MIC in Mangasarian & Wild (2008). The linear ranking function 1 is replaced by the nonlinear function:

$$f(\boldsymbol{x}) = K(\boldsymbol{x}^T, H^T)\boldsymbol{\alpha} \tag{7}$$

where $\boldsymbol{x} \in R^n$ is an item, $\boldsymbol{\alpha} \in R^m$ are the dual variables and the matrix $H \in R^{n \times m}$ has as its rows all of the m items found collectively in all of the bags and boxes, and $K(\boldsymbol{x}^T, H^T)$ is an arbitrary kernel map. The bilinear program generating the nonlinear MI-Rank function becomes:

$$\min_{\boldsymbol{\xi}, \boldsymbol{\alpha}, \boldsymbol{v_{I,J}}} \quad \nu \boldsymbol{e}^T \boldsymbol{\xi} + \|\boldsymbol{w}\|_1 \tag{8}$$

subject to

$$\boldsymbol{v_{I,J}}^T K(X_I, H^T)\boldsymbol{w} - K(\boldsymbol{x}_j^T, H^T)\boldsymbol{\alpha} \geq 1 - \xi_{I,j} \ \forall \ (I, J, j) \tag{9}$$

$$\boldsymbol{e}^T \boldsymbol{v_{I,J}} = 1 \ \forall \ (I, J) \tag{10}$$

$$\boldsymbol{v_{I,J}} \geq \boldsymbol{0} \ \forall \ (I, J) \tag{11}$$

$$\boldsymbol{\xi} \geq \boldsymbol{0}. \tag{12}$$

The kernel formulation remains a bilinear program and thus can be solved using Algorithm 1 by substituting $\boldsymbol{\alpha}$ for $\boldsymbol{w}$ and bilinear program 8-12 for bilinear program 2-6.

6. Datasets

In addition to the hydrogen abstraction dataset, several additional datasets are used in modeling experiments. All three are described here.

6.1. CYP3A4 substrate dataset

The CYP3A4 substrate dataset is made up of 227 small drug-like compounds. A series of 36 descriptors for each hydrogen atom for all molecules are calculated:

- the charge of the hydrogen;
- the surface area of the hydrogen;
- the non hydrogen surface area of the base atom the hydrogen is attached to;
- the hydrophobic moment: the hydrogen's location with regards to the hydrophobic or hydrophilic end of the molecule;
- the span: a measure of whether the candidate hydrogen is located at the end or within the middle of the molecule.
- the topological neighborhood: the distributions of atom types within a various topological distances from the hydrogen.

Recall that, for each molecule, the goal is to predict from which group a hydrogen atom is abstracted, and it is not known which hydrogen from the abstracted site is removed.

These 227 molecules form are a subset of the 305 non-proprietary molecules used by Sheridan et al. (2007), and represent all those for which descriptor generation could be completed.

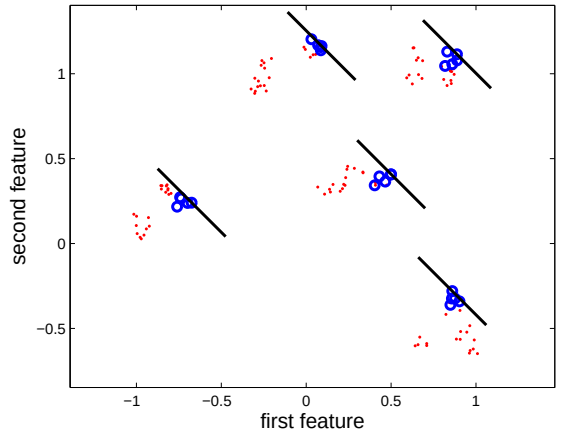

Figure 4. Synthetic dataset visualisation. Preferred bags contain circles and other bags contain dots. Sliding line represents the ranking function found by MIRank that separates at least one circle from remaining items in each box.

6.2. Synthetic datasets

This dataset consists of 227 boxes, five bags per box and five items per bag. There are two features. Each feature is calculated as follows:

$$\mu_i^{box} + \mu_j^{bag} + \mu_k^{item}$$

with μ_i^{box} drawn from the uniform distribution $\mathcal{U}(-1, 1)$, μ_j^{bag} drawn from the distribution $\mathcal{U}(-A, A)$ and μ_k^{item} drawn from the distribution $\mathcal{U}(-B, B)$. Put in words, the center of each box is chosen from a uniform distribution, and the center of each bag with respect to its box is chosen from a different uniform distribution, and each item with respect to its bag is chosen from yet another uniform distribution. Parameters A and B characterize these synthetic datasets. For each item, the response is the sum of the features. The goal is, for each box, to find the bag containing the item of greatest response. Five boxes of this dataset are portrayed as Figure 4. It illustrates the difficulty in constructing a linear function separating at least one circle from each box from the remaining circles and dots, as MIC attempts to do. On the other hand, it it possible to find a ranking function (the sliding line) that does this for each box, as MIRank does.

Different values for dataset parameters A and B were attempted:

- Synthetic-1 set $A = B = 0.01$.
- Synthetic-2 set $A = 0.1$ and $B = 0.01$.

Table 1. Prediction accuracies

Dataset	MIC	MIRank
CYP3A4 substrate	$67.1\% \pm 7.1$	$70.9\% \pm 6.9$
Synthetic-1	$90.8\% \pm 8.6$	$99.8\% \pm 0.53$
Synthetic-2	$96.8\% \pm 4.6$	$99.1\% \pm 1.8$
Synthetic-3	$95.5\% \pm 8.3$	$99.9\% \pm 0.38$
Synthetic-4	$95.7\% \pm 5.2$	$99.7\% \pm 0.91$
Census-16h	$52.8\% \pm 17.4$	$60.3\% \pm 15.1$
Census-16l	$46.2\% \pm 17.7$	$57.5\% \pm 16.0$

- Synthetic-3 set $A = 0.01$ and $B = 0.1$.
- Synthetic-4 set $A = B = 0.1$.

6.3. Census datasets

The two census datasets (census-16h and census-16l) belong to the *Data for Evaluating Learning in Valid Experiments* (DELVE, `http://www.cs.toronto.edu/~delve/`) repository. It consists of 22784 towns spread amongst the 50 states of the United States of America. This study only considered the 3054 towns of more than 10000 inhabitants. Each town is assigned a 5-digit Federal Information Processing Standard (FIPS) place code (that is not a zip code). Typically, this dataset is used in a regression setting to model the response—which is the town's median housing unit price. The census-16h and census-16l datasets differ in their features: each consists of 16 features drawn from the 1990 census.

These datasets are fitted into the multiple instance ranking framework as follows. States are boxes, divisions of towns are bags and towns are items. For each state, towns whose place code begin with the same number are assigned to the same division. As no place code commences with the number 9, there are up to 9 divisions per state. The task is to predict, for each state, the division that contains the town with the highest median housing unit price.

7. Results

For each dataset, results were obtained using both the MIC and MIRank algorithms. For MIC, preferred bags were treated as active bags and other bags were treated as inactive bags. All results reported are for linear functions.

The experimental design is as follows. Each dataset was randomly split into training, validation and testing subsets consisting of 60%, 20% and 20% of the boxes, respectively. The training subset was used to

Table 2. Hypothesis testing

Dataset	P-value
CYP3A4 substrate	$5.59 \cdot 10^{-3}$
Synthetic-1	$1.62 \cdot 10^{-6}$
Synthetic-2	$1.31 \cdot 10^{-2}$
Synthetic-3	$5.84 \cdot 10^{-3}$
Synthetic-4	$1.46 \cdot 10^{-4}$
Census-16h	$4.51 \cdot 10^{-2}$
Census-16l	$3.92 \cdot 10^{-4}$

train both MIC and MIRank models for 19 values of tradeoff parameter ν spread logarithmically over the range $[10^{-3}, 10^{6}]$. The model corresponding to the value of ν that resulted in the best prediction accuracy over the validation set was retained, and a prediction using this model was obtained for the testing subset. This process was repeated 32 times, and the average performance across these 32 testing subsets is reported in Table 1, along with the standard deviation as a measure of spread.

All results in Table 1 are presented as a percentage of boxes for which the preferred bag was accurately predicted, allowing for 2 guesses per box, which is the metric employed by Sheridan et al. (2007). The algorithm tolerance τ defined in Algorithm 1 was set to 10^{-3}.

For all datasets, the hypothesis that MIC and MIRank results are statistically equal is dismissed using paired t-testing at a 5% significance level. The p-values are reported in Table 2.

8. Discussion

The results of Section 7 make a strong case supporting the hypothesis that these problems, when framed in a multiple instance ranking paradigm, are better solved by an algorithm that is designed to solve problems of that paradigm over one that is not. Forcing MIRank problems into a MIC paradigm was not as successful. In other words, the improvement is due to choosing a model that better fits the problem.

The MIRank result for the CYP3A4 substrate dataset reported in this paper compare favourably with existing approaches to hydrogen abstraction. It clearly outperforms the results of Singh et al. (2003). Their results are reproducible and their reported error holds on new molecules. Comparison with Sheridan et al. (2007) is more difficult. Reproduction of their results is challenging since since their descriptors are not public and the details of the learning and model selection methods they used are not entirely clear. Our descriptors attempt to reproduce those of Sheridan et al. (2007), but could not be generated for all molecules. Hence, we regard their results as optimistic.

A future controlled experiment is needed to fully compare the approaches of Sheridan et al. (2007) and those of this paper. This experiment would validate which descriptor set and modeling paradigm is most well suited for this chemistry application. To facilitate future investigations into MIRank and hydrogen abstraction, the datasets and Matlab source codes used in this paper are available from `http://www.rpi.edu/~bennek/MIRank/`.

9. Conclusion

This paper introduced a framework that tackles a novel machine learning question arising from an important chemistry problem. A first working algorithm produces excellent results on it and other problems. We believe that this first paper for MIRank will generate future research into new algorithms and applications. This section explores several possible extensions.

In the chemistry domain, we often restrict ourselves to sparse and linear models because model interpretability is a desired property in the particular application of drug discovery. However, this interpretability analysis is a paper of its own, and does not appear here.

Hydrogen abstraction is an important application of MIRank modeling of great practical value for drug discovery. We are working to expand the efficacy and applicability of the MIRank hydrogen abstraction models in several ways. First, we are increasing the number of molecules in the database of CYP3A4 substrates that can be used to develop and test new MIRank models. Second, we hope to build databases and models for new substrates, such as CYP2D6 and CYP2C9. Third, we are developing novel descriptors that are believed to be indicative of hydrogen abstraction.

We are working to improve the MIRank modeling paradigm and investigating other potential multiple instance ranking problems. Reports here are limited to the linear MIRank models, but as discussed the approach can be readily applied with nonlinear models using kernel functions. Research is needed to investigate how modeling results are affected by changing the loss functions in the empirical risk and/or regularization terms of the optimization problem.

Finally, further improvements to the MIRank algo-

rithm are possible. More scalable and efficient algorithms for finding locally optimal solutions could be developed by exploiting recent developments in large scale support vector machine algorithms. In addition, integer programming or cutting plane algorithms could be used to find global minima of the optimization problem, but at much greater computational cost.

Abstract

We address the problem of learning classifiers for a large number of tasks. We derive a solution that produces resampling weights which match the pool of all examples to the target distribution of any given task. Our work is motivated by the problem of predicting the outcome of a therapy attempt for a patient who carries an HIV virus with a set of observed genetic properties. Such predictions need to be made for hundreds of possible combinations of drugs, some of which use similar biochemical mechanisms. Multi-task learning enables us to make predictions even for drug combinations with few or no training examples and substantially improves the overall prediction accuracy.

1. Introduction

In *multi-task learning* one seeks to solve many classification problems in parallel. Some of the classification problems will likely relate to one another, but one cannot assume that the tasks share a joint conditional distribution of the class label given the input variables. The challenge of multi-task learning is to come to a good generalization across tasks: each task should benefit from the wealth of data available for the entirety of tasks, but the optimization criterion needs to remain tied to the individual task at hand.

Our work is motivated by the problem of predicting the therapeutic success of a given combination of drugs for a given strain of the *Human Immunodeficiency Virus-1* (HIV-1). HIV is associated with the *acquired immunodeficiency syndrome* (AIDS). Being a disease that claimed more than 25 million lives since 1981, AIDS is one of the most destructive epidemics in recorded history. Currently there are more than 33 million people infected with HIV (UNAIDS/WHO, 2007).

Antiretroviral therapy is hampered by HIV's strong ability to mutate and develop viral quasi-species that can quickly be dominated by resistant variants. In order to decide on a course of therapy, virus samples taken from each individual patient are tested for a set of resistance-relevant mutations. Given this set of identified mutations together with the patient's medication history, a medical practitioner needs to decide which combination of drugs to administer. The large number of genetic mutations and the wide array of available drug combinations render the process of predicting the success of a potential therapy difficult, at best, for a human doctor.

Historic treatment records of HIV patients cover only a small portion of all possible drug combinations. For many of these combinations, only few treatments have been recorded. This scarceness of training data precludes separate training of a powerful prediction model for each combination from only records of treatments which used the same drug combination. Distinct combinations can have similar effects when they intersect in jointly contained drugs, or when they include drugs that use similar mechanisms to affect the virus. Therefore, in order to predict the outcome of a given drug combination, it is desirable to exploit data from related combinations and thereby achieve generalization over both virus mutations and combinations of drugs.

We contribute a new multi-task learning model that can handle arbitrarily different data distributions for different tasks without making assumptions about the data generation process or the relation between tasks. We show that by appropriately weighting each instance in the pool of all examples, one can match the distribution that governs the pool of examples of all tasks to each of the single task distributions. We show

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

how appropriate weights can be obtained by discriminating the labeled sample for a given task against the pooled sample.

The rest of this paper is structured as follows. After formalizing the problem setting in Section 2, we review related transfer learning models in Section 3. We devise the model for multi-task learning by distribution matching in Section 4. In Section 5 we describe the data sets and the experimental setting and report on experimental results. Section 6 concludes.

2. Problem Setting

In *supervised multi-task learning*, each of several tasks z is characterized by an unknown joint distribution $p(\mathbf{x}, y|z)$ of features $\mathbf{x}$ and label y given the task z. The joint distributions of different tasks may differ arbitrarily but usually some tasks have similar distributions. A training sample $D = \langle(\mathbf{x}_1, y_1, z_1), \ldots, (\mathbf{x}_m, y_m, z_m)\rangle$ collects examples from all tasks. There may be tasks with no data. For each example, input attributes $\mathbf{x}_i$, class label y_i, and the originating task z_i are known. The entire sample D is governed by the mixed joint density $p(z)p(\mathbf{x}, y|z)$. The prior $p(z)$ specifies the task proportions.

The goal is to learn a hypothesis $f_z : \mathbf{x} \mapsto y$ for each task z. This hypothesis $f_z(\mathbf{x})$ should correctly predict the true label y of unseen examples drawn from $p(\mathbf{x}|z)$ for all z. That is, it should minimize the expected loss

$$\mathbf{E}_{(\mathbf{x},y)\sim p(\mathbf{x},y|z)}[\ell(f_z(\mathbf{x}), y)]$$

with respect to the unknown joint distribution $p(\mathbf{x}, y|z)$ for each individual z.

This abstract problem setting models the HIV therapy screening application as follows. Input $\mathbf{x}$ describes the genotype of the virus that a patient carries, together with the patient's treatment history. Genotype information is encoded as a binary vector indicating the presence and absence of each out of a predefined set of resistance-relevance mutations, respectively. The treatment history can be represented as a binary vector indicating which drugs have been administered over the course of past treatments. A candidate combination of drugs plays the role of the task z: each task has an associated binary vector $\mathbf{z}$ that indicates a set of drugs that a medical practitioner is currently giving consideration. The binary class label y indicates whether the therapy will be successful.

In addition to training data, we may have prior knowledge on the similarity of tasks which is encoded in a kernel function $k(z, z')$. Prediction models for different drug combinations can be similar because the sets of drugs intersect (we will later refer to this as the drug feature kernel), or because similar sets of mutations in the virus render the drugs in the set ineffective (mutation table kernel).

3. Prior Work

One obvious strategy for multi-task learning is to learn independent models for each target task t by minimizing an appropriate loss function on the portion of $D_t = \{(\mathbf{x}_i, y_i, z_i) \in D : z_i = t\}$. The other extreme could be a one-size-fits-all model $f_*(\mathbf{x})$ trained on the entire sample.

In many applications, task-level descriptions or prior knowledge on task similarity encoded in a kernel are available. Bonilla et al. (2007) study an extension of the one-size-fits-all model and find that training with a kernel defined as the multiplication of an input feature kernel and a task-level kernel outperforms a gating network. Task-level features have also been utilized for task clustering and for a task-dependent prior on the model parameters (Bakker & Heskes, 2003).

Another simple extension to the one-size-fits-all model would be to train a model for a target task from all data with weighted examples from other tasks, using one fixed uniform weight for each task. Such a model is described by Wu and Dietterich (2004).

Our work is inspired by learning under covariate shift. In the covariate shift setting the marginals $p_{train}(\mathbf{x})$ and $p_{test}(\mathbf{x})$ of training and test distributions differ, but the conditionals are identical $p_{train}(y|\mathbf{x}) = p_{test}(y|\mathbf{x})$. If training and test distributions were known, then the loss on the test distribution could be minimized by weighting the loss on the training distribution with an instance-specific factor. Shimodaira (2000) illustrates that the scaling factor has to be $\frac{p_{test}(\mathbf{x})}{p_{train}(\mathbf{x})}$. Bickel et al. (2007) derive a discriminative expression for this marginal density ratio that can be estimated – without estimating the potentially high-dimensional densities of training and test distributions – by discriminating training against test data.

Hierarchical Bayesian models for multi-task learning are based on the assumption that task-specific model parameters are drawn from a common prior. The task dependencies are captured by estimating the common prior. Yu et al. (2005) impose a normal-inverse Wishart hyperprior on the mean and covariance of a Gaussian process prior that is shared by all task-specific regression functions. Mean and covariance of the Gaussian process are estimated using the EM algorithm. A Dirichlet process can serve as prior in a hierarchical Bayesian model and cluster the tasks (Xue

et al., 2007); all tasks in one cluster share the same model parameters. Evgeniou and Pontil (2004) derive a kernel that is based on a hierarchical Bayesian model with Gaussian prior (covariance matrix is scalar) on the parameters of a regularized regression.

Larder et al. (2007) tackle the problem of predicting virological response to a given HIV drug combination with neural networks. Lathrop and Pazzani (1999) apply combinatorial optimization to the same problem using features extracted from the viral genotype and the drugs in the combination. Altmann et al. (2007) approach the problem by including various phenotypic information and an estimate of future evolutionary development of the virus in the learning process.

4. Multi-Task Learning by Distribution Matching

In learning a classifier $f_t(\mathbf{x})$ for target task t, we seek to minimize the loss function with respect to $p(\mathbf{x}, y|t)$. Simply pooling the available data for all tasks would create a sample governed by $\sum_z p(z)p(\mathbf{x}, y|z)$. Our approach now is to create a task-specific resampling weight $r_t(\mathbf{x}, y)$ for each element of the pool of examples. The sampling weights match the pool to the target distribution $p(\mathbf{x}, y|t)$. The weighted sample is governed by the correct target distribution, but is still larger as it draws from the sample pool for all tasks.

Instead of sampling from the pool, one can weight the loss incurred by each instance by the resampling weight. The expected weighted loss with respect to the mixture distribution that governs the pool equals the loss with respect to the target distribution $p(\mathbf{x}, y|t)$. Equation 1 defines the resampling weights.

$$\begin{aligned} &\mathbf{E}_{(\mathbf{x},y)\sim p(\mathbf{x},y|t)}[\ell(f(\mathbf{x},t),y)] \qquad (1)\\ &\quad = \mathbf{E}_{(\mathbf{x},y)\sim \sum_z p(z)p(\mathbf{x},y|z)}\left[r_t(\mathbf{x},y)\ell(f(\mathbf{x},t),y)\right] \end{aligned}$$

In the following, we will show that

$$r_t(\mathbf{x}, y) = \frac{p(\mathbf{x}, y|t)}{\sum_z p(z)p(\mathbf{x}, y|z)}$$

satisfies Equation 1. Equation 2 expands the expectation and introduces a fraction that equals one. Equation 3 expands the sum over z in the numerator to run over the entire expression because the integral over $(\mathbf{x}, y)$ is independent of z. Equation 4 is the expected loss over the distribution of all tasks weighted by $\frac{p(\mathbf{x},y|t)}{\sum_z p(z)p(\mathbf{x},y|z)}$.

$$\begin{aligned} &\mathbf{E}_{(\mathbf{x},y)\sim p(\mathbf{x},y|t)}[\ell(f(\mathbf{x},t),y)] \qquad (2)\\ &\quad = \int \frac{\sum_z p(z)p(\mathbf{x},y|z)}{\sum_{z'} p(z')p(\mathbf{x},y|z')} p(\mathbf{x},y|t)\ell(f(\mathbf{x},t),y)d\mathbf{x}dy\\ &\quad = \int \sum_z \Bigg(p(z)p(\mathbf{x},y|z)\frac{p(\mathbf{x},y|t)}{\sum_{z'} p(z')p(\mathbf{x},y|z')} \qquad (3)\\ &\qquad\qquad \ell(f(\mathbf{x},t),y)\Bigg) d\mathbf{x}dy\\ &\quad = \mathbf{E}_{(\mathbf{x},y)\sim \sum_z p(z)p(\mathbf{x},y|z)} \qquad (4)\\ &\qquad \left[\frac{p(\mathbf{x},y|t)}{\sum_{z'} p(z')p(\mathbf{x},y|z')}\ell(f(\mathbf{x},t),y)\right] \end{aligned}$$

Equation 4 signifies that we can train a hypothesis for task t by minimizing the expected loss over the distribution of all tasks weighted by $r_t(\mathbf{x}, y)$. This amounts to minimizing the expected loss with respect to the target distribution $p(\mathbf{x}, y|t)$.

Equation 4 leaves us with the problem of estimating the joint density ratio $r_t(\mathbf{x}, y) = \frac{p(\mathbf{x},y|t)}{\sum_z p(z)p(\mathbf{x},y|z)}$. One might be tempted to train density estimators for $p(\mathbf{x}, y|t)$ and $\sum_z p(z)p(\mathbf{x}, y|z)$. However, obtaining estimators for potentially high-dimensional densities is unnecessarily difficult because ultimately only a scalar weight is required for each example.

4.1. Discriminative Density Ratio Model

In this section, we derive a discriminative model that directly estimates the resampling weights $r_t(\mathbf{x}, y) = \frac{p(\mathbf{x},y|t)}{\sum_z p(z)p(\mathbf{x},y|z)}$ without estimating the individual densities. We reformulate the density ratio $\frac{p(\mathbf{x},y|t)}{\sum_z p(z)p(\mathbf{x},y|z)}$ in terms of a conditional model $p(t|\mathbf{x}, y)$. This conditional has the following intuitive meaning: Given that an instance $(\mathbf{x}, y)$ has been drawn at random from the pool $\cup_z D_z = D$ of samples for all tasks (including D_t); the probability that $(\mathbf{x}, y)$ originates from D_t is $p(t|\mathbf{x}, y)$. The following equations assume that the prior on the size of the target sample is greater than zero, $p(t) > 0$. In Equation 6 Bayes' rule is applied twice and in Equation 7 $p(\mathbf{x}, y)$ and $p(z)$ are canceled out. Equation 8 follows by $\sum_z p(z|\mathbf{x}, y) = 1$.

$$\begin{aligned} r_t(\mathbf{x}, y) &= \frac{p(\mathbf{x}, y|t)}{\sum_z p(z)p(\mathbf{x}, y|z)} \qquad (5)\\ &= \frac{p(t|\mathbf{x}, y)p(\mathbf{x}, y)}{p(t)} \frac{1}{\sum_z p(z)\frac{p(z|\mathbf{x},y)p(\mathbf{x},y)}{p(z)}} \qquad (6)\\ &= \frac{p(t|\mathbf{x}, y)}{p(t)\sum_z p(z|\mathbf{x}, y)} \qquad (7)\\ &= \frac{p(t|\mathbf{x}, y)}{p(t)} \qquad (8) \end{aligned}$$

The significance of Equation 8 is that it shows how the resampling weights $r_t(\mathbf{x}, y) = \frac{p(\mathbf{x},y|t)}{\sum_z p(z)p(\mathbf{x},y|z)}$ can be determined without knowledge of any of the task densities $p(\mathbf{x}, y|z)$. The right hand side of Equation 8 can be evaluated based on a model $p(t|\mathbf{x}, y)$ that discriminates labeled instances of the target task against labeled instances of the pool of examples for all tasks. Intuitively, $p(t|\mathbf{x}, y)$ characterizes how much more likely $(\mathbf{x}, y)$ is to occur in the target distribution than it is to occur in the mixture distribution of all tasks. Instead of potentially high-dimensional densities $p(\mathbf{x}, y|t)$ and $p(\mathbf{x}, y|z)$, a conditional distribution with a single variable needs to be modeled. One can apply any probabilistic classifier to model this conditional distribution.

4.2. Soft-Max Model for Density Ratio Estimation

We model $p(t|\mathbf{x}, y)$ of Equation 8 for all tasks jointly with a soft-max model (the multi-class generalization of the logistic model) with model parameters $\mathbf{v}$, displayed in Equation 9. The parameter vector $\mathbf{v}$ is a concatenation of task-specific subvectors $\mathbf{v}_z$, one for each task z. With this model an estimate for $p(t|\mathbf{x}, y)$ is given by $p(z = t|\mathbf{x}, y, \mathbf{v})$; this is the evaluation of the soft-max model with respect to task t.

$$p(z|\mathbf{x}, y, \mathbf{v}) = \frac{\exp(\mathbf{v}_z^\mathsf{T}\Phi(\mathbf{x}, y))}{\sum_{z'} \exp(\mathbf{v}_{z'}^\mathsf{T}\Phi(\mathbf{x}, y))} \quad (9)$$

Equation 9 requires a problem-specific feature mapping $\Phi(\mathbf{x}, y)$. Without loss of generality we define this mapping for binary labels $y \in \{+1, -1\}$ in Equation 10; δ is the Kronecker delta. In the absence of prior knowledge about the similarity of classes, input features $\mathbf{x}$ of examples with different class labels y are mapped to disjoint subsets of the feature vector.

$$\Phi(\mathbf{x}, y) = \begin{bmatrix} \delta(y, +1)\Phi(\mathbf{x}) \\ \delta(y, -1)\Phi(\mathbf{x}) \end{bmatrix} \quad (10)$$

With this feature mapping the models for positive and negative examples do not interact and can be trained independently.

For training the soft-max model we maximize the regularized log-likelihood of the data. Prior knowledge on the similarity of tasks in the form of a positive semi-definite kernel function $k(z, z')$ can be be encoded in the covariance matrix of a Gaussian prior $N(0, \Sigma)$ on parameter vector $\mathbf{v}$. We set all main diagonal entries of Σ to the scalar parameter $\sigma_\mathbf{v}^2$ and set the secondary diagonal entries corresponding to the covariances between $\mathbf{v}_z$ and $\mathbf{v}'_z$ to $k(z, z')\rho\sigma_\mathbf{v}^2$ (assuming kernel values $0 \leq k(z, z') \leq 1$). Parameter $\sigma_\mathbf{v}^2$ specifies the variance of each element in $\mathbf{v}$. $k(z, z')\rho$ is the correlation coefficient between elements of subvectors $\mathbf{v}_z$ and $\mathbf{v}'_z$; parameter ρ specifies the strength of this correlation. The covariance matrix Σ is required to be invertible and therefore $0 \leq \rho < 1$. All other entries of Σ are set to zero. When prior knowledge on the task similarities is encoded in the prior on the model parameters, then this prior knowledge dominates the optimization criterion for small samples while the data-driven portion of the criterion becomes dominant and overrides prior beliefs as more data arrives.

Optimization Problem 1 *Over parameters* $\mathbf{v}$*, maximize*

$$\sum_{(\mathbf{x}_i, y_i, z_i) \in D} \log(p(z_i|\mathbf{x}_i, y_i, \mathbf{v})) + \mathbf{v}^\mathsf{T}\Sigma^{-1}\mathbf{v}.$$

The solution of Optimization Problem 1 is a maximum *a posteriori* estimation of the soft-max model (Equation 9) over the model parameters $\mathbf{v}$ using a Gaussian prior with covariance matrix Σ. Tasks with no training examples are covered naturally in Optimization Problem 1. In this case, the Gaussian prior with the task kernel $k(z, z')$ encoded in the covariance matrix determines the model.

For our experiments we use a kernelized variant of Optimization Problem 1 by applying the representer theorem. Details on the kernelization of multi-class logistic regression can be learned from Zhu and Hastie (2002).

4.3. Weighted Empirical Loss and Target Model

The multi-task learning procedure first determines resampling weights $r_z(\mathbf{x}, y)$ for all tasks and instances by solving Optimization Problem 1. In this section we describe the second step of training an array of target models, one for each task, using weighted examples.

With the results of Optimization Problem 1 the discriminative expression for the weights of Equation 8 can be estimated. Using these weights we can evaluate the expected loss over the weighted training data as displayed in Equation 11. It is the regularized empirical counterpart of Equation 4.

$$\mathbf{E}_{(\mathbf{x},y)\sim D}\left[\frac{p(t|\mathbf{x}, y, \mathbf{v})}{p(t)}\ell(f(\mathbf{x}, t), y)\right] + \frac{\mathbf{w}_t^\mathsf{T}\mathbf{w}_t}{2\sigma_\mathbf{w}^2} \quad (11)$$

An instance of Optimization Problem 2 is solved for each task independently to produce a separate model for this task. Optimization Problem 2 minimizes Equation 11, the weighted regularized loss over the training data using a standard Gaussian log-prior with variance $\sigma_\mathbf{w}^2$ on the parameters $\mathbf{w}_t$. Each example is weighted by the discriminatively estimated density

fraction from Equation 8 using the solution of Optimization Problem 1.

Optimization Problem 2 *For task t: over parameters $\mathbf{w}_t$, minimize*

$$\sum_{(\mathbf{x}_i,y_i)\in D} \frac{p(t|\mathbf{x}_i,y_i,\mathbf{v})}{p(t)}\ell(f(\mathbf{x}_i,\mathbf{w}_t),y_i) + \frac{\mathbf{w}_t^\mathsf{T}\mathbf{w}_t}{2\sigma_\mathbf{w}^2}.$$

5. HIV Therapy Screening

We model HIV therapy screening as a multi-task learning problem. The input $\mathbf{x}$ to the prediction problem is given by attributes of the viral genotype and the patient's treatment history. The combination of drugs z plays the role of the task. Success or failure of the therapy constitutes class-label y.

In the next subsections we describe the data sets, reference methods, and the empirical results of our study.

5.1. Data Sets and Prior Knowledge on Task Similarity

We use data from the EuResist project (Rosen-Zvi et al., 2008). The data set comprises a total number of 52846 treatment records from the treatment histories of 16999 HIV patients treated in hospitals in the period of 1977 through 2007.

We use two different definitions of therapeutic success and failure to tag the data: *virus load labeling* and *multi-conditional labeling*.

According to our *virus load labeling* definition a therapy is successful if the viral load (number of virus copies per ml blood plasma, cp/ml) drops below the established level of virus detection of 400 cp/ml during the time of the treatment. Otherwise the treatment is a failure. In *multi-conditional labeling*, a therapy is successful if the viral load measured in the time range between 28 and 84 days after the start of the therapy decreases by at least 2 orders of magnitude compared to the most recent viral load measured one to three months before the start of the therapy, or the viral load drops below 400 cp/ml 56 days after the start of the therapy. A drawback of this definition is that due to the strict time intervals it imposes on the measurements, class labels that adhere to this labeling are only available for a small number of records. The *virus load labeling* does not require these strict time intervals by making use of any viral load measurement during the course of therapy to label it.

Out of all available treatment records we extract two different data sets using the two labelings. With the virus load labeling we extract 3260 and with the multi-conditional labeling 2011 treatment records with corresponding ratios of 65.7% and 64.1% successful treatments. The size of these data sets is much smaller than the size of the original data due to missing viral load measurements, or missing virus sequence information.

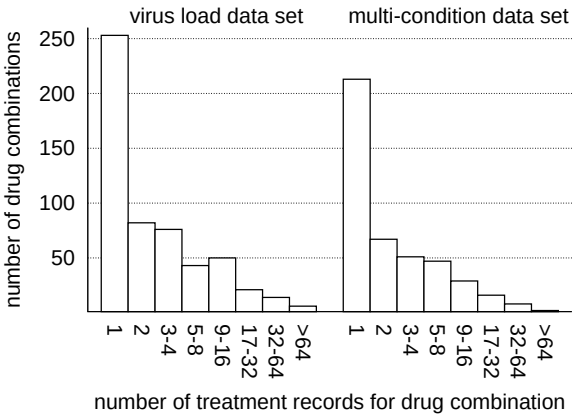

Figure 1. Histogram over number of treatment records for drug combinations (tasks) in the virus load data set (left) and multi-condition data set (right).

A number of 545 distinct drug combinations (tasks z) occur at least once in the virus load data set; 433 occur in the the multi-conditional data set. The histogram over sample sizes per task is displayed in Figure 1. For many combinations, only a few examples occur in the data. For instance, in the virus load data set we observe 253 out of 545 drug combinations with only one data point and 411 with less than 5 instances. Similarly, the multi-conditional data set has 213 out of 433 drug combinations with a single data point and 331 with less than 5 observations.

We extract two types of features for each instance: a genotypic description of the virus and information about the treatment history of the patient. We use the viral genotype taken from the patient shortly before the treatment and represent it by a binary vector indicating the presence of resistance-relevant mutations of the viral sequence (Johnson et al., 2007). Drug-resistant viral quasi-species evolve during the course of the treatment due to selective pressure imposed by the drug. As they remain in the patient's body, the treatment history plays an important role for predicting the outcome of a potential treatment. Hence, we extract all drugs given to the patient in previous treatments and use a binary vector representation with a one entry for each drug given to the patient in the treatment history. The 82-dimensional feature vector $\mathbf{x}$ for each data point results from the concatenation

Table 1. Classification accuracies with standard errors of differences to distribution matching method (ste.Δ). of 65 genotypic and 17 historic treatment features.

We have prior knowledge about the similarity of combinations and encode this knowledge into two different task similarity kernels $k(z, z')$. The binary drug indicator vector has an entry for each drug; entries of one indicate the presence of a drug in the combination. The *drug indicator kernel* is the inner product between the normalized drug indicator vectors of two combinations. The *mutation table kernel* is based on tables about the resistance-associated mutations of single drugs (Johnson et al., 2007). We construct binary vectors indicating resistance-relevant mutations for the set of drugs occurring in a combination. The kernel computes the normalized inner product between such binary vectors for two drug combinations.

5.2. Reference Methods

The first reference method is training of a separate logistic regression model for each task without any interaction ("separate"). Tasks without any training examples get a constant classifier that assigns each test example with 50% to each of both classes.

The next baseline is a one-size-fits-all model; all examples are pooled and only one common logistic regression is trained for all tasks ("pooled"). For the experiments with prior knowledge on task similarity we multiply the feature kernel with the task kernel values $k(\mathbf{x}, \mathbf{x}')(k(z, z') + 1)$ and train one model using this kernel (Bonilla et al., 2007). For task kernels that can have a value of zero we include a "+1" term to ensure that the feature kernel does not vanish.

The third reference method ("hier. Bayes kernel") is a logistic regression with the hierarchical Bayesian kernel $k_{hBayes}(\mathbf{x}, \mathbf{x}') = (\lambda + \delta(z, z'))k(\mathbf{x}, \mathbf{x}')$ of Evgeniou and Pontil (2004); $\delta(z, z')$ is the Kronecker delta and λ is a tuning parameter. For the experiments with task similarity kernel the hierarchical Bayes and the task kernel are multiplied. As second hierarchical Bayesian method ("hier. Bayes Gauss. proc.") we use the Gaussian process regression of Yu et al. (2005).

5.3. Experimental Setting and Results

In our experiments we study the benefit of distribution matching for HIV therapy screening compared to the reference methods described in Section 5.2. Optimization Problem 1 is solved with limited-memory BFGS and Optimization Problem 2 with Newton gradient descent using a logistic loss. For the prior term $p(t)$ required in Optimization Problem 2 we use a MAP estimate $\frac{|D_t|+\gamma}{\sum_z(|D_z|+\gamma)}$ with a symmetric Dirichlet prior. We use RBF kernels for all methods.

We apply a training-test split of the data consistent with the dates of the treatment records. We sort the treatment records by date and use the first 80% of the records as training data and the last 20% as test data. This procedure yields 653 and 403 test examples for the virus load and multi-conditional data set, respectively. The date consistent split is necessary because new drugs get approved over time, and under pressure of new drugs the viral population evolves. In such environments, the prediction models should be able to learn from data seen in the *past* and perform well on unseen data in the *future*.

We tune the prior and regularization parameters of all methods, the Dirichlet parameter γ, and the variance of the RBF kernels on tuning data resulting from a date consistent split of the training data.

The evaluation measure is the accuracy of predicting the correct label (success or failure of a treatment)

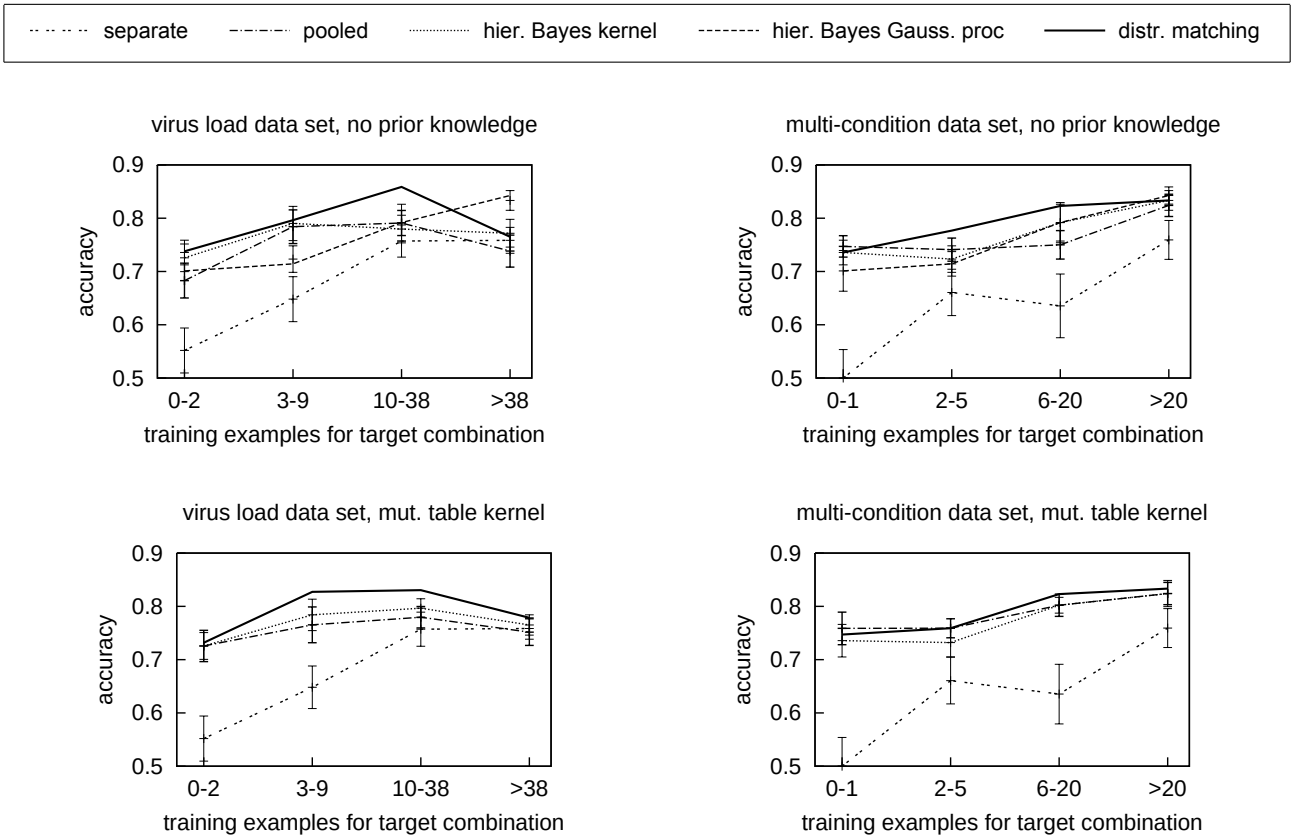

Figure 2. Accuracy over different number of training examples for target combination; virus load data set (left), multi-condition data set (right). Error bars indicate the standard error of the differences to distribution matching. The key can be found in the box right above the diagrams.

on the test set. Table 1 shows the results of the prediction accuracy for all methods over both data sets without and with two different types of prior knowledge on combination similarity. The columns "ste.Δ" placed next to the accuracy columns display the standard error of the differences to the distribution matching method.

Multi-task learning by distribution matching outperforms, or is as good as, the best alternative method in all cases. The improvement over the separate model baseline is about 10-14%. We can reject the null hypothesis that the pooled and the hierarchical Bayesian kernel baseline is at least as accurate as distribution matching in four and five cases respectively out of six according to a paired t-test at $\alpha = 0.05$.

For distribution matching, prior knowledge does not improve the accuracy. The pooled baseline benefits from prior knowledge for the multi-condition data set. For the case without prior knowledge we do not observe a statistically significant difference of the two hierarchical Bayesian methods, but they are both significantly worse than distribution matching according to the paired t-test. Note that the Gaussian process baseline is a regression model; all other methods are classification models.

Figure 2 displays the accuracy over the combinations in the test set grouped by the number of available examples for the settings without and with the mutation table kernel. For instance, an accuracy of 74% for the first group "0-2" means, that only test examples from combinations are selected that have zero, one, or two training examples each, and the accuracy on this subset of the test examples is 74%. Each of the four groups covers about the same number of test examples. The error bars indicate the standard error of the differences to the distribution matching method. Note, that the statistical tests described above are based on all test data and are not directly related to the group-specific error bars in the diagrams.

All methods benefit from larger numbers of training

examples per drug combination. The slightly decreasing accuracy for the virus load data set with ">38" training examples is surprising. Further analysis reveals that in this case there is an accumulation of test examples with history profiles very different from the training examples of the same combination.

For all methods that generalize over the tasks the benefit compared to the separate model baseline is the largest for the smallest group ("0-2" and "0-1" training examples respectively).

6. Conclusion

We devised a multi-task learning method that centers around resampling weights which match the distribution of the pool of examples of multiple tasks to the target distribution for a given task at hand. The method creates a weighted sample that reflects the desired target distribution and exploits the entire corpus of training data for all tasks. We showed how appropriate weights can be obtained by discriminating the labeled sample for a given task against the pooled sample. After weighting the pooled sample, a classifier for the given task can be trained. In our experiments on HIV therapy screening we found that the distribution matching method improves on the prediction accuracy over independently trained models by 10-14%. According to a paired t-test, distribution matching is significantly better than the reference methods for 17 out of 20 experiments.

A combination of drugs is the standard way of treating HIV patients. The accuracy to which the likely outcome of a combination therapy can be anticipated can therefore directly impact the quality of HIV treatments.

Acknowledgment

We thank Kai Yu for providing his Gaussian process implementation and Barbara Pogorzelska who adapted this code and conducted the experiments. We also thank the EuResist project with contract number EU-STREP IST-2004-027173 for providing the data. We gratefully acknowledge support from the German Science Foundation DFG.

Nonnegative Matrix Factorization via Rank-One Downdate

Michael Biggs MBIGGS@ALUMNI.UWATERLOO.CA

Abstract

Nonnegative matrix factorization (NMF) was popularized as a tool for data mining by Lee and Seung in 1999. NMF attempts to approximate a matrix with nonnegative entries by a product of two low-rank matrices, also with nonnegative entries. We propose an algorithm called rank-one downdate (R1D) for computing an NMF that is partly motivated by the singular value decomposition. This algorithm computes the dominant singular values and vectors of adaptively determined submatrices of a matrix. On each iteration, R1D extracts a rank-one submatrix from the original matrix according to an objective function. We establish a theoretical result that maximizing this objective function corresponds to correctly classifying articles in a nearly separable corpus. We also provide computational experiments showing the success of this method in identifying features in realistic datasets. The method is also much faster than other NMF routines.

1. Nonnegative Matrix Factorization

Several problems in information retrieval can be posed as low-rank matrix approximation. The seminal paper by Deerwester et al. (1990) on latent semantic indexing (LSI) showed that approximating a term-document matrix describing a corpus of articles via the SVD led to powerful query and classification techniques. A drawback of LSI is that the low-rank factors in general will have both positive and negative entries, and there is no obvious statistical interpretation of the negative entries. This led Lee and Seung (1999) among others to propose *nonnegative matrix factorization* (NMF), that is, approximation of a matrix $A \in \mathbf{R}^{m\times n}$ as a product of two factors WH^T, where $W \in \mathbf{R}^{m\times k}$, $H \in \mathbf{R}^{n\times k}$, both have nonnegative entries, and $k \leq \min(m, n)$. Lee and Seung showed intriguing results with a corpus of images. In a related work, Hofmann (1999) showed the application of NMF to text retrieval. Nonnegative matrix factorization has its roots in work of Gregory and Pullman (1983), Paatero and Tapper (1994) and Cohen and Rothblum (1993).

Since the problem is NP-hard (Vavasis, 2007), it is not surprising that no algorithm is known to solve NMF to optimality. Heuristic algorithms proposed for NMF have generally been based on incrementally improving the objective $\|A - WH^T\|$ in some norm using local moves. A particularly sophisticated example of local search is due, e.g., to Kim and Park (2007). A drawback of local search is that it is sensitive to initialization and it is also sometimes difficult to establish convergence.

We propose an NMF method based on greedy rank-one downdating that we call R1D. R1D is partly motived by Jordan's algorithm for computing the SVD, which is described in Section 2. Unlike local search methods, greedy methods do not require an initial guess. In Section 3, we compare our algorithm to Jordan's SVD algorithm, which is the archetypal greedy downdating procedure. Previous work on greedy downdating algorithms for NMF is the subject of Section 4. In Section 5, we present the main theoretical result of this paper, which states that in a certain model of text due to Papadimitriou et al. (2000), optimizing our objective function means correctly identifying a topic in a text corpus; and Section 6 discusses the complexity of this problem. We then turn to computational experiments: in Section 7, we present results for R1D on image datasets, and in Section 8, we present results on text.

2. Algorithm and Objective Function

Rank-one downdate (R1D) is based on the simple observation that the leading singular vectors of a nonnegative matrix are nonnegative. This is a consequence of the Perron-Frobenius theorem (Golub & Van Loan, 1996). Based on this observation, it is trivial to compute a rank-one NMF. This idea can be extended to approximate a higher order NMF. Suppose we compute the rank-one NMF and then subtract it from the original matrix. The original matrix will not be nonnegative any more but all negative entries can be forced to be zero or positive and the procedure can be repeated.

An improvement on this idea takes only a submatrix of the original matrix and applies the Perron-Frobenius theorem. The point is that taking the whole matrix will in some sense average the features, whereas a submatrix can pick out particular features. A second reason to take a submatrix is that a correctly chosen submatrix may be very close to having a rank of one, so the step of forcing the residuals to be zero will not introduce significant inaccuracy (since they will already be close to zero).

The outer loop of the R1D algorithm may be described as follows.

Algorithm 1 R1D

input $A \in \mathbf{R}^{m\times n}$, $k > 0$
output $W \in \mathbf{R}^{m\times k}$, $H \in \mathbf{R}^{n\times k}$

1: **for** $\mu = 1$ **to** k **do**
2: $[M, N, \mathbf{u}, \mathbf{v}, \sigma] =$ `ApproxRankOneSubmatrix`(A)
3: $W(M, \mu) = \mathbf{u}(M)$
4: $H(N, \mu) = \sigma\mathbf{v}(N)$
5: $A(M, N) = 0$
6: **end for**

Here, M is a subset of $\{1, \ldots, m\}$, N is a subset of $\{1, \ldots, n\}$, $\mathbf{u} \in \mathbf{R}^m$, $\mathbf{v} \in \mathbf{R}^n$ and $\sigma \in \mathbf{R}$, and $\mathbf{u}, \mathbf{v}$ are both unit vectors. The function `ApproxRankOneSubmatrix` selects these five values so that the submatrix of A indexed by rows M and N is approximately rank one, and in particular, is approximately equal to $\mathbf{u}(M)\sigma\mathbf{v}^T(N)$. We follow Matlab subscripting conventions, so that $A(M, N)$ denotes this particular submatrix.

This outer loop for R1D may be called "greedy rank-one downdating" since it greedily tries to fill the columns of W and H from left to right by finding good rank-one submatrices of A and subtracting them from A. The classical greedy rank-one downdating algorithm is Jordan's algorithm for the SVD, described in Section 3. Related work on greedy rank-one downdating for NMF is the topic of Section 4.

The subroutine `ApproxRankOneSubmatrix`, presented later in this section, is a heuristic routine to maximize the following objective function:

$$f(M, N, \mathbf{u}, \sigma, \mathbf{v}) = \|A(M, N)\|_F^2 - \gamma\|A(M, N) - \mathbf{u}\sigma\mathbf{v}^T\|_F^2 \tag{1}$$

Here, γ is a penalty parameter. The Frobenius norm of an $m \times n$ matrix B, denoted $\|B\|_F$ is defined to be $\sqrt{B(1,1)^2 + B(1,2)^2 + \cdots + B(m,n)^2}$. The rationale for (1) is as follows: the first term in (1) expresses the objective that $A(M, N)$ should be large, while the second term penalizes departure of $A(M, N)$ from being a rank-one matrix.

Since the optimal $\mathbf{u}, \sigma, \mathbf{v}$ come from the SVD (once M, N are fixed), the above objective function can be rewritten just in terms of M and N as

$$\begin{aligned} f(M, N) &= \sum_{i=1}^{p} \sigma_i(A(M, N))^2 - \gamma \sum_{i=2}^{p} \sigma_i(A(M, N))^2 \\ &= \sigma_1(A(M, N))^2 \\ &\quad - (\gamma - 1) \cdot \left(\sigma_2(A(M, N))^2 \right. \\ &\quad \left. + \cdots + \sigma_p(A(M, N))^2\right), \end{aligned} \tag{2}$$

where $p = \min(|M|, |N|)$. The penalty parameter γ should be greater than 1 so that the presence of low-rank contributions is penalized rather than rewarded.

We conjecture that maximizing (1) is NP-hard (see Section 6), so we instead propose a heuristic routine for optimizing it. The procedure alternates improving M, N, $\mathbf{u}$, σ and $\mathbf{v}$ cyclically. First, observe that if M, N are already known, then the optimal choice of $\mathbf{u}$, σ, $\mathbf{v}$ can be found with the SVD. For fixed $(\mathbf{v}, N)$, the objective function (1) is separable by rows of the matrix. In particular, the contribution of row $i \in M$ is

$$\|A(i, N)\|^2 - \gamma\|A(i, N) - \beta_i\mathbf{v}^T\|^2,$$

where $\beta_i = u_i\sigma$. Note that β_i may be undefined if $i \notin M$. Nonetheless, given $\mathbf{v}$, the optimal β_i (i.e., the choice that minimizes $\|A(i, N) - u_i\mathbf{v}^T\|$) is easy to compute: it is $A(i, N)\mathbf{v}$, the solution to a simple least-squares minimization. Thus, we conclude that putting column i into index set M is favorable for the overall objective function provided that $f_i > 0$, where

$$f_i = \|A(i, N)\|^2 - \gamma\|A(i, N) - A(i, N)\mathbf{v}\mathbf{v}^T\|^2.$$

The formula for f_i can be simplified as follows:

$$\begin{aligned} f_i &= A(i, N)A(i, N)^T - \gamma(A(i, N) \\ &\quad - A(i, N)\mathbf{v}\mathbf{v}^T)(A(i, N) - A(i, N)\mathbf{v}\mathbf{v}^T)^T \\ &= -(\gamma - 1)A(i, N)A(i, N)^T + \gamma(A(i, N)\mathbf{v})^2. \end{aligned}$$

If we rescale by $\gamma - 1$ (which does not affect the acceptance criterion), and we define new penalty parameters $\bar{\gamma} := \gamma/(\gamma - 1)$, then we see that row i is accepted provided that

$$\bar{\gamma}(A(i,N)\mathbf{v})^2 - A(i,N)A(i,N)^T > 0.$$

A similar analysis applies to the columns, and leads to the conclusion that, given values for M and $\mathbf{u}$, column j should be accepted provided that

$$\bar{\gamma}(\mathbf{u}^T A(M,j))^2 - A(M,j)^T A(M,j) > 0.$$

The next issue is the choice of a starting guess for $M, N, \mathbf{u}, \sigma, \mathbf{v}$. The algorithm should be initialized with a starting guess that has a positive score, or else the rules for discarding rows and columns could conceivably discard all rows or columns. To put this more strongly, in order to improve the score of a converged solution, it seems sensible to select a starting guess with a high score. For this reason, R1D uses a single column of A as its starting guess, and in particular, the column of A with the greatest norm. (A single row may also be chosen.) It then chooses $\mathbf{u}$ to be the normalization of this column. This column is exactly rank one, so for the correct values of σ and $\mathbf{v}$ the first penalty term of (1) is zero. We have derived the following algorithm for the subroutine `ApproxRankOneSubmatrix` occuring in statement ⟨2⟩ in R1D.

Algorithm 2 ApproxRankOneSubmatrix

input $A \in \mathbf{R}^{m\times n}$, **parameter** $\bar{\gamma} > 1$
output $M \subset \{1,\ldots,m\}$, $N \subset \{1,\ldots,n\}$,
$\mathbf{u} \in \mathbf{R}^m$, $\mathbf{v} \in \mathbf{R}^n$, $\sigma \in \mathbf{R}$

1: Select $j_0 \in \{1,\ldots,n\}$ to maximize $\|A(:,j_0)\|$
2: $M = \{1,\ldots,m\}$
3: $N = \{j_0\}$
4: $\sigma = \|A(:,j_0)\|$
5: $\mathbf{u} = A(:,j_0)/\sigma$
6: **repeat**
7: Let $\bar{\mathbf{v}} = A(M,:)^T\mathbf{u}(M)$
8: $N = \{j : \bar{\gamma}\bar{v}(j)^2 - \|A(M,j)\|^2 > 0\}$
9: $\mathbf{v}(N) = \bar{\mathbf{v}}(N)/\|\bar{\mathbf{v}}(N)\|$
10: Let $\bar{\mathbf{u}} = A(:,N)\mathbf{v}(N)$
11: $M = \{i : \bar{\gamma}\bar{u}(i)^2 - \|A(i,N)\|^2 > 0\}$
12: $\sigma = \|\mathbf{u}(M)\|$
13: $\mathbf{u}(M) = \bar{\mathbf{u}}(M)/\sigma$
14: **until** stagnation in $M, N, \mathbf{u}, \sigma, \mathbf{v}$

The 'Repeat' loop is guaranteed to make progress because each iteration increases the value of the objective function. On the other hand, there does not seem to be any easy way to derive a useful prior upper bound on its number of iterations. In practice, it proceeds quite quickly, usually converging in 10–15 iterations. But to guarantee fast termination, monotonicity can be forced on M and N by requiring M to shrink and N to grow. In other words, statement ⟨8⟩ can be replaced by

$$N = N \cup \{j : \bar{\gamma}\bar{v}(j)^2 - \|A(M,j)\|^2 > 0\},$$

and statement ⟨11⟩ by

$$M = M - \{i : \bar{\gamma}\bar{u}(i)^2 - \|A(i,N)\|^2 \le 0\}.$$

Our experiments indicate that this change does not have a major impact on the performance of R1D.

Another possible modification to the algorithm is as follows: we modify the objective function by adding a second penalty term $-\rho|M|\cdot|N|$ to (1) where $\rho > 0$ is a parameter. The purpose of this term is to penalize very low-norm rows or columns from being inserted into $A(M,N)$ since they are probably noisy. For data with larger norm, the first term of (1) should dominate this penalty. Notice that this penalty term is also separable so it is easy to implement: the formula in ⟨8⟩ is changed to $\bar{\gamma}\bar{v}(j)^2 - \|A(M,j)\|^2 - \bar{\rho}|M| > 0$ while the formula in ⟨11⟩ becomes $\bar{\gamma}\bar{u}(i)^2 - \|A(i,N)\|^2 - \bar{\rho}|N| > 0$, where $\bar{\rho} = \rho/(\gamma - 1)$. A good value for $\bar{\rho}$ is to set it so that in the initial starting point, the third penalty term is a small fraction (say $\bar{\eta} = 1/20$) of the other terms. This leads to the following definition for ρ:

$$\rho = \bar{\eta}(\bar{\gamma} - 1)\sigma^2/m,$$

which may be computed immediately after ⟨4⟩.

Greedy rank-one downdating appears to be much faster than other NMF algorithms. Generating each column of W and H requires approximately 20 matrix-vector multiplications; these multiplications are always at least as sparse as the original data. There is no iterative improvement phase. It can also be much faster than the SVD, especially for sparse data.

3. Relationship to the SVD

The classical rank-one greedy downdating algorithm is Jordan's algorithm for computing the singular value decomposition (SVD) (Stewart, 1993). Recall that the SVD takes as input an $m \times n$ matrix A and returns three factors U, Σ, V such that $U \in \mathbf{R}^{m\times k}$ and U has orthonormal columns (i.e., $U^TU = I$), $\Sigma \in \mathbf{R}^{k\times k}$ and is diagonal with nonnegative diagonal entries, and $V \in \mathbf{R}^{n\times k}$ also with orthonormal columns, such that $U\Sigma V^T$ is the optimal rank-k approximation to A in either the 2-norm or Frobenius norm. (Recall that the 2-norm of an $m \times n$ matrix B, denoted $\|B\|_2$, is

Algorithm 3 JordanSVD

input $A \in \mathbf{R}^{m \times n}$ and $k \leq \min(m, n)$
output U, Σ, V as above.

for $\mu = 1$ **to** k **do**
  Select a random nonzero $\bar{\mathbf{u}} \in \mathbf{R}^m$
  $\sigma = \|\bar{\mathbf{u}}\|$
  $\mathbf{u} = \bar{\mathbf{u}}/\sigma$
  repeat {power method}
    $\bar{\mathbf{v}} = A^T\mathbf{u}$
    $\mathbf{v} = \bar{\mathbf{v}}/\|\bar{\mathbf{v}}\|$
    $\bar{\mathbf{u}} = A\mathbf{v}$
    $\sigma = \|\bar{\mathbf{u}}\|$
    $\mathbf{u} = \bar{\mathbf{u}}/\sigma$
  until stagnation in $\mathbf{u}, \sigma, \mathbf{v}$
  $A = A - \mathbf{u}\sigma\mathbf{v}^T$
  $U(:, \mu) = \mathbf{u}$
  $V(:, \mu) = \mathbf{v}$
  $\Sigma(\mu, \mu) = \sigma$
end for

defined to be $\sqrt{\lambda_{\max}(B^T B)}$, where $\lambda_{\max}$ denotes the maximum eigenvalue.)

Thus, we see that R1D is quite similar to the SVD. The principal difference is that R1D tries to find a submatrix indexed by $M \times N$ at the same time that it tries to identify the optimal $\mathbf{u}$ and $\mathbf{v}$. Hence, the formulas for $\mathbf{u}$ and $\mathbf{v}$ occurring in ⟨9⟩ and ⟨13⟩ of subroutine `ApproxRankOneSubmatrix`, which were presented earlier as solutions to a least-squares problem, may also be regarded as steps in a power method. In particular, this means that if M and N are fixed, then the inner repeat loop of this subroutine will indeed converge to the dominant singular triple of $A(M, N)$.

As mentioned earlier, a shortcoming of the SVD is that its factors contain both positive and negative numbers. It has another subtler shortcoming when used for clustering which is as follows: because the SVD always operates on the entire matrix, it can return a singular vector that averages the results from two nearly disjoint topics in a corpus (see Biggs et al. (2008) for an example). R1D avoids this pitfall by seeking a submatrix that is approximately rank-one as it applies the power method.

4. Related Work

As mentioned in the introduction, most algorithms proposed in the literature are based on forming an initial W and H and then improving them by local search on an objective function. The objective function usually includes a term of the form $\|A - WH^T\|$ in some norm, and may include other terms.

A few previous works follow an approach similar to ours, namely, greedy subtraction of rank-one matrices. This includes the work of Bergmann et al. (2003), who identify the rank-one matrix to subtract as the fixed point of an iterative process. Asgarian and Greiner (2006) find the dominant singular pair and then truncate it. Gillis (2006) finds a rank-one understimator and subtracts that. Boutsidis and Gallopoulos (2007) consider the use of a greedy algorithm for initializing other algorithm and make the following interesting observation: The nonnegative part of a rank-one matrix has rank at most 2.

The main innovation herein is the idea that the search for the rank-one submatrix should itself be an optimization subproblem. This observation allows us to compare one candidate submatrix to another. (Gillis also phrases his subproblem as optimization, although his optimization problem does not explicitly seek submatrices like ours.) A second innovation is our analysis in Section 5 showing that if the subproblem were solved optimally, then R1D would be able to accurately find the topics in the model of ϵ-separable corpora (Papadimitriou et al., 2000).

5. Behavior of this objective function on a nearly separable corpus

In this section, we establish the main theoretical result of the paper, namely, that the objective function given by (1) is able to correctly identify a topic in a nearly separable corpus. We define our *text model* as follows. There is a universe of *terms* numbered $1, \ldots, m$. There is also a set of *topics* numbered $1, \ldots, t$. Topic k, for $k = 1, \ldots, t$, is a probability distribution over the terms. Let $P(i, k)$ denote the probability of term i occurring in topic k. Thus, P is a singly stochastic matrix, i.e., it has nonnegative entries with column sums exactly 1. We assume also that there is a probability distribution over topics; say the probability of topic k is τ_k, for $k = 1, \ldots, t$. The text model is thus specified by P and $\tau_1, \ldots, \tau_t$. We use the Zipf distribution as the model of document length. In particular, there is a number L such that all documents have length less than L, and the probability that a document of length l occurs is

$$\frac{1/l}{1 + 1/2 + \cdots + 1/(L-1)}.$$

We have checked that the Zipf model is a good fit for several common datasets.

A *document* is generated from this text model as follows. First, topic k is chosen at random according to the probability distribution $\{\tau_1, \ldots, \tau_t\}$. Then, a

length l is chosen at random from $\{1, \ldots, L-1\}$ according to the Zipf distribution. Finally, the document itself is chosen at random by selecting l terms independently according to the probability distribution $P(:, k)$. A *corpus* is a set of n documents chosen independently using this text model. Its *term-document matrix* is the $m \times n$ matrix A such that $A(i, j)$ is the frequency of term i in document j.

We further assume that the text model is ϵ-*separable*, meaning that each topic k is associated with a set of terms $T_k \subset \{1, \ldots, m\}$, that $T_1, \ldots, T_t$ are mutually disjoint, and that $P(i, k) \leq \epsilon$ for $i \notin T_k$, i.e., the probability that a document on topic k will use a term outside of T_k is small. Let $P_{\min} = \min\{P(i, k) : i \in T_k, k = 1, \ldots, t\}$. Without loss of generality, $P_{\min} > 0$ since any row $i \in T_k$ such that $P(i, k) = 0$ may be removed from T_k without affecting the validity of the model. Parameter ϵ must satisfy an inequality mentioned below. This corpus model is quite similar to that of Papadimitriou et al. (2000). One difference is in the the document length model. Our model also relaxes several assumptions of Papadimitriou et al.

Our main theorem is that the objective function given by (1) correctly finds documents associated with a particular topic in a corpus.

Theorem 1. *Let $(P, (\tau_1, \ldots, \tau_t))$ specify a text model, and let $\alpha > 0$ be chosen arbitrarily. Assume $\epsilon > 0$ is chosen smaller than a function $\epsilon(P_{\min}, m, t, \alpha)$ (see Biggs et al. (2008) for this function). Suppose that the text-model is ϵ-separable with respect to $T_1, \ldots, T_t$, the subsets of terms defining the topics. Let A be the term-document matrix of a corpus of n documents drawn from this model when the document-length parameter is L.*

Choose $\gamma = 4$ in (1). Then with probability tending to 1 as $n \to \infty$ and $L \to \infty$, the optimizing pair (M, N) of (1) satisfies the following. Let $D_1, \ldots, D_t$ be the partitioning of the columns of A according to topics. There exists a topic $k \in \{1, \ldots, t\}$ such that $A(M, N)$ and $A(T_k, D_k)$ are nearly coincident in the following sense.

$$\sum_{(i,j) \in (M \times N) \triangle (T_k \times D_k)} A(i, j)^2 \leq \alpha \sum_{(i,j) \in M \times N} A(i, j)^2.$$

Here, $X \triangle Y$ denotes the set-theoretic symmetric difference $(X - Y) \cup (Y - X)$. The proof of this theorem is lengthy and appears in Biggs et al. (2008). It relies on Chernoff-Hoeffding estimates and perturbation results for singular vectors such as Theorem 8.6.5 of Golub and Van Loan (1996).

6. On the complexity of maximizing $f(M, N)$

In this section, we observe that the problem of globally maximizing (2) is NP-hard at least in the case that γ is treated as an input parameter. This observation explains why R1D settles for a heuristic maximization of (2) rather than exact maximization. First, observe that the maximum biclique (MBC) problem is NP-hard as proved by Peeters (2003). We show that the MBC problem can be transformed to an instance of (2).

Let us recall the definition of the MBC problem. The input is a bipartite graph G. The problem is to find an (m, n)-complete bipartite subgraph K (sometimes called a *biclique*) of G such that mn is maximized, i.e., the number of edges of K is maximized.

Suppose we are given G, an instance of the maximum biclique problem. Let A be the left-right adjacency matrix of G, that is, if $G = (U, V, E)$ where $U \cup V$ is the bipartition of the node set, then A has $|U|$ rows and $|V|$ columns, and $A(i, j) = 1$ if $(i, j) \in E$ for $i \in U$ and $j \in V$, else $A(i, j) = 0$.

Consider maximizing (2) for this choice of A. We require the following preliminary lemmas whose proofs are omitted.

Lemma 2. *Let A be a matrix that has either of the following as a submatrix:*

$$U_1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \text{ or } U_2 = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}. \tag{3}$$

Then $\sigma_2(A) > 0.618$.

This lemma leads to the following lemma.

Lemma 3. *Suppose all entries of $A \in \mathbf{R}^{m \times n}$ are either 0 or 1, and suppose and at least one entry is 1. Suppose M, N are the optimal solution for maximizing $f(M, N)$ given by (2). Suppose also that the parameter γ is chosen to be $2.7mn + 1$ or larger. Then the optimal choice of M, N must yield a matrix $A(M, N)$ of all 1's, possibly augmented with some rows or columns that are entirely zeros.*

Now consider the main claim, namely, that optimize (M, N) of the objective function for this A corresponds to the max biclique. If $A(M, N)$ includes a row or column entirely of zeros, then this row or column may be dropped without affecting the value of the objective function (2). Hence it follows from the lemma that without loss of generality that the optimizer (M, N) of (2) indexes a matrix of all 1's. In that case, $\sigma_1(A(M, N)) = \sqrt{|M| \cdot |N|}$ while $\sigma_2(A(M, N)) =$

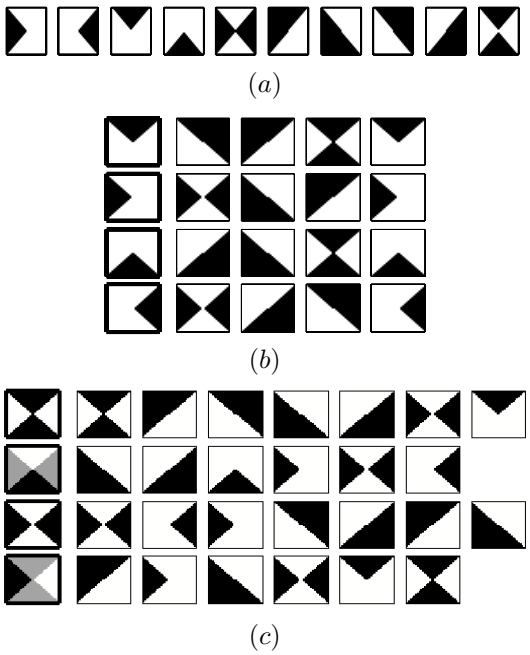

Figure 1. A binary image dataset is depicted in (a); white indicates zeros. The result of R1D on this dataset is shown in (b), and LSI in (c).

$\cdots = \sigma_p(A(M,N)) = 0$ (where $p = \min(|M|,|N|)$), and hence $f(M,N) = |M| \cdot |N|$. Thus, the value of the objective function corresponds exactly to the number of edges in the biclique. This completes the proof that biclique is reducible in polynomial time to maximizing (2).

We note that Gillis (2006) also uses the result of Peeters for a similar purpose, namely, to show that the subproblem arising in his NMF algorithm is also NP-hard.

The NP-hardness result in this section requires that γ be an input parameter. We conjecture that (2) is NP-hard even when γ is fixed (say $\gamma = 4$ as used herein).

7. Image dataset test cases

We first demonstrate the performance of R1D on a simple binary image dataset, depicted in Figure 1 (a). Each of the ten dataset images is composed of one or two "basis" triangles. The results of R1D (with parameter $\bar{\gamma} = 4$) and LSI on this dataset are shown in Figure 1 (b) and (c), respectively, and the interpretation is as follows. The leftmost column illustrates the four leading columns of W, which are the learned features. For each of these, the images on the right are the dataset images with the largest entries in the corresponding column of H; they should be closely associated with the feature on the left.

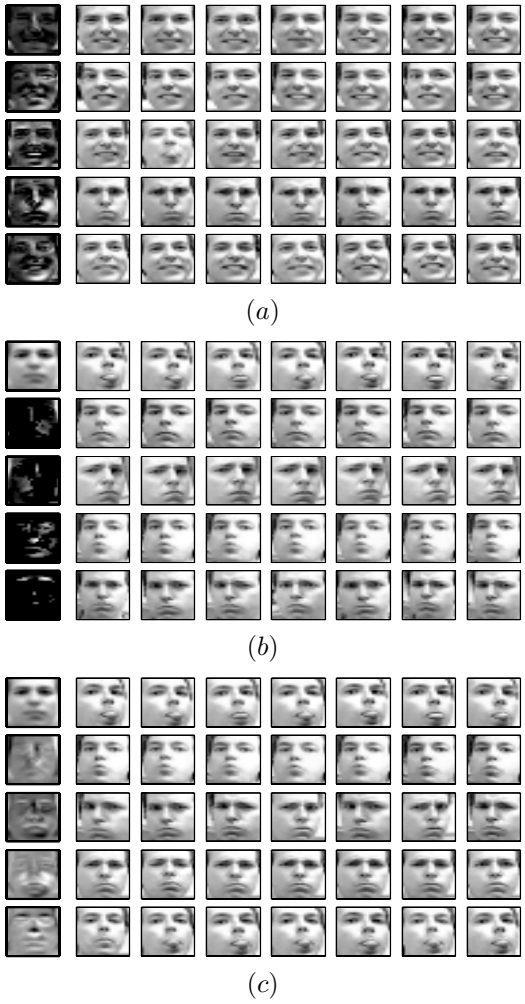

Figure 2. Three algorithms applied to the Frey face dataset (black indicates zeros): (a) NMF with divergence criterion, (b) our R1D algorithm for NMF, and (c) LSI

R1D discovered the four triangles as a basis, and to each it associated exactly the dataset images which contain the appropriate triangle. Alternatively, the LSI factorization is not as interpretable.

We have also compared results against NMFDIV from nmfpack (Hoyer, 2000; Hoyer, 2004). NMFDIV requires k, the number of basis vectors to compute, as an input parameter which globally affects the factors W and H. If k is correctly set to 4, NMFDIV is able to compute the same correct result as R1D. Otherwise, some or all of the basis vectors will appear incorrect, including the first ones. R1D and LSI will each compute the same leading columns regardless of k, and on this dataset they will not compute more than 4 columns; all subsequent columns of W and H will be

Table 1. The amount of sparsity in the NMF computed by R1D ($\bar{\gamma} = 2$) on the Frey face dataset. It is presented as the percentage of zero values in the first few columns of W and H.

Column	% zeros in W	% zeros in H
1	0.00	0.00
2	0.82	0.69
3	0.69	0.68
4	0.82	0.88
5	0.94	0.73

zero.

Figure 2 conducts a similar experiment on the Frey face dataset, which consists of 1965 registered face images of size 28×20. Again, the leading columns of W present the "eigenfaces" or "features" discovered in the dataset, and the corresponding column of H selects dataset images that are classified as carrying the feature most prominently. R1D seems to be the most successful at finding features and classifying images; in each case, the column of W shows a particular highlight that distinguishes some images in the dataset from others. NMFDIV appears to be slightly inferior to R1D, while LSI is noticeably worse.

In this experiment, the algorithms computed 30 basis vectors of the NMF. NMFDIV was allowed 500 iterations which took 727 seconds; in contrast, LSI required 20 seconds and R1D took 47 seconds.

Additionally, R1D is effective at finding a sparse factorization. Table 1 demonstrates the sparsity in the first few columns of W and H. The first column of W and H is fully dense, because the data matrix appears to be approximately rank-one; its first singular value is dominant. Apart from this, the other columns of the NMF are sparse, and the sparsity can be controlled by the $\bar{\gamma}$ parameter (here we have used $\bar{\gamma} = 2$). Alternatively, both NMFDIV and LSI perform a dense factorization with very few values near zero in any column.

8. Text dataset test cases

In Tables 2 and 3 we illustrate LSI versus R1D (with parameter $\bar{\gamma} = 4$) on the TDT Pilot Study (TDT Study, 1997). The columns of each table are the leading columns of W, with the leading terms per column displayed. The LSI results show that the topics are not properly separated and terms from different topics recur or are mixed. The columns in the R1D table are clearly identifiable topics, and the terms in each columns are all correctly associated with the given topics.

Table 2. Topics found by LSI on the TDT Pilot Study corpus (tf-idf normalization).

Topic 1	Topic 2	Topic 3	Topic 4
SIMPSON	ISRAEL	ISRAEL	BOSNIAN
PRESIDENT	ISRAELI	ISRAELI	SERBS
CLINTON	BOSNIAN	PALESTINIAN	SERB
POLICE	PEACE	GAZA	SARAJEVO
HOUSE	SERBS	ARAFAT	BOSNIA
ISRAEL	BOSNIA	PLO	NATO
BOSNIAN	SERB	JERUSALEM	SIMPSON
HAITI	SARAJEVO	PEACE	BIHAC
UNITED	PALESTINIAN	PALESTINIANS	AIR
GOVERNMENT	NATO	SIMPSON	TROOPS

Table 3. Topics found by R1D on the TDT Pilot Study corpus (tf-idf normalization). Note that all words in a column do in fact refer to the same news event.

Topic 1	Topic 2	Topic 3	Topic 4
SIMPSON	MASTERS	KOREA	DENG
JUDGE	PAIRINGS	KOREAN	XIAOPING
ITO	AUGUSTA	NORTH	RONG
JURY	AMATEUR	KIM	PARAMOUNT
DEFENSE	TOURNAMENT	PYONGYANG	CHINA
TRIAL	ROUND	SEOUL	HEALTH
ANGELES	GOLF	SUNG	CHINESE
LOS	NOTED	NUCLEAR	KONG
PROSECUTION	PLAYERS	SOUTH	HONG
CASE	GEORGIA	COMMUNIST	DAUGHTERS

NMFDIV (and the other implementations of NMF in nmfpack) were not run on this dataset because they would exhaust all of the computer's memory. As noted earlier, R1D on text datasets is able to efficiently work with sparse matrices throughout its operation. R1D was able to compute 80 basis vectors of the TDT corpus in 171 seconds, whereas LSI required 269 seconds.

9. Conclusions

We have proposed an algorithm called R1D for nonnegative matrix factorization. It is based on greedy rank-one downdating according to an objective function, which is heuristically maximized. We have shown that the objective function is well suited for identifying topics in the ϵ-separable text model. Finally, we have shown that the algorithm performs well in practice.

This work raises several interesting open questions. First, the ϵ-separable text model seems rather too simple to describe real text, so it would be interesting to see if the results generalize to more realistic models.

A second arising question asks whether a result like Theorem 1 will hold for the R1D algorithm. In other words, if the heuristic subroutine `ApproxRankOneSubmatrix` is applied to an ϵ-separable corpus, does it successfully identify a topic? Here is an example of a difficulty. Suppose $n \to \infty$ much faster than L. In this case, the document j with the highest norm will be the one in which l_j is very close to L and in which one entry $A(i,j)$ is very close to L while the rest are mostly zeros. This is because the maximizer of $\|\mathbf{x}\|_2$ subject to the constraint that $\|\mathbf{x}\|_1 = C$ occurs when one entry of $\mathbf{x}$ is equal to C and the rest are zero. It is likely that at least one instance of such a document will occur regardless of the matrix $P(\cdot,\cdot)$ if n is sufficiently large. This document will then act as the seed for expanding M and N, but it may not be similar to any topic. This scenario can perhaps be prevented by a more intelligent selection of a starting vector for `ApproxRankOneSubmatrix`.

Abstract

Typically agent evaluation is done through Monte Carlo estimation. However, stochastic agent decisions and stochastic outcomes can make this approach inefficient, requiring many samples for an accurate estimate. We present a new technique that can be used to simultaneously evaluate many strategies while playing a single strategy in the context of an extensive game. This technique is based on importance sampling, but utilizes two new mechanisms for significantly reducing variance in the estimates. We demonstrate its effectiveness in the domain of poker, where stochasticity makes traditional evaluation problematic.

1. Introduction

Evaluating an agent's performance is a component of nearly all research on sequential decision making. Typically, the agent's expected payoff is estimated through Monte Carlo samples of the (often stochastic) agent acting in an (often stochastic) environment. The degree of stochasticity in the environment or agent behavior determines how many samples are needed for an accurate estimate of performance. For results in synthetic domains with artificial agents, one can simply continue drawing samples until the estimate is accurate enough. For non-synthetic environments, domains that involve human participants, or when evaluation is part of an on-line algorithm, accurate estimates with a small number of samples are critical. This paper describes a new technique for tackling this problem in the context of extensive games.

An extensive game is a formal model of a sequential interaction between multiple, independent agents with imperfect information. It is a powerful yet compact framework for describing many strategic interactions between decision-makers, artificial and human[1]. Poker, for example, is a domain modeled very naturally as an extensive game. It involves independent and self-interested agents making sequential decisions based on both public and private information in a stochastic environment. Poker also demonstrates the challenge of evaluating agent performance. In one typical variant of poker, approximately 30,000 hands (or samples of playing the game) are sometimes needed to distinguish between professional and amateur levels of play. Matches between computer and human opponents typically involve far fewer hands, yet still need to draw similar statistical conclusions.

In this work, we present a new technique for deriving low variance estimators of agent performance in extensive games. We employ importance sampling while exploiting the fact that the strategy of the agent being evaluated is typically known. However, we reduce the variance that importance sampling normally incurs by selectively adding synthetic data that is derived from but consistent with the sample data. As a result we derive low-variance unbiased estimators for agent performance given samples of the outcome of the game. We further show that we can efficiently evaluate one strategy while only observing samples from another. Finally, we examine the important case where we only get partial information of the game outcome (e.g., if a player folds in poker, their private cards are not revealed during the match and so the sequence of game states is not fully known). All of our estimators are then evaluated empirically in the domain of poker in both full and partial information scenarios.

This paper is organized as follows. In Section 2 we introduce the extensive game model, formalize our problem, and describe previous work on variance reduction in agent evaluation. In Section 3 we present a general procedure for deriving unbiased estimators and give four examples of

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] In this work we use the words "agent", "player", and "decision-maker" interchangeably and, unless explicitly stated, aren't concerned if they are humans or computers.

these estimators. We then briefly introduce the domain of poker in Section 4 and describe how these estimators can be applied to this domain. In Section 5 we show empirical results of our approach in poker. Finally, we conclude in Section 6 with some directions for future work.

2. Background

We begin by describing extensive games and then we formalize the agent evaluation problem.

2.1. Extensive Games

Definition 1 *(Osborne & Rubenstein, 1994, p. 200) a finite extensive game with imperfect information has the following components:*

- *A finite set N of **players**.*
- *A finite set H of sequences, the possible **histories** of actions, such that the empty sequence is in H and every prefix of a sequence in H is also in H. $Z \subseteq H$ are the **terminal histories** (those which are not a prefix of any other sequences). $A(h) = \{a : (h, a) \in H\}$ are the actions available after a non-terminal history $h \in H$,*
- *A **player function** P that assigns to each non-terminal history (each member of $H \backslash Z$) a member of $N \cup \{c\}$, where c represents chance. $P(h)$ is the player who takes an action after the history h. If $P(h) = c$, then chance determines the action taken after history h.*
- *A function f_c that associates with every history h for which $P(h) = c$ a probability measure $f_c(\cdot|h)$ on $A(h)$ ($f_c(a|h)$ is the probability that a occurs given h), where each such probability measure is independent of every other such measure.*
- *For each player $i \in N$ a partition $\mathbf{I}_i$ of $\{h \in H : P(h) = i\}$ with the property that $A(h) = A(h')$ whenever h and h' are in the same member of the partition. $\mathbf{I}_i$ is the **information partition** of player i; a set $I_i \in \mathbf{I}_i$ is an **information set** of player i.*
- *For each player $i \in N$ a utility function u_i from the terminal states Z to the reals $\mathbf{R}$. If $N = \{1, 2\}$ and $u_1 = -u_2$, it is a **zero-sum extensive game**.*

A **strategy of player i** σ_i in an extensive game is a function that assigns a distribution over $A(I_i)$ to each $I_i \in \mathbf{I}_i$. A **strategy profile** σ consists of a strategy for each player, $\sigma_1, \sigma_2, \ldots$, with σ_{-i} referring to all the strategies in σ except σ_i.

Let $\pi^\sigma(h)$ be the probability of history h occurring if players choose actions according to σ. We can decompose $\pi^\sigma = \Pi_{i \in N \cup \{c\}} \pi_i^\sigma(h)$ into each player's contribution to this probability. Hence, $\pi_i^\sigma(h)$ is the probability that if player i plays according to σ then for all histories h' that are a proper prefix of h with $P(h') = i$, player i takes the subsequent action in h. Let $\pi_{-i}^\sigma(h)$ be the product of all players' contribution (including chance) except player i. The overall value to player i of a strategy profile is then the expected payoff of the resulting terminal node, i.e., $u_i(\sigma) = \sum_{z \in Z} u_i(z)\pi^\sigma(z)$. For $Y \subseteq Z$, a subset of possible terminal histories, define $\pi^\sigma(Y) = \sum_{z \in Y} \pi^\sigma(z)$, to be the probability of reaching any outcome in the set Y given σ, with $\pi_i^\sigma(Y)$ and $\pi_{-i}^\sigma(Y)$ defined similarly.

2.2. The Problem

Given some function on terminal histories $V : Z \to \Re$ we want to estimate $E_{z|\sigma}[V(z)]$. In most cases V is simply u_i, and the goal is to evaluate a particular player's expected payoff. We explore three different settings for this problem. In all three settings, we assume that σ_i (our player's strategy) is known, while $\sigma_{j \neq i}$ (the other players' strategies) are not known.

- *On-policy full-information*. In the simplest case, we get samples $z_{1...t} \in Z$ from the distribution π^σ.
- *Off-policy full-information*. In this case, we get samples $z_{1...t} \in Z$ from the distribution $\pi^{\hat{\sigma}}$ where $\hat{\sigma}$ differs from σ only in player i's strategy: $\pi_{-i}^\sigma = \pi_{-i}^{\hat{\sigma}}$. In this case we want to evaluate one strategy for player i from samples of playing a different one.
- *Off-policy partial-information*. In the hardest case, we don't get full samples of outcomes z_t, but rather just player i's view of the outcomes. For example, in poker, if a player folds, their cards are not revealed to the other players and so certain chance actions are not known. Formally, in this case we get samples of $K(z_t) \in \mathbf{K}$, where K is a many-to-one mapping and z_t comes from the distribution $\pi^{\hat{\sigma}}$ as above. K intuitively must satisfy the following conditions: for $z, z' \in Z$, if $K(z) = K(z')$ then,
  - $V(z) = V(z')$, and
  - $\forall \sigma \quad \pi_i^\sigma(z) = \pi_i^\sigma(z')$.

2.3. Monte Carlo Estimation

The typical approach to estimating $E_{z|\sigma}[V(z)]$ is through simple Monte Carlo estimation. Given independent samples $z_1, \ldots, z_t$ from the distribution π^σ, simply estimate the expectation as the sample mean of outcome values.

$$\frac{1}{t} \sum_{i=1}^{t} V(z_i) \tag{1}$$

As the estimator has zero bias, the mean squared error of the estimator is determined by its variance. If the variance of $V(z)$ given σ is large, the error in the estimate can be large and many samples are needed for accurate estimation.

Recently, we proposed a new technique for agent evaluation in extensive games (Zinkevich et al., 2006). We showed that value functions over non-terminal histories could be used to derive alternative unbiased estimators. If the chosen value function was close to the true expected value given the partial history and players' strategies, then the estimator would result in a reduction in variance. The approach essentially derives a real-valued function $\tilde{V}(z)$ that is used in place of V in the Monte Carlo estimator from Equation 1. The expectation of $\tilde{V}(z)$ matches the expectation of $V(z)$ for any choice of σ, and so the result is an unbiased estimator, but potentially with lower variance and thus lower mean-squared error. The specific application of this approach to poker, using an expert-defined value function, was named the DIVAT estimator and was shown to result in a dramatic reduction in variance. A simpler choice of value function, the expected value assuming the betting is "bet-call" for all remaining betting rounds, can even make a notable reduction. We refer to this conceptually and computationally simpler estimator as (Bet-Call) BC-DIVAT.

Both traditional Monte Carlo estimation and DIVAT are focused on the *on-policy* case, requiring outcomes sampled from the joint strategy that is being evaluated. Furthermore, DIVAT is restricted to *full-information*, where the exact outcome is known. Although limited in these regards, they also don't require any knowledge about any of the players' strategies.

3. General Approach

We now describe our new approach for deriving low-variance, unbiased estimators for agent evaluation. In this section we almost exclusively focus on the *off-policy full-information* case. Within this setting we observe a sampled outcome z from the distribution $\pi^{\hat{\sigma}}$, and the goal is to estimate $E_{z|\sigma}\left[V(z)\right]$. The outcomes are observed based on the strategy $\hat{\sigma}$ while we want to evaluate the expectation over σ, where they differ only in player i's strategy. This case subsumes the on-policy case, and we touch on the more difficult partial-information case at the end of this section. In order to handle this more challenging case, we require full knowledge of player i's strategies, both the strategy being observed $\hat{\sigma}_i$ and the one being evaluated σ_i.

At the core of our technique is the idea that synthetic histories derived from the sampled history can also be used in the estimator. For example, consider the unlikely case when σ is known entirely. Given an observed outcome $z \in Z$ (or even without an observed outcome) we can exactly compute the desired expectation by examining every outcome.

$$V_Z(z) \equiv \sum_{z' \in Z} V(z')\pi^{\sigma}(z') = E_{z|\sigma}\left[V(z)\right] \qquad (2)$$

Although impractical since we don't know σ, $V_Z(z)$ is an unbiased and zero variance estimator.

Instead of using every terminal history, we could restrict ourselves to a smaller set of terminal histories. Let $U(z' \in Z) \subseteq Z$ be a mapping of terminal histories to a set of terminal histories, where at least $z' \in U(z')$. We can construct an unbiased estimator that considers the history z' in the estimation whenever we observe a history from the set $U(z')$. Another way to consider things is to say that $U^{-1}(z)$ is the set of synthetic histories considered when we observe z. Specifically, we define the estimator $V_U(z)$ for the observed outcome z as,

$$V_U(z) \equiv \sum_{z' \in U^{-1}(z)} V(z')\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))} \qquad (3)$$

The estimator considers the value of every outcome z' where the observed history z is in the set $U(z')$. Each outcome though is weighted in a fashion akin to importance sampling. The weight term for z' is proportional to the probability of that history given σ, and inversely proportional to the probability that z' is one of the considered synthetic histories when observing sampled outcomes from $\hat{\sigma}$. Note that $V_U(z)$ is not an estimate of $V(z)$, but rather has the same expectation.

At first glance, V_U may seem just as impractical as V_Z since σ is not known. However, with a careful choice of U we can insure that the weight term depends only on the known strategies σ_i and $\hat{\sigma}_i$. Before presenting example choices of U, we first prove that V_U is unbiased.

Theorem 1 *If $\pi_i^{\hat{\sigma}}(z)$ is non-zero for all outcomes $z \in Z$, then,*

$$E_{z|\hat{\sigma}}\left[V_U(z)\right] = E_{z|\sigma}\left[V(z)\right],$$

i.e., V_U is an unbiased estimator.

Proof: First, let us consider the denominator in the weight term of V_U. Since $z' \in U(z')$ and $\pi_i^{\hat{\sigma}}$ is always positive, the denominator can only be zero if $\pi_{-i}^{\hat{\sigma}}(z')$ is zero. If this were true, $\pi_{-i}^{\sigma}(z')$ must also be zero, and as a consequence so must the numerator. As a result the terminal history z' is never reached and so it is correct to simply exclude such histories from the estimator's summation.

Define $\mathbf{1}(x)$ to be the indicator function that takes on the

value 1 if x is true and 0 if false.

$$E_{z|\hat{\sigma}}\left[V_U(z)\right]$$

$$= E_{z|\hat{\sigma}}\left[\sum_{z' \in U^{-1}(z)} V(z')\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))}\right] \tag{4}$$

$$= E_{z|\hat{\sigma}}\left[\sum_{z'} \mathbf{1}(z \in U(z'))V(z')\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))}\right] \tag{5}$$

$$= \sum_{z'} V(z')\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))}E_{z|\hat{\sigma}}\left[\mathbf{1}(z \in U(z'))\right] \tag{6}$$

$$= \sum_{z'} V(z')\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))}\pi^{\hat{\sigma}}(U(z')) \tag{7}$$

$$= \sum_{z'} V(z')\pi^{\sigma}(z') = E_{z|\sigma}\left[V(z)\right] \tag{8}$$

The derivation follows from the linearity of expectation, the definition of $\pi^{\hat{\sigma}}$, and the definition of expectation. ∎

We now look at four specific choices of U for which the weight term can be computed while only knowing player i's portion of the joint strategy σ.

Example 1: Basic Importance Sampling. The simplest choice of U for which V_U can be computed is $U(z) = \{z\}$. In other words, the estimator considers just the sampled history. In this case the weight term is:

$$\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))} = \frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(z')} \tag{9}$$

$$= \frac{\pi^{\sigma}_i(z')\pi^{\sigma}_{-i}(z')}{\pi^{\hat{\sigma}}_i(z')\pi^{\hat{\sigma}}_{-i}(z')} \tag{10}$$

$$= \frac{\pi^{\sigma}_i(z')}{\pi^{\hat{\sigma}}_i(z')} \tag{11}$$

The weight term only depends on σ_i and $\hat{\sigma}_i$ and so is a known quantity. When $\hat{\sigma}_i = \sigma_i$ the weight term is 1 and the result is simple Monte Carlo estimation. When $\hat{\sigma}_i$ is different, the estimator is a straightforward application of importance sampling.

Example 2: Game Ending Actions. A more interesting example is to consider all histories that differ from the sample history by only a single action by player i and that action must be the last action in the history. For example, in poker, the history where the player being evaluated chooses to fold at an earlier point in the betting sequence is considered in this estimator. Formally, define $S_{-i}(z) \in H$ to be the shortest prefix of z where the remaining actions in z are all made by player i or chance. Let $U(z) = \{z' \in Z : S_{-i}(z) \text{ is a prefix of } z'\}$. The weight term becomes,

$$\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))} = \frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(S_{-i}(z'))} \tag{12}$$

$$= \frac{\pi^{\sigma}_{-i}(z')\pi^{\sigma}_i(z')}{\pi^{\hat{\sigma}}_{-i}(S_{-i}(z'))\pi^{\hat{\sigma}}_i(S_{-i}(z'))} \tag{13}$$

$$= \frac{\pi^{\sigma}_{-i}(S_{-i}(z'))\pi^{\sigma}_i(z')}{\pi^{\hat{\sigma}}_{-i}(S_{-i}(z'))\pi^{\hat{\sigma}}_i(S_{-i}(z'))} \tag{14}$$

$$= \frac{\pi^{\sigma}_i(z')}{\pi^{\hat{\sigma}}_i(S_{-i}(z'))} \tag{15}$$

As this only depends on the strategies of player i, we can compute this quantity and therefore the estimator.

Example 3: Private Information. We can also use all histories in the update that differ only in player i's private information. In other words, any history that the other players wouldn't be able to distinguish from the sampled history is considered. For example, in poker, any history where player i receiving different private cards is considered in the estimator since the opponents' strategy cannot depend directly on this strictly private information. Formally, let $U(z) = \left\{z' \in Z : \forall \sigma\ \pi^{\sigma}_{-i}(z') = \pi^{\sigma}_{-i}(z)\right\}$. The weight term then becomes,

$$\frac{\pi^{\sigma}(z')}{\pi^{\hat{\sigma}}(U(z'))} = \frac{\pi^{\sigma}(z')}{\sum_{z'' \in U(z')}\pi^{\hat{\sigma}}(z'')} \tag{16}$$

$$= \frac{\pi^{\sigma}_{-i}(z')\pi^{\sigma}_i(z')}{\sum_{z'' \in U(z')}\pi^{\hat{\sigma}}_{-i}(z'')\pi^{\hat{\sigma}}_i(z'')} \tag{17}$$

$$= \frac{\pi^{\sigma}_{-i}(z')\pi^{\sigma}_i(z')}{\sum_{z'' \in U(z')}\pi^{\hat{\sigma}}_{-i}(z')\pi^{\hat{\sigma}}_i(z'')} \tag{18}$$

$$= \frac{\pi^{\sigma}_{-i}(z')\pi^{\sigma}_i(z')}{\pi^{\hat{\sigma}}_{-i}(z')\sum_{z'' \in U(z')}\pi^{\hat{\sigma}}_i(z'')} \tag{19}$$

$$= \frac{\pi^{\sigma}_i(z')}{\pi^{\hat{\sigma}}_i(U(z'))} \tag{20}$$

As this only depends on the strategies of player i, we can again compute this quantity and therefore the estimator as well.

Example 4: Combined. The past two examples show that we can consider histories that differ in the player's private information or by the player making an alternative game ending action. We can also combine these two ideas and consider any history that differs by both an alternative game ending action and the player's private information. Define $Q(z) = \left\{h \in H : |h| = |S_{-i}(z)| \text{ and } \forall \sigma \pi^{\sigma}_{-i}(h) = \pi^{\sigma}_{-i}(S_{-i}(z))\right\}$,

Let $U(z) = \{z' \in Z : \text{ a prefix of } z' \text{ is in } Q(z)\}$.

$$\frac{\pi^\sigma(z')}{\pi^{\hat{\sigma}}(U(z'))} = \frac{\pi^\sigma(z')}{\pi^{\hat{\sigma}}(Q(z'))} \tag{21}$$

$$= \frac{\pi^\sigma_{-i}(z')\pi^\sigma_i(z')}{\sum_{h \in Q(z')} \pi^{\hat{\sigma}}_{-i}(h)\pi^{\hat{\sigma}}_i(h)} \tag{22}$$

$$= \frac{\pi^\sigma_{-i}(z')\pi^\sigma_i(z')}{\sum_{h \in Q(z')} \pi^{\hat{\sigma}}_{-i}(S_{-i}(z))\pi^{\hat{\sigma}}_i(h)} \tag{23}$$

$$= \frac{\pi^\sigma_{-i}(S_{-i}(z'))\pi^\sigma_i(z')}{\pi^{\hat{\sigma}}_{-i}(S_{-i}(z')) \sum_{h \in Q(z')} \pi^{\hat{\sigma}}_i(h)} \tag{24}$$

$$= \frac{\pi^\sigma_i(z')}{\pi^{\hat{\sigma}}_i(Q(z'))} \tag{25}$$

Once again this quantity only depends on the strategies of player i and so we can compute this estimator as well.

We have presented four different estimators that try to extract additional information from a single observed game outcome. We can actually combine any of these estimators with other unbiased approaches for reducing variance. This can be done by replacing the V function in the above estimators with any unbiased estimate of V. In particular, these estimators can be combined with our previous DIVAT approach by choosing V to be the DIVAT (or BC-DIVAT) estimator instead of u_i.

3.1. Partial Information

The estimators above are provably unbiased for both the-policy and off-policy full-information case. We now briefly discuss the off-policy partial-information case. In this case we don't directly observe the actual terminal history z_t but only a many-to-one mapping $K(z_t)$ of the history. One simple adaptation of our estimators to this case is to use the history z' in the estimator whenever it is possible that the unknown terminal history could be in $U(z')$, while keeping the weight term unchanged. Although we lose the unbiased guarantee with these estimators, it is possible that the reduction in variance is more substantial than the error caused by the bias. We investigate empirically the magnitude of the bias and the resulting mean-squared error of such estimators in the domain of poker in Section 5.

4. Application to Poker

To analyze the effectiveness of these estimators, we will use the popular game of Texas Hold'em poker, as played in the AAAI Computer Poker Competition (Zinkevich & Littman, 2006). The game is two-player and zero-sum. Private cards are dealt to the players, and over four rounds, public cards are revealed. During each round, the players place bets that the combination of their public and private cards will be the strongest at the end of the game. The game has just under 10^{18} game states, and has the properties of imperfect information, stochastic outcomes, and observations of the game outcome during a match exhibit partial information.

Each of the situations described in Section 2, on-policy and off-policy as well as full-information and partial information, have relevance in the domain of poker. In particular, the *on-policy full-information* case is the situation where one is trying to evaluate a strategy from full-information descriptions of the hands, as might be available after a match is complete. For example, this could be used to more accurately determine the winner of a competition involving a small number of hands (which is always the case when humans are involved). In this situation it is critical, that the estimator is unbiased, i.e., it is an accurate reflection of the expected winnings and therefore does not incorrectly favor any playing style.

The *off-policy full-information* case is useful for examining past games against an opponent to determine which of many alternative strategies one might want to use against them in the future. The introduction of bias (depending on the strategy used when playing the past hands) is not problematic, as the goal in this case is an estimate with as little error as possible. Hence the introduction of bias is acceptable in exchange for significant decreases in variance.

Finally, the *off-policy partial-information* case corresponds to evaluating alternative strategies during an actual match. In this case, we want to evaluate a set of strategies, which aren't being played, to try and identify an effective choice for the current opponent. The player could then choose a strategy whose performance is estimated to be strong even for hands it wasn't playing.

The estimators from the previous section all have natural applications to the game of poker:

- **Basic Importance Sampling**. This is a straightforward application of importance sampling. The value of the observed outcome of the hand is weighted by the ratio of the probability that the strategy being evaluated (σ_i) takes the same sequence of actions to the probability that the playing strategy ($\hat{\sigma}_i$) takes the sequence of actions.

- **Game ending actions**. By selecting the *fold* betting action, a player surrenders the game in order to avoid matching an opponent's bet. Therefore, the game ending actions estimator can consider all histories in which the player could have folded during the observed history.[2] We call this the **Early Folds** (EF) estimator. The estimator sums over all possible prefixes

[2] In the full-information setting we can also consider situations where the player could have *called* on the final round of betting to end the hand.

of the betting sequence where the player could have chosen to fold. In the summation it weights the value of surrendering the pot at that point by the ratio of the probability of the observed betting up to that point and then folding given the player's cards (and σ_i) to the probability of the observed betting up to that point given the player's cards (and $\hat{\sigma}_i$).

- **Private information**. In Texas Hold'em, a player's private information is simply the two private cards they are dealt. Therefore, the private information estimator can consider all histories with the same betting sequence in which the player holds different private cards. We call this the **All Cards** (AC) estimator. The estimator sums over all possible two-card combinations (excepting those involving exposed board or opponent cards). In the summation it weights the value of the observed betting with the imagined cards by the ratio of the probability of the observed betting given those cards (and σ_i) to the probability of the observed betting (given $\hat{\sigma}_i$) summed over all cards.

5. Results

Over the past few years we have created a number of strong Texas Hold'em poker agents that have competed in the past two AAAI Computer Poker Competitions. To evaluate our new estimators, we consider games played between three of these poker agents: S2298 (Zinkevich et al., 2007), PsOpti4 (Billings et al., 2003), and CFR8 (Zinkevich et al., 2008). In addition, we also consider Orange, a competitor in the First Man-Machine Poker Championship.

To evaluate these estimators, we examined records of games played between each of three candidate strategies (S2298, CFR8, Orange) against the opponent PsOpti4. Each of these three records contains one million hands of poker, and can be viewed as full information (both players' private cards are always shown) or as partial information (when the opponent folds, their private cards are not revealed). We begin with the full-information experiments.

5.1. Full Information

We used the estimators described previously to find the value of each of the three candidate strategies, using full-information records of games played from just one of the candidate strategies. The strategy that actually played the hands in the record of games is called the on-policy strategy and the others are the off-policy strategies. The results of one these experiments is presented in Table 1. In this experiment, we examined one million full-information hands of S2298 playing against PsOpti4. S2298 (the on-policy strategy) and CFR8 and Orange (the off-policy strategies) are evaluated by our importance sampling estimators, as well as DIVAT, BC-DIVAT, and a few combination estimators. We present the empirical bias and standard deviation of the estimators in the first two columns. The third column, "RMSE", is the root-mean-squared error of the estimator if it were used as the method of evaluation for a 1000 hand match (a typical match length). All of the numbers are reported in millibets per hand played. A millibet is one thousandth of a small-bet, the fixed magnitude of bets used in the first two rounds of betting. To provide some intuition for these numbers, a player that always folds will lose 750 millibets per hand, and strong players aim to achieve an expected win rate over 50 millibets per hand.

Table 1. Full Information Case. Empirical bias, standard deviation, and root mean-squared-error over a 1000 hand match for various estimators. 1 million hands of poker between S2298 and PsOpti4 were observed. A bias of 0* indicates a provably unbiased estimator.

	Bias	StdDev	RMSE
S2298			
Basic	0*	5103	161
DIVAT	0*	1935	61
BC-DIVAT	0*	2891	91
Early Folds	0*	5126	162
All Cards	0*	4213	133
AC+BC-DIVAT	0*	2146	68
AC+EF+BC-DIVAT	0*	1778	56
CFR8			
Basic	200 ± 122	62543	1988
DIVAT	62 ± 104	53033	1678
BC-DIVAT	84 ± 45	22303	710
Early Folds	123 ± 120	61481	1948
All Cards	12 ± 16	8518	270
AC+BC-DIVAT	35 ± 13	3254	109
AC+EF+BC-DIVAT	2 ± 12	2514	80
Orange			
Basic	159 ± 40	20559	669
DIVAT	3 ± 25	11350	359
BC-DIVAT	103 ± 28	12862	420
Early Folds	82 ± 35	17923	572
All Cards	7 ± 16	8591	272
AC+BC-DIVAT	8 ± 13	3154	100
AC+EF+BC-DIVAT	6 ± 12	2421	77

In the on-policy case, where we are evaluating S2298, all of the estimators are provably unbiased, and so they only differ in variance. Note that the Basic estimator, in this case, is just the Monte-Carlo estimator over the actual money lost or won. The Early Folds estimator provides no variance reduction over the Monte-Carlo estimate, while the All Cards estimator provides only a slight reduction. However, this is not nearly as dramatic as the reduction provided by the DIVAT estimator. The importance sampling estimators, however, can be combined with the DIVAT es-

timator as described in Section . The combination of BC-DIVAT with All Cards ("AC+BC-DIVAT") results in lower variance than either of the estimators separately.[3] The addition of Early Folds ("AC+EF+BC-DIVAT") produces an even further reduction in variance, showing the best-performance of all the estimators, even though Early Folds on its own had little effect.

In the off-policy case, where we are evaluating CFR8 or Orange, we report the empirical bias (along with a 95% confidence bound) in addition to the variance. As DIVAT and BC-DIVAT were not designed for off-policy evaluation, we report numbers by combining them with the Basic estimator (i.e., using traditional importance sampling). Note that bias is possible in this case because our on-policy strategy (S2298) does not satisfy the assumption in Theorem 1, as there are some outcomes the strategy never plays. Basic importance sampling in this setting not only shows statistically significant bias, but also exhibits impractically large variance. DIVAT and BC-DIVAT, which caused considerable variance reduction on-policy, also should considerable variance reduction off-policy, but not enough to offset the extra variance from basic importance sampling. The All Cards estimator, on the other hand, shows dramatically lower variance with very little bias (in fact, the empirical bias is statistically insignificant). Combining the All Cards estimator with BC-DIVAT and Early Folds further reduces the variance, giving off-policy estimators that are almost as accurate as our best on-policy estimators.

The trends noted above continue in the other experiments, when CFR8 and Orange are being observed. For space considerations, we don't present the individual tables, but instead summarize these experiments in Table 2. The table shows the minimum and maximum empirically observed bias, standard deviation, and the root-mean-squared error of the estimator for a 1000 hand match. The strategies being evaluated are separated into the on-policy case, when the record involves data from that strategy, and the off-policy case, when it doesn't.

5.2. Partial Information

The same experiments were repeated for the case of partial information. The results of the experiment involving S2298 playing against PsOpti4 and evaluating our three candidate strategies under partial information is shown in Table 3. For DIVAT and BC-DIVAT, which require full information of the game outcome, we used a partial information variant where the full-information estimator was used when the game outcome was known (i.e., no player folded) and winnings was used when it was not. This variant can result in a biased estimator, as can be seen in the table of results. The All Cards estimator, although also without any guarantee of being unbiased, actually fares much better in practice, not displaying a statistically significant bias in either the off-policy or on-policy experiments. However, even though the DIVAT estimators are biased their low variance makes them preferred in terms of RMSE in the on-policy setting. In the off-policy setting, the variance caused by Basic importance sampling (as used with DIVAT and BC-DIVAT) makes the All Cards estimator the only practical choice. As in the full-information case we can combine the All Cards and BC-DIVAT for further variance reduction. The resulting estimator has lower RMSE than either All Cards or BC-DIVAT alone both in the on-policy and off-policy cases. The summary of the results of the other experiments, showing similar trends, are shown in Table 4.

Table 3. Partial-Information Case. Empirical bias, standard deviation, and root mean-squared-error over a 1000 hand match for various estimators. 1 million hands of poker between S2298 and PsOpti4 with partial information were observed. A bias of 0* indicates a provably unbiased estimator.

	Bias	StdDev	RMSE

All Cards	3±19	8092	256
AC+BC-DIVAT	203±16	3880	237

6. Conclusion

We introduced a new method for estimating agent performance in extensive games based on importance sampling. The technique exploits the fact that the agent's strategy is typically known to derive several low variance estima-

[3]The importance sampling estimators were combined with BC-DIVAT instead of DIVAT because the original DIVAT estimator is computationally burdensome, particularly when many evaluations are needed for every observation as is the case with the All Cards estimator.

Table 2. Summary of the Full-Information Case. Summary of empirical bias, standard deviation, and root-mean-squared error over a 1000 hand match for various estimators. tors that can simultaneously evaluate many strategies while playing a single strategy. We prove that these estimators are unbiased in both the on-policy and off-policy case. We empirically evaluate the techniques in the domain of poker, showing significant improvements in terms of lower variance and lower bias. We show that the estimators can also be used even in the challenging problem of estimation with partial information observations.

Abstract

Scientists frequently have multiple types of experiments and data sets on which they can test the validity of their parameterized models and locate plausible regions for the model parameters. By examining multiple data sets, scientists can obtain inferences which typically are much more informative than the deductions derived from each of the data sources independently. Several standard data combination techniques result in target functions which are a weighted sum of the observed data sources. Thus, computing constraints on the plausible regions of the model parameter space can be formulated as finding a level set of a target function which is the sum of observable functions. We propose an active learning algorithm for this problem which selects both a sample (from the parameter space) and an observable function upon which to compute the next sample. Empirical tests on synthetic functions and on real data for an eight parameter cosmological model show that our algorithm significantly reduces the number of samples required to identify the desired level-set.

1. Introduction

Scientists frequently have multiple types of experiments and data sets on which they can test the validity of their parameterized models and the plausible or optimal regions for the model parameters. One task that can be considered is that of computing the parameter setting (from a pre-defined model parameter space) which maximizes the likelihood of all the observations given the models. However, this calculation does not determine whether or not the derived parameter setting is consistent with the data given the models. Instead, a more prudent approach is to compute the set of model parameters (from the parameter space) which cannot be statistically rejected by the combination of the observed data and theoretical models.

When given a single model and data set pair, computation of the feasible regions of parameter space can be done by performing a simple hypothesis test for all points in the space; that is, we are interested in the regions of parameter space where the null hypothesis — that the data was generated by the model — cannot be rejected at some specified confidence level. Extending this to the multiple model and data setting, we are interested in determining regions of parameter space where we cannot reject the hypothesis that each of the data sets was generated by its respective model at a given confidence level.

For example, when determining the spatial location of a disease outbreak, a researcher might use information derived from medical records (e.g. hospital admits), as well as sales of over the counter and prescription medications (Shmueli & Fienberg, 2006). Note that the presence (or lack thereof) of a single indicator may be enough to accept or reject a single hypothesis, resulting in increased data efficiency. Specifically, if there are many hospital admits from a single locality, the probability of disease is extremely high regardless of the over the counter and prescription drug sales. Moreover, while we believe that the underlying cause affects each of the signals we observe, we do not necessarily believe that the signals themselves are correlated. For instance, colds result in significant over the counter sales with few hospital visits or prescription sales. However, anthrax attacks will affect all three data streams.

There are many other examples of the multiple model setting. Here, we focus on finding $1 - \alpha$ confidence regions for statistical analyses involving multiple related data sets. Traditionally, the combination of statistical evidence has been achieved in the sciences in a somewhat ad-hoc fashion. For instance, a joint analysis can be performed by (loosely) intersecting the confidence regions of several studies. Additionally, results from one publication might be used to guide the selection of parameters in future experiments, possibly in the form of a prior.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

A more rigorous and efficient approach is to consider multiple experimental sources of evaluation simultaneously and choose samples in light of their contribution to the combined target function. This target function is the composition of the "observable" test functions: one for each data set and model pair. We assume that the observable functions share the same parameter space, but are functionally independent. As such, hierarchical models do not apply. Moreover, whereas multi-task learning problems are based on learning the commonality between the constituent models, the task of locating confidence regions benefits from the discrepancies between the models to efficiently accept or reject a parameter vector. While in theory we could check each point in the parameter space to determine whether or not it should be included within our $1{-}\alpha$ confidence region, in practice each experiment is too expensive.

As such, we develop active learning algorithms to learn the confidence regions. Active learning using informed choices of future experiments has long been known to drastically decrease a problem's sample complexity (Angluin, 1988). Many sampling heuristics have been developed to learn either the entire target function (e.g. MacKay (1992); Guestrin, C., et al. (2005)) or some feature of the target function, such as its level sets (e.g. Bryan, B., et al. (2005); Ramakrishnan, N., et al. (2005)). While we cannot directly observe the value of the target function, we can use the observable functions to infer its value. By measuring all observable functions at a particular parameter setting, we can compute the value of the target function, reducing the problem to a standard active learning problem. However, such an approach disregards any strong evidence provided by a single statistical test, and hence may result in extraneous sampling of the remaining statistical models.

Rather, we are interested in active learning algorithms which use information about each observable function to learn some composite target function. In Section 2, we propose a heuristic for actively learning level sets of composite functions of sums for continuous valued input spaces. In Section 3, we show that this heuristic performs the level-set discovery task more efficiently than both random and sequential sampling of the constituent functions using state of the art heuristics. In Section 4, we discuss how the task of finding joint confidence regions can be formulated as a level set problem, where the target function is the sum of several observable functions. Section 5 concludes by demonstrating the computation of 95% confidence regions for eight cosmological parameters using our algorithm.

2. Active Learning Algorithm

Let f be a target function we are interested in learning on the domain $\Theta \subseteq \mathbb{R}^d$. Suppose that f is the linear combination of m observable functions, f_i ($i = 1, \ldots, m$). Without loss of generality, we can drop the coefficients from the summation (as they can be included in the f_i's) and write $f(\theta) = \sum_{i=1}^{m} f_i(\theta)$ for all $\theta \in \Theta$. We are now interested in finding the level set, $\mathcal{S}$, of f at the threshold t:

$$\mathcal{S} = \left\{ \theta \in \Theta \,\middle|\, \sum_{i=1}^{m} f_i(\theta) = f(\theta) = t \right\}.$$

In general, computing the value of each f_i may not incur the same cost. However, we begin by assuming that the costs are similar, and hence try to minimize the total number of samples of observable functions required to accurately estimate $\mathcal{S}$. Moreover, we assume that f cannot be directly sampled, and that neither f nor any of the f_i's is invertible. That is, the only way to estimate a level-set of f is to sample points from the f_i's and infer f. As we will see in Section 4, this formulation accurately mimics combining p-values using Fisher's method, as the method for finding the individual p-values may be entirely unknown.

We must now determine how best to choose samples both among and within the f_i's. Ideally, we want to sample the observable function f_i at the point $\tilde{\theta} \in \Theta$ which best increases our prediction accuracy (e.g. whether another point is above or below the threshold) over f. Since the parameter space is continuous and multi-dimensional, we cannot afford to test all possible points and observable functions.

Instead, we model each of the observable functions independently given the current samples taken from that function, as illustrated in Figure 1. For each experiment, we randomly select a small subset of the parameter space (usually 1000 points drawn uniformly at random, although other distributions are possible based on domain knowledge) and choose the best point and observable function pair upon which to experiment from among these candidates. We find the value of the observable function at the selected point and add it to the data set used to model that function. The process is then repeated.

There are several methods one could use to model each of the f_i's, notably some form of parametric regression. However, we chose to approximate the f_i's using Gaussian process regression, as other forms of regression may over smooth the data, ignoring subtle features of the function that may become pronounced with more data. While much work has been done studying Gaussian processes, we only touch on the basic concepts here; we refer interested readers to Cressie (1991); Rasmussen and Williams (2006).

Gaussian processes are non-parametric forms of regression. Predictions for unobserved points are computed by using a weighted combination of the function values for those points which have already been observed, where a distance-based kernel function is used to determine the relative weights. These distance-based kernels generally weight

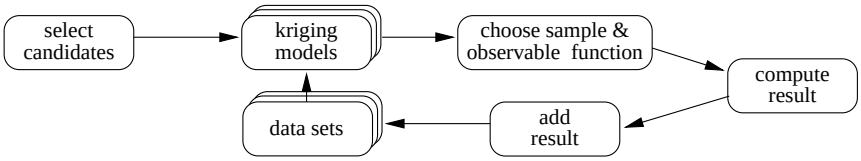

Figure 1. Outline of our sampling algorithm. Given an initial set of points (typically empty), we randomly select a set of candidates and score them using a set of Gaussian process models. The best scoring point and observable function pair is chosen, and we evaluate the selected observable function at the given point. This data is added to the corresponding data set.

nearby points significantly more than distant points. Thus, assuming the underlying function is continuous, Gaussian processes will perfectly describe the function given an infinite set of unique data points. While, in many applications the assumption of continuity is violated, Gaussian processes have been successfully used to model response surfaces in many domains with limited smoothness guarantees (Cressie, 1991; Santner et al., 2003).

In this work we use ordinary kriging (Cressie, 1991), which assumes a linear semivariance as a function of distance, as it is both data and computationally efficient. While other forms of Gaussian Processes could be used — most notably adaptive kernel methods (e.g. Kersting, K. et al. (2007)) — we find that a learned model based upon a simple kriging approximator performs well in practice and ensures that we do not spend more time computing the next sample than we do running the experiment.

Regardless of the kernel used, Gaussian processes predict that the value of a target point, $\tilde{\theta}$, will be Normally distributed with a mean and variance ($f_i(\tilde{\theta})$ and $\sigma_i^2(\tilde{\theta})$, respectively) given by:

$$f_i(\tilde{\theta}) = \bar{f}_i + \vec{\Sigma}_{i,\tilde{\theta}}^T \mathbf{\Sigma}_i^{-1} \vec{\mathcal{F}}_i \quad (1)$$

$$\sigma^2(\tilde{\theta}) = \vec{\Sigma}_{i,\tilde{\theta}}^T \mathbf{\Sigma}_i^{-1} \vec{\Sigma}_{i,\tilde{\theta}} \quad (2)$$

where $\mathcal{T}_i$ is the set of observed experiments of f_i,

$$\bar{f}_i = \frac{1}{|\mathcal{T}_i|} \sum_{j=1}^{|\mathcal{T}_i|} f_i(a_j),$$

$$\mathcal{F}_i[j] = f_i(\theta_j) - \bar{f}_i,$$

$\mathbf{\Sigma_i}$ denotes the covariance matrix between the elements of $\mathcal{T}_i$, and $\vec{\Sigma}_{i,\tilde{\theta}}$ is the covariance vector between elements of $\mathcal{T}_i$ and $\tilde{\theta}$.

For a set of n_i observed points ($|\mathcal{T}_i| = n_i$), prediction with a Gaussian process requires $O(n_i^3)$ time, as a $n_i \times n_i$ linear system of equations must be solved. However, for many Gaussian processes — and ordinary kriging in particular — the correlation between two points decreases as a function of distance. Thus, the full Gaussian process model is approximated well by a local Gaussian process in which only the k nearest neighbors of the query point are used, for some fixed constant k. This reduces the computation time to $O(k^3 + k \log(n_i))$ per prediction. Here, we let $k = 1000$.

2.1. Choosing Experiments

Given this active learning framework, we must now decide how to choose sample / observable function pairs. We consider the following heuristics:

Random One of the candidate points and an observable function pair is chosen uniformly at random. This method serves as a baseline for comparison of the other heuristics.

Variance The candidate point and observable function pair which has the highest predicted variance (out of all the candidate / observable function pairs) is selected. Using model variance to pick the next experiment is common for active learning methods whose goal is to map out the target function over a parameter space (MacKay, 1992; Guestrin, C., et al., 2005). In particular, (Guestrin, C., et al., 2005) showed that greedily picking experiments based upon model variance performs nearly as well as using a mutual information heuristic when learning the target over the entire parameter space; this is significant, as the mutual information heuristic can be shown to be $(1 - 1/e)$ optimal (Guestrin, C., et al., 2005). Since variance is closely related to distance for kriging models, this heuristic samples points which are far from their nearest neighbors. However, when searching for level-sets, we are less interested in the function away from the level-set boundary, and instead want to focus our sampling resources near the predicted boundary. In particular, sampling based solely on variance results in substantially worse performance than heuristics that concentrate on the function level-set (Bryan, B., et al., 2005).

Information Gain Information gain is a common myopic metric used in active learning. Computing the information gain over the whole state space for each observable function provides an optimal 1-step experiment choice. In some discrete or linear problems this can be done, but it is intractable for continuous non-linear spaces. As such we do not consider a traditional information gain heuristic, but rely on efficient point estimates which act as proxies for global information gain.

Sequential-Straddle As noted in Section 1, the problem can be simplified to a standard active learning problem if one sequentially samples each of the observable functions in order to directly compute f. (Bryan, B., et al., 2005) showed that in a setting where experiments yield the (approximately) true values of the target function, a good heuristic for level set identification is the straddle heuristic: $\text{straddle}(\tilde{\theta}) = 1.96\sigma^2(\tilde{\theta}) - |f(\tilde{\theta}) - t|$. This heuristic balances the need to explore uncertain parts of parameter space, with the desire to refine the model's estimate around those regions already known to be close to the level-set boundary; the constant 1.96 ensures that points with negative scores are far from the desired level set with at least a 95% probability. This heuristic leverages the straddle heuristic by choosing the candidate point with the highest combined straddle score,

$$\text{combined-straddle}(\tilde{\theta}) = 1.96 \sum_{i=1}^{m} \sigma_i^2(\tilde{\theta}) - \left| \sum_{i=1}^{m} f_i(\tilde{\theta}) - t \right|, \quad (3)$$

and then sequentially sampling all m observable functions at this point.

Variance-Straddle While (Bryan, B., et al., 2005) showed that the straddle heuristic works well when directly sampling the target function, we can hope to do better by considering the output from each observable function individually. For instance, if a sample point results in a very large value for one of the observable functions, it may be unlikely that the results of the other f_i's will be such that the resulting value of f is near the level-set. In particular, when dealing with χ^2 models (see Section 4), we know that $f_i \geq 0$ for all i. Thus, if a single f_i is greater than the level-set boundary, the target function will also be greater than the level-set boundary, and hence it may be more efficient to sample elsewhere. This heuristic simply chooses the next sample from among the candidates based on the combined-straddle score, and then selects the observable function with the largest variance at that point.

Variance-MaxVarStraddle Finally, we consider a variant of the straddle heuristic. This heuristic tries to mimic the information gain of choosing a particular point and observable function pair. Note that after observing a point, the variance of the kriging model is effectively zero at that point (since we have set c to be a very small positive value). The original straddle heuristic balances the expected gain in the model fit ($\sigma(\tilde{\theta})$) with the expected distance of the point to the level-set boundary.

However, with the multiple model formulation, we do not expect the model variance to decrease by $\sigma^2(\tilde{\theta}) = \sum_{i=1}^{m} \sigma_i^2(\tilde{\theta})$, but rather by $\sigma_i(\tilde{\theta})$ where f_i is the observable function we pick. Thus, a more accurate proxy for the information gain of a candidate point and observable function pair is:

$$\text{variance-maxvarstraddle}(\tilde{\theta}) = \max_i \left\{ 1.96\sigma_i^2(\tilde{\theta}) \right\} - \left| \sum_{i=1}^{m} f_i(\tilde{\theta}) - t \right|. \quad (4)$$

We choose the candidate point that maximizes this heuristic and the corresponding f_i.

3. Experiments

We now assess the accuracy with which our active learning model reproduces synthetic target functions for the sampling heuristics just described. This is done by computing the fraction of test points in which the predictive model (the sum of the kriging models associated with each observable function) agrees with the true target function about on which side of the threshold the test points lie. This process was repeated 20 times to account for variations due to the random nature of the candidate generation process. The first three target functions considered were sums of two observable functions, while the fourth was a sum of four observable functions. The kriging parameters for each model were computed *a priori* from the observable functions. The considered functions are:

Gaussian This problem consisted of determining the 95% acceptance region of two axis aligned perpendicular two dimensional Gaussian distributions centered at the origin. Both Gaussians had diagonal covariance matrices with on diagonal elements of 1 and 16. Since working in probability space results in many near-zero values, the problem was considered in log-space. As such, the target function was a 2 dimensional symmetric quadratic function, and the level-set was a circle centered at the origin. The range of the parameter space was ($\theta_1, \theta_2 \in [-3.4, 3.4]$)

Sin2D The second problem consists of finding where the two 2D sinusoidal observable functions

$$\begin{aligned} f_1(\theta_1, \theta_2) &= \sin(10\theta_1) + \cos(4\theta_2) - \cos(3\theta_1\theta_2) \\ f_2(\theta_1, \theta_2) &= \sin(10\theta_2) + \cos(4\theta_1) - \cos(3\theta_1\theta_2) \end{aligned}$$

sum to zero where $\theta_1, \theta_2 \in [0, 2]$. These observable functions were chosen because 1) the target threshold winds through the plot giving ample length to test the accuracy of the approximating model, 2) the boundary is discontinuous with several small pieces, 3) there is an ambiguous region around $(0.9, 1)$, where the true function is approximately equal to the threshold, and the gradient is small and 4) there are areas in the domain where the function is far from the threshold and hence we can see whether algorithms refrain from oversampling in these regions.

Table 1. Number of samples required to achieve a 99% accuracy on the Gaussian and SimpleSin2D tests, and a 90% accuracy on the Sin2D and 4-Sin2D tests based on 20 trials. The variance-maxvarstraddle heuristic consistently performs better than competitors.

	Gaussian	SimpleSin2D	Sin2D	4-Sin2D
random	> 1000	> 1000	> 1000	> 1000
variance	95.0 ± 11.0	> 500	105.0 ± 11.5	188.6 ± 32.2
variance-straddle	89.5 ± 5.0	157.9 ± 12.3	90.4 ± 9.0	72.5 ± 12.0
sequential-straddle	76.2 ± 3.5	150.3 ± 6.5	87.0 ± 7.3	98.1 ± 14.0
variance-maxvarstraddle	71.7 ± 3.3	127.3 ± 6.8	82.9 ± 10.2	54.9 ± 16.9

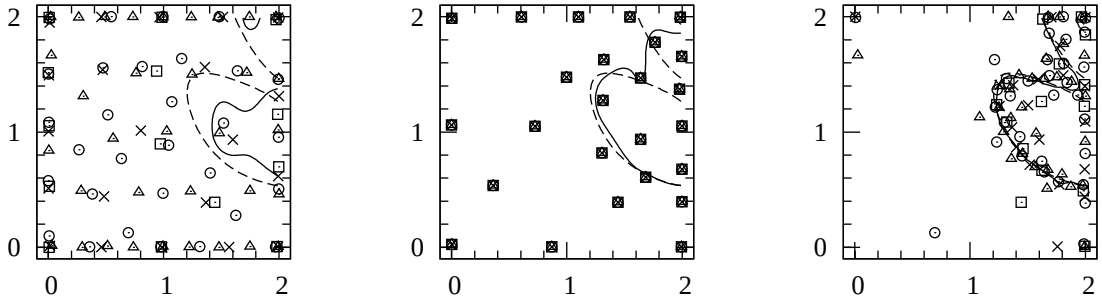

Figure 2. Predicted level-set (solid), true level-set (dashed) and experiments (squares, circle, triangles and x's) for the 4-Sin2D function after sampling 100 points using the Variance heuristic (left), the sequential-straddle heuristic (center), and the variance-maxvarstraddle heuristic (right).

SimpleSin2D This problem is a simplified version of the previous problem, where the observable functions

$$f_1(\theta_1, \theta_2) = \sin(4\theta_1) + \cos(4\theta_2) - \cos(\theta_1\theta_2)$$
$$f_2(\theta_1, \theta_2) = \sin(4\theta_2) + \cos(4\theta_1) - \cos(\theta_1\theta_2)$$

were chosen to reduce the problem's semi-variances (again $\theta_1, \theta_2 \in [0:2]$). Since problems with large semi-variances result in large model variance estimates in the kriging models, such problems require extensive sampling to correctly identify function level-sets. Performance on this function highlights an algorithm's ability to quickly rule out portions of the function.

4-Sin2D This task consisted of finding where four 2D sinusoids sum to -2. The sinusoids chosen for this problem were similar to those of the SimpleSin2D problem:

$$f_1(\theta_1, \theta_2) = \sin(4\theta_1) + \cos(2\theta_2) - \cos(3\theta_1)$$
$$f_2(\theta_1, \theta_2) = \sin(2\theta_2 - 2) + \cos(2\theta_1) - \cos(3\theta_1)$$
$$f_3(\theta_1, \theta_2) = \sin(3\theta_1\theta_2) + \cos(2\theta_1) + 1$$
$$f_4(\theta_1, \theta_2) = \cos(\theta_1\theta_2) - \sin(\theta_1\theta_2)$$

The resulting target function contains regions with both high and low derivatives near the specified threshold.

Classification accuracy results for the four tests are given in Table 1. variance-maxvarstraddle outperforms all of the other heuristics on each of the target functions. Unsurprisingly, the straddle-based heuristics beat the random and variance-weighted heuristics, as both the random and variance-weighted heuristics choose samples (roughly) uniformly throughout the parameter space, while the straddle-based heuristics focus on the level-set of interest. Additionally, the advantage of variance-maxvarstraddle over sequential-straddle grows as the number of observable functions increases, as the relative cost of a bad choice is increased. These results demonstrate that learning the models independently allows for better overall prediction.

One surprising result of our experimentation is that the sequential-straddle performs as well as the variance-straddle heuristic on the test functions which are sums of two observable functions. We believe that this result illustrates the fact that the variance-straddle heuristic is over estimating the importance of the variance component of the candidate points to the information gain of a point, while the fact that there are only two observable functions reduces the efficiency of the sequential-straddle heuristic only by a factor of two. The variance-straddle heuristic will be as likely to choose a candidate point where the predicted observable functions are moderate but equal, as it is to choose a point with a large predicted variance for one of the observable functions, and zero variance for the other observable functions. However, the second candidate has much more information than the first, as selecting the second candidate will give us the (approximately) exact value of the target function, while selecting the first will only reduce the overall variance by a moderate amount. On the 4-Sin2D task the variance-straddle heuristic is able to make use of the individual observable functions, but still does not

do as well as the variance-maxvarstraddle heuristic.

To illustrate the differences in sampling patterns between these heuristics, we plot the samples chosen for the observable functions (with squares, circles, triangles and x's, respectively) with the true (dashed) and predicted (solid) function level-sets for the 4-Sin2D task in Figure 2. The variance-maxvarstraddle heuristic is much better at picking points than the other two heuristics. Note that the variance-maxvarstraddle heuristic is able to learn that some regions of the space are poor by sampling just one of the observable functions; as such, its samples lie much closer to the target level-set. This reinforces our hypothesis that modeling the observable functions separately results in additional learning opportunities.

4. Joint Statistical Analyses

Now let us look at a concrete application of this sampling algorithm: joint statistical analyses. Let X_i be a random variable denoting a data source and x_i be a generic observation of X_i. For each data set, X_i, let m_i be a corresponding model of X_i given some $\theta \in \Theta$. We are interested in constructing a confidence region for the true value of the parameter, denoted $\theta^\star$, based on the observation that $X_i = x_i$ for each model / data set pair.

For a single data set, consider testing the hypothesis that $\theta^\star = \theta$ at level α for some arbitrary $\theta \in \Theta$. The associated acceptance region for the test, $\mathcal{A}_i(\theta)$, is the set of data values (model outputs) for which the test will not reject the hypothesis $\theta^\star = \theta$ for model m_i. Since we are interested in tests with significance level α, we require $P_\theta(X_i \in \mathcal{A}_i(\theta)) \geq 1 - \alpha$. We can then use $\mathcal{A}_i$ to construct a $1-\alpha$ confidence region, $\mathcal{C}_{\mathcal{A}_i}(x_i)$, for $\theta^\star$ based on the observed data x_i: $C_{\mathcal{A}_i}(x_i) = \{\theta \in \Theta | x_i \in \mathcal{A}_i(\theta)\}$.

We consider two approaches to combine the individual confidence tests above into joint confidence regions. In the first we create a statistical model which simultaneously considers all data sets. For instance, when performing an analysis on two data sets using χ^2 tests, we will have one χ^2 test for data set A and a second for data set B. Since the χ^2 test assumes that each of the data points have dependencies given by the covariance matrix, we can combine the two tests into a single χ^2 test of the form

$$\begin{bmatrix} \vec{x}_A - \vec{m}_A \\ \vec{x}_B - \vec{m}_B \end{bmatrix}^T \begin{bmatrix} \Sigma_A & \Sigma_{AB} \\ \Sigma_{AB} & \Sigma_B \end{bmatrix}^{-1} \begin{bmatrix} \vec{x}_A - \vec{m}_A \\ \vec{x}_B - \vec{m}_B \end{bmatrix} \sim \chi^2_{(a+b)}$$

where $m_\dagger, x_\dagger$ and $\Sigma_\dagger$ are the associated test model, observed data and observed covariance of data set $\dagger$ given some vector from the parameter space, a and b are the degrees of freedom of the tests associated with data sets A and B respectively, and Σ_{AB} is the covariance of the data points between data sets A and B. If data sets A and B are independent, then all elements of Σ_{AB} are zero and we can write the above expression as:

$$(\vec{x}_A - \vec{m}_A)^T \Sigma_A^{-1} (\vec{x}_A - \vec{m}_A) + (\vec{x}_B - \vec{m}_B)^T \Sigma_B^{-1} (\vec{x}_B - \vec{m}_B) \sim \chi^2_{(a+b)}.$$

That is, the target function is merely the sum of the two observable functions: the variance weighted sum of squares for both data sets.

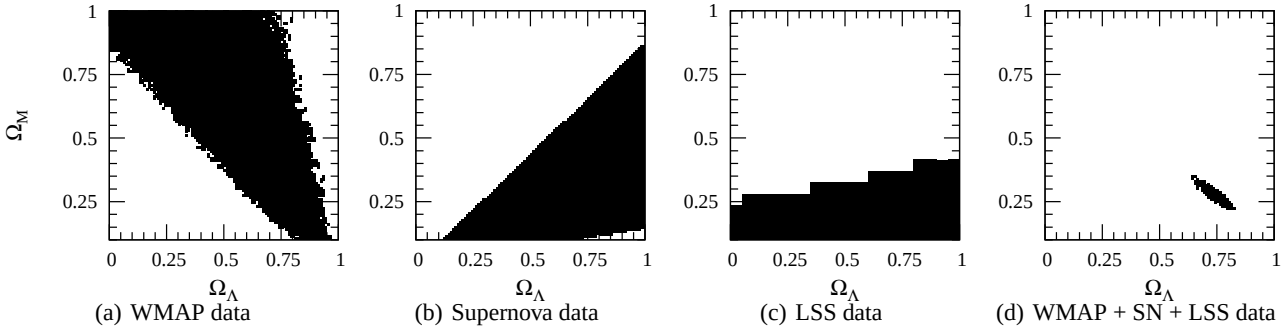
Another approach to performing simultaneous joint analysis is to combine the models' p-values. There are many ways to combine test procedures, including using Bonferroni corrections, the inverse normal method, and inverse logit methods (Hedges, 1985). A common method to combine p-values is Fisher's method (Fisher, 1932). Fisher noted that since a p-value, p_i, has a Uniform distribution, $-2\log(p_i)$ will have a $\chi^2_{(2)}$ distribution. Again, using the fact that the sum of independent χ^2 random variables has a χ^2 distribution, the test becomes: reject H_0 if and only if $-2\sum_{i=1}^{k} \log(p_i) \geq C$ where C is the critical value of a $\chi^2_{(2k)}$ distribution for some particular level α. Again, we see that the target function is the sum of observable functions.

Thus, given the models m_i and data sets X_i, we are interested in locating those $\theta \in \Theta$, such that the the resulting models m_i ($i = 1, \ldots, m$) are accepted by the chosen hypothesis test. This, in turn, reduces to testing whether the sum of a set of observable functions is below a specified threshold. Specifically, given a threshold t, we want to find the set of points, Θ', where the target function f is equal or less than the threshold: $\Theta' = \{\theta \in \Theta | f(\theta) \leq t\}$. However, note that we need only discover the boundary, $\mathcal{S} = \{\theta \in \Theta | f(\theta) = t\}$, as $\mathcal{S}$ implicitly defines Θ'. Therefore, using either χ^2 tests or Fisher's method, we can apply the algorithm described in Section 2 to locate the boundaries of the $1-\alpha$ confidence region.

5. Cosmological Data Example

To illustrate our algorithm and its application to joint statistical analyses, we show how it can be applied to an analysis of eight cosmological parameters that affect the formation and evolution of our universe using three data sets: the Comic Microwave Background (CMB) power spectrum as observed by Wilkinson Microwave Anisotropy Project (WMAP) (Bennett, C. L., et al., 2003), the Davis, T. M., et al. (2007) supernovae (SN) survey and a large scale structure survey (LSS) from Tegmark, M., et al. (2006).

While models for each of these data sets try to determine what the Universe is formed of and how it has evolved, they measure significantly different aspects of the Universe. The CMB data set records temperature fluctuations in the Uni-



(a) WMAP data (b) Supernova data (c) LSS data (d) WMAP + SN + LSS data

Figure 3. Comparison of the confidence regions derived for WMAP (a), supernova (b), and LSS (c) data sets with those derived using all three data sets together (d). Regions of solid color indicate values for $\Omega_{\rm M}$ and Ω_Λ for which some combination of the remaining parameters results in a model with probability greater than $1-\alpha$. The WMAP and LSS models are 7 parameter models, while the supernova is a 3 parameter model, and the combination model is an 8 parameter model.

verse just after the Big-Bang. The size and spatial proximity of these temperature fluctuations depict the types and rates of particle interactions in the early universe and hence characterize the formation of large scale structure (galaxies, clusters, walls and voids) in the current observable universe. Meanwhile, the supernovae data measures the expansion of the universe as a function of time, in order to constrain the total mass and eventual fate of the Universe. Finally, the large scale structure survey measures the degree of galaxy cluster clumping in order to determine the relative importance of dark matter and Baryonic (normal) matter. Combined, these data sets can be used to determine the age, composition and eventual fate of the Universe, as well as provide strong evidence for the presence of dark energy — a large-scale negative gravitational force.

In this analysis we look at an eight dimensional parameter space comprised of the optical depth (τ), dark energy mass fraction (Ω_Λ), total mass fraction ($\Omega_{\rm m}$), baryon density ($\omega_{\rm b}$), dark matter density ($\omega_{\rm dm}$), neutrino fraction (f_n), spectral index (n_s) and galaxy bias (b). The CMB model constrains the first seven parameters while the supernova model constrains $\omega_{\rm dm}$, $\omega_{\rm B}$, $\Omega_{\rm M}$ and Ω_Λ. The LSS model constrains all of the parameters except for τ.

Fisher's method was used to combine p-values from each of the three models. While for small p-values the log of the p-value goes to infinity, note that the algorithm is interested in determining where the sum of the p-values corresponds to the 95% quantile of a $\chi^2_{(6)}$ distribution. Since this results in $t \approx 12.6$, the algorithm has no incentive to select points which are expected to have near zero p-values.

Computing expected observations given parameter vectors is fast for the supernovae and large scale structure models, and hence we can quickly compute the p-values associated with these two models using χ^2 tests. However, computing the expected observations for the CMB data set is much more time consuming. Typically one employs a numerical solver, such as CMBFast to approximate the Boltzmann equation and yield the expected power spectrum.

To alleviate the problem posed by the computational costs of CMBFast, we initialize the Gaussian process model associated with the WMAP data using the one million p-values derived by Bryan, B., et al. (2005). Bryan, B., et al. (2005) uses confidence balls — a statistical procedure similar to χ^2 tests, generally with better inference properties — to map out the level-set associated with the 95% confidence region of the seven CMB parameters. Additional models were selected using the variance-maxvarstraddle heuristic with one small change: If the heuristic selects the observable function associated with the CMB data, we first compute the p-values associated with the supernova and large scale structure data sets to see if we can exclude the parameter vector without needing to run CMBFast. That is, we determine whether the sum of the log p-values from the supernovae and large scale structure data sets alone is larger than the threshold for the combined model. This modification allows us to reduce the number of CMBFast computations by about a factor of five. Using this modified variance-maxvarstraddle heuristic, we sampled roughly 1.5 million additional parameter vectors, about 300,000 of these points resulted in CMBFast runs. Note that 1.5 million parameter vectors corresponds to a grid with roughly six elements per side. Since the variance-based metrics sample the entire parameter space, their prediction performance is typically similar to this naive gird. Thus, using an active learning metric that focuses on the boundary that we are interested in (and ignores large parts of the parameter space which can be proved to be infeasible) significantly reduces the computational complexity of the algorithm.

In Figures 3(a)-3(c) we depict 95% confidence regions derived using only a single data set projected into the $\Omega_{\rm M}$ versus Ω_Λ space. Confidence regions are derived by binning the samples selected by the algorithm and including those bins in the confidence region which contain points where

$f \leq t$, resulting in the blockiness in the diagrams. The figures illistrate that the shapes of the 95% confidence regions for each of the data sources are quite different, validating our supposition that different observable functions can be used to efficiently reject parts of parameter space.

In Figure 3(d), depicts the 95% confidence region found using the joint analysis for all three data sets; one and two dimensional projections onto the other parameters can be found in Bryan (2007). It is clear that using the combination of all three data sets dramatically improves the inferences that can be made on the cosmological parameters' values. In particular, note that the derived confidence region is significantly smaller than what would have been obtained using a simple intersection. As a result, we cannot blindly combine the WMAP p-values of Bryan, B., et al. (2005) with p-values derived for the supernova and large scale structure data sets, as the surface of the combined target function is drastically different from the surfaces of each of the models independently. Specifically, all of the models in the Bryan, B., et al. (2005) data set can be rejected at the 95% confidence level by the supernova and large scale structure data. This is not surprising; the analysis of Bryan, B., et al. (2005) used only CMBFast one the WMAP data, and it is well known that CMBFast only loosly fits the WMAP data (Spergel, D. et al., 2003). Thus in order to accurately compute the 95% confidence regions of the joint model (using all three data sets), we must sample new models in the multiple model framework, as we did in Figure 3(d). Only then will we correctly learn the true level-set of the composite target function.

6. Conclusions

We have described the problem of learning a target function based on a set of related observable functions. This problem naturally arises in many situations including the joint analysis of multiple data sets which describe a single physical phenomenon. We have developed an algorithm for locating the level set of this target function while minimizing the number of experiments necessary. We described and showed how several different heuristics for choosing experiments from a set of candidates perform on synthetic target functions. Our experiments indicate that variance-maxvarstraddle outperforms both random and variance-weighted heuristics typically applied to active learning problems. Moreover, variance-maxvarstraddle is better than both the sequential- and variance-straddle heuristics, as it appears to better approximate the information gain of a candidate point.

Using the variance-maxvarstraddle heuristic, we were able to efficiently learn the level set of an eight dimensional surface. This level-set corresponds to the 95% confidence region of a joint analysis between three data sources. Using the CMB, supernovae and large scale structure data sets results in much tighter confidence regions than those obtained using only a single source of data, allowing for stronger scientific inferences. Standard ad hoc techniques for combining evidence, such as intersecting the data, or using weak priors do not result in such a significant reduction in the accepted parameter space.

Sparse Bayesian Nonparametric Regression

François Caron CARONFR@CS.UBC.CA
Arnaud Doucet ARNAUD@CS.UBC.CA

Abstract

One of the most common problems in machine learning and statistics consists of estimating the mean response $X\beta$ from a vector of observations y assuming $y = X\beta + \varepsilon$ where X is known, β is a vector of parameters of interest and ε a vector of stochastic errors. We are particularly interested here in the case where the dimension K of β is much higher than the dimension of y. We propose some flexible Bayesian models which can yield sparse estimates of β. We show that as $K \to \infty$ these models are closely related to a class of Lévy processes. Simulations demonstrate that our models outperform significantly a range of popular alternatives.

1. Introduction

Consider the following linear regression model

$$y = X\beta + \varepsilon \tag{1}$$

where $y \in \mathbb{R}^L$ is the observation, $\beta = (\beta_1, \ldots, \beta_K) \in \mathbb{R}^K$ is the vector of unknown parameters, X is an known $L \times K$ matrix. We will assume that ε follows a zero-mean normal distribution $\varepsilon \sim \mathcal{N}\left(0, \sigma^2 I_L\right)$ where I_L is the identity matrix of dimension L.

We do not impose here any restriction on L and K but we are particularly interested in the case where $K >> L$. This scenario is very common in many application domains. In such cases, we are interested in obtaining a sparse estimate of β; that is an estimate $\widehat{\beta} = (\widehat{\beta}_1, \ldots, \widehat{\beta}_K)$ such that only a subset of the components $\widehat{\beta}_k$ differ from zero. This might be for sake of variable selection (Tibshirani, 1996; Figueiredo, 2003; Griffin & Brown, 2007) or to decompose a signal over an overcomplete basis (Lewicki & Sejnowski, 2000; Chen et al., 2001).

Numerous models and algorithms have been proposed in the machine learning and statistics literature to address this problem including Bayesian stochastic search methods based on the 'spike and slab' prior (West, 2003), Lasso (Tibshirani, 1996), projection pursuit or the Relevance Vector Machine (RVM) (Tipping, 2001). We follow here a Bayesian approach where we set a prior distribution on β and we will primarily focus on the case where $\widehat{\beta}$ is the resulting Maximum a Posteriori (MAP) estimate or equivalently the Penalized Maximum Likelihood (PML) estimate. Such MAP/PML approaches have been discussed many times in the literature and include the Lasso (the corresponding prior being the Laplace distribution) (Tibshirani, 1996; Lewicki & Sejnowski, 2000; Girolami, 2001), the normal-Jeffreys (NJ) prior (Figueiredo, 2003) or the normal-exponential gamma prior (Griffin & Brown, 2007). Asymptotic theoretical properties of such PML estimates are discussed in (Fan & Li, 2001).

We propose here a class of prior distributions based on scale mixture of Gaussians for β. For a finite K, our prior models correspond to normal-gamma (NG) and normal-inverse Gaussian (NIG) models. This class of models includes as limiting cases both the popular Laplace and normal-Jeffreys priors but is more flexible. As $K \to \infty$, we show that the proposed priors are closely related to the variance gamma and normal-inverse Gaussian processes which are Lévy processes (Applebaum, 2004). In this respect, our models are somehow complementary to two recently proposed Bayesian nonparametric models: the Indian buffet process (Ghahramani et al., 2006) and the infinite gamma-Poisson process (Titsias, 2007). Under given conditions, the normal-gamma prior yields sparse MAP estimates $\widehat{\beta}$. The log-posterior distributions associated to these prior distributions are not convex but we propose an Expectation-Maximization (EM) algorithm to find modes of the posteriors and

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

a Markov Chain Monte Carlo (MCMC) algorithm to sample from them. We demonstrate through simulations that these Bayesian models outperform significantly a range of established procedures on a variety of applications.

The rest of the paper is organized as follows. In Section 2, we propose the NG and NIG models for β. We establish some properties of these models for K finite and in the asymptotic case where $K \to \infty$. We also relate our model to the Indian buffet process (Ghahramani et al., 2006) and the infinite gamma-Poisson process (Titsias, 2007). In Section 3, we establish conditions under which the MAP/PML estimate $\widehat{\beta}$ can enjoy sparsity properties. Section 4 presents an EM algorithm to find modes of the posterior distributions and a Gibbs sampling algorithm to sample from them. We demonstrate the performance of our models and algorithms in Section 5. Finally we discuss some extensions in Section 6.

2. Sparse Bayesian Nonparametric Models

We will consider models where the components β are independent and identically distributed

$$p(\beta) = \prod_{k=1}^{K} p(\beta_k)$$

and $p(\beta_k)$ is a scale mixture of Gaussians; that is

$$p(\beta_k) = \int \mathcal{N}(\beta_k; 0, \sigma_k^2) p(\sigma_k^2)\, d\sigma_k^2 \qquad (2)$$

where $\mathcal{N}(x; \mu, \sigma^2)$ denotes the Gaussian distribution of argument x, mean μ and variance σ^2. We propose two conjugate distributions for σ_k^2; namely the gamma and the inverse Gaussian distributions. The resulting marginal distribution for β_k belongs in both cases to the class of generalized hyperbolic distributions.

In the models presented here, the unknown scale parameters are random and integrated out so that the marginal priors on the regression coefficients are not Gaussian. This differs from the RVM (Tipping, 2001) where these parameters are unknown and estimated through maximum likelihood.

2.1. Normal-Gamma Model

2.1.1. Definition

Consider the following gamma prior distribution

$$\sigma_k^2 \sim \mathcal{G}(\frac{\alpha}{K}, \frac{\gamma^2}{2})$$

whose probability density function (pdf) $\mathcal{G}(\sigma_k^2; \frac{\alpha}{K}, \frac{\gamma^2}{2})$ is given by

$$\frac{(\frac{\gamma^2}{2})^{\frac{\alpha}{K}}}{\Gamma(\frac{\alpha}{K})} (\sigma_k^2)^{\frac{\alpha}{K}-1} \exp(-\frac{\gamma^2}{2}\sigma_k^2).$$

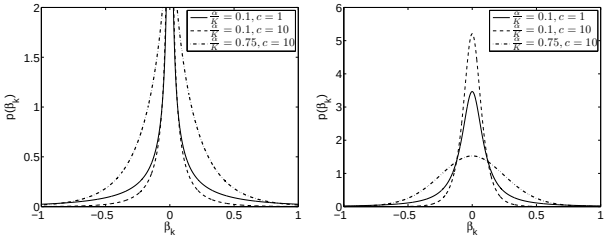
Following Eq. (2), the marginal pdf of β_k is given for $\beta_k \neq 0$ by

$$p(\beta_k) = \frac{\gamma^{\alpha/K+1/2}}{\sqrt{\pi} 2^{\alpha/K-1/2} \Gamma(\frac{\alpha}{K})} |\beta_k|^{\frac{\alpha}{K}-\frac{1}{2}} \mathcal{K}_{\frac{\alpha}{K}-\frac{1}{2}}(\gamma|\beta_k|) \qquad (3)$$

where $\mathcal{K}_\nu(\cdot)$ is the modified Bessel function of the second kind. We have

$$\lim_{\beta_k \to 0} p(\beta_k) = \begin{cases} \frac{\gamma}{2\sqrt{\pi}} \frac{\Gamma(\frac{\alpha}{K}-\frac{1}{2})}{\Gamma(\frac{\alpha}{K})} & \text{if } \frac{\alpha}{K} > \frac{1}{2} \\ \infty & \text{otherwise} \end{cases}$$

and the tails of this distribution decrease in $|\beta_k|^{\frac{\alpha}{K}-1} \exp(-\gamma|\beta_k|)$, see Figure 1(a). The parameters α and γ resp. control the shape and scale of the distribution. When $\alpha \to 0$, there is a high discrepancy between the values of σ_k^2, while when $\alpha \to \infty$, most of the values are equal.



(a) Normal-gamma (b) Normal-inverse Gaussian

Figure 1. Probability density functions of the NG and NIG for different values of the parameters.

This class of priors includes many standard priors. Indeed, Eq. (3) reduces to the Laplace prior when $\frac{\alpha}{K} = 1$ and we obtain the NJ prior when $\frac{\alpha}{K} \to 0$ and $\gamma \to 0$.

In Figure 2 some realizations of the process are given for different values $\alpha = 1, 5, 100$ and $\gamma^2/2 = \alpha$.

2.1.2. Properties

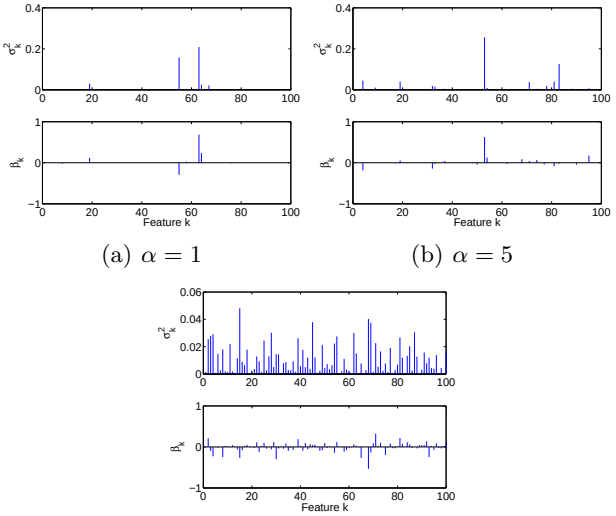
It follows from Eq. (3) that

$$\mathbb{E}[|\beta_k|] = \sqrt{\frac{4}{\pi\gamma^2}} \frac{\Gamma(\frac{\alpha}{K}+\frac{1}{2})}{\Gamma(\frac{\alpha}{K})}, \; \mathbb{E}[\beta_k^2] = \frac{2\alpha}{\gamma^2 K}$$

and we obtain

$$\lim_{K\to\infty} \mathbb{E}[\sum_{k=1}^{K} |\beta_k|] = \frac{2\alpha}{\gamma}, \; \mathbb{E}[\sum_{k=1}^{K} \beta_k^2] = \frac{2\alpha}{\gamma^2}.$$

Hence the sum of the terms remains bounded whatever being K.



(a) $\alpha = 1$ (b) $\alpha = 5$

(c) $\alpha = 100$

Figure 2. Realizations (top) $\left\{\sigma_k^2\right\}_{k=1,\ldots,K}$ and (bottom) $\{\beta_k\}_{k=1,\ldots,K}$ from the NG model for $\alpha = 1, 5, 100$.

Using properties of the gamma distribution, it is possible to relate β to a Lévy process known as the variance gamma process as $K \to \infty$. First consider a finite K. Let $\sigma^2_{(1)} \geq \sigma^2_{(2)} \geq \ldots \geq \sigma^2_{(K)}$ be the order statistics of the sequence $\sigma_1^2, \sigma_2^2, \ldots, \sigma_K^2$ and let $\pi_1, \ldots, \pi_K$ be random variables verifying the following (finite) stick-breaking construction

$$\pi_k = \zeta_k \prod_{j=1}^{k-1}(1-\zeta_j) \text{ with } \zeta_j \sim \mathcal{B}(1+\frac{\alpha}{K}, \alpha - \frac{k\alpha}{K}) \quad (4)$$

where $\mathcal{B}$ is the Beta distribution. Finally if $g \sim \mathcal{G}(\alpha, \frac{\gamma^2}{2})$ then we can check that the order statistics $\left(\sigma^2_{(k)}\right)$ follow the same distribution as the order statistics of $(g\pi_k)$. The characteristic function of β_k is given by

$$\Phi_{\beta_k}(u) = \frac{1}{\left(1 - \frac{iu}{\gamma}\right)^{\frac{\alpha}{K}}} \frac{1}{\left(1 + \frac{iu}{\gamma}\right)^{\frac{\alpha}{K}}}$$

and therefore

$$\beta_k \stackrel{d}{=} w_1 - w_2 \text{ where } w_1 \sim \mathcal{G}(\frac{\alpha}{K},\gamma) \text{ and } w_2 \sim \mathcal{G}(\frac{\alpha}{K},\gamma)$$

It follows that β_k can be written as the difference of two variables following a gamma distribution.

As $K \to \infty$, the order statistics $\left(\sigma^2_{(k)}\right)$ are the conic part of a gamma process with shape parameter α and scale parameter $\gamma^2/2$; see (Tsilevich et al., 2000) for details. In particular $\overline{\sigma}^2 = \left(\frac{\sigma^2_{(1)}}{\sum_k \sigma^2_{(k)}}, \frac{\sigma^2_{(2)}}{\sum_k \sigma^2_{(k)}}, \ldots\right)$ and $\sum_k \sigma^2_{(k)}$ are independent and respectively distributed according to $PD(\alpha)$ and $\mathcal{G}(\alpha, \gamma^2/2)$ where $PD(\alpha)$ is the Poisson-Dirichlet distribution of scale parameter α. It is well-known that this distribution can be recovered by the following (infinite) stick-breaking construction (Tsilevich et al., 2000) as if we set

$$\pi_k = \zeta_k \prod_{j=1}^{k-1}(1-\zeta_j) \text{ with } \zeta_j \sim \mathcal{B}(1, \alpha) \quad (5)$$

for any k then the order statistics $\left(\pi_{(k)}\right)$ are distributed from the Poisson-Dirichlet distribution.

The coefficients (β_k) are thus nothing but the weights (jumps) of the so-called variance gamma process which is a Brownian motion evaluated at times given by a gamma process (Applebaum, 2004; Madan & Seneta, 1990).

2.2. Normal-Inverse Gaussian Model

2.2.1. Definition

Consider the following inverse Gaussian prior distribution

$$\sigma_k^2 \sim \mathcal{IG}(\frac{\alpha}{K}, \gamma) \quad (6)$$

whose pdf $\mathcal{IG}(\sigma_k^2; \frac{\alpha}{K}, \gamma)$ is given by (Barndorff-Nielsen, 1997)

$$\frac{1}{\sqrt{2\pi}} \frac{\alpha}{K} \exp(\gamma \frac{\alpha}{K})(\sigma_k^2)^{-3/2} \exp(-\frac{1}{2}(\frac{\alpha^2}{K^2\sigma_k^2} + \gamma^2\sigma_k^2)) \quad (7)$$

Following Eq. (2), the marginal pdf of β_k is given

$$\frac{\alpha\gamma}{\pi K} \exp(\frac{\alpha\gamma}{K}) \left(\frac{\alpha^2}{K^2} + \beta_k^2\right)^{-\frac{1}{2}} \mathcal{K}_1\left(\gamma\sqrt{\frac{\alpha^2}{K^2} + \beta_k^2}\right) \quad (8)$$

and the tails of this distribution decrease in $|\beta_k|^{-3/2} \exp(-\gamma|\beta_k|)$. It is displayed in Figure 1(b). The parameters α and γ resp. control the shape and scale of the distribution. When $\alpha \to 0$, there is a high discrepancy between the values of σ_k^2, while when $\alpha \to \infty$, most of the values are equal. Some realizations of the model, for different values of α are represented in Figure 3.

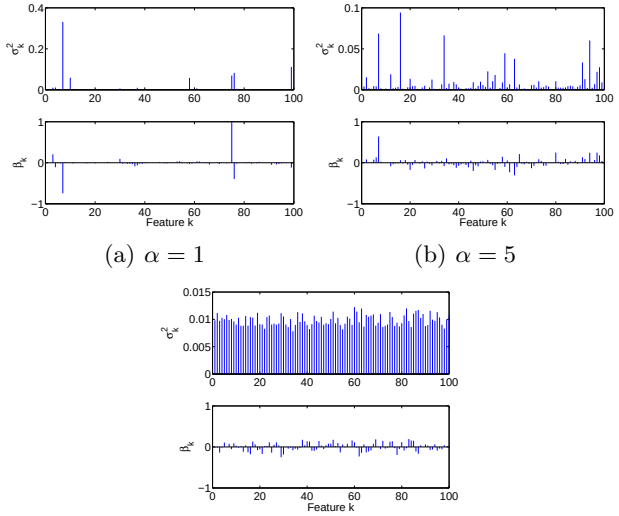
2.2.2. Properties

The moments are given

$$\mathbb{E}[|\beta_k|] = \frac{2\alpha}{K\pi} \exp(\frac{\gamma\alpha}{K}) \mathcal{K}_0(\frac{\alpha\gamma}{K}), \; \mathbb{E}[\beta_k^2] = \frac{\alpha}{K\gamma}$$

Therefore, as $K \to \infty$, the mean of sum of the absolute values is infinite while the sum of the square is $\frac{\alpha}{\gamma}$.

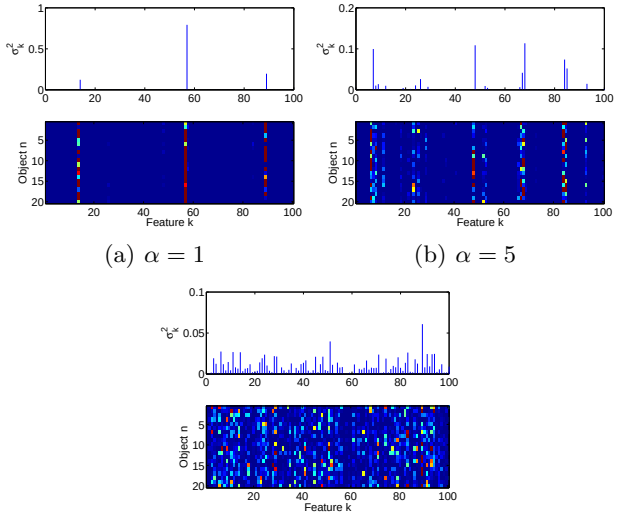
We can also establish in this case that the coefficients (β_k) tend to weights (jumps) of a normal-inverse Gaussian process (Barndorff-Nielsen, 1997).



(a) $\alpha = 1$ (b) $\alpha = 5$

(c) $\alpha = 100$

Figure 3. Realizations (top) $(\sigma_k^2)_{k=1,\dots,K}$ and (bottom) $(\beta_k)_{k=1,\dots,K}$ from the NIG model for $K = 100$, $N = 20$, $\alpha = 1, 10, 100$ and $\gamma = \alpha$.



(a) $\alpha = 1$ (b) $\alpha = 5$

(c) $\alpha = 100$

Figure 4. Realizations (top) $(\sigma_k^2)_{k=1,\dots,K}$ and (bottom) $(\beta_k^n)_{n=1,\dots,N,k=1,\dots,K}$ from the normal-gamma model for $K = 100$, $N = 20$, $\alpha = 1, 10, 100$ and $\gamma^2/2 = \alpha$. The lighter the colour, the larger $|\beta_k^n|$.

2.3. Extension

Consider now the case where we have N vectors of observations $\{y_n\}_{n=1}^N$ where $y_n \in \mathbb{R}^L$. We would like to model the fact that for a given k the random variables $\{\beta_k^n\}_{n=1}^N$ are statistically dependent and exchangeable. We consider the following hierarchical model

$$\sigma_k^2 \sim \mathcal{G}(\frac{\alpha}{K}, \frac{\gamma^2}{2}) \text{ or } \sigma_k^2 \sim \mathcal{IG}(\frac{\alpha}{K}, \gamma)$$

for $k = 1, \dots, K$ and

$$\beta_k^n \sim \mathcal{N}(0, \sigma_k^2)$$

for $n = 1, \dots, N$. Some realizations of the process for different values $\alpha = 1, 5, 100$ are represented in Figure 4.

In this respect, this work is complementary to two recently proposed Bayesian nonparametric models: the Indian buffet process (Ghahramani et al., 2006) and the infinite gamma-Poisson process (Titsias, 2007). In these two contributions, prior distributions over infinite matrices with integer-valued entries are defined. These models are constructed as the limits of finite-dimensional models based respectively on the beta-binomial and gamma-Poisson models. They enjoy the following property: while the number of non-zero entries of an (infinite) row is potentially infinite, the expected number of these entries is finite. These models are also closely related to the beta and gamma processes which are Lévy processes (Applebaum, 2004; Teh et al., 2007; Thibaux & Jordan, 2007). Our models could be interpreted as prior distributions over infinite matrices with real-valued entries. In our case, the number of non-zero entries of an (infinite) row is always infinite but we can have

$$\lim_{K\to\infty} \mathbb{E}\left[\sum_{k=1}^{K} |\beta_k^n|^\rho\right] < \infty \tag{9}$$

for $\rho = 1$ or $\rho = 2$. Morever for some values of $\frac{\alpha}{K}$ and γ we can also ensure that for any $x > 0$

$$\lim_{K\to\infty} \Pr\left(\exists k : |\beta_k^n| > x\right) > 0; \tag{10}$$

that is there is still a non-vanishing probability of having coefficients with large values as $K \to \infty$ despite Eq. (9).

The joint distribution is given by $p(\beta_{1:K}^{1:N}) = \prod_{k=1}^K p(\beta_k^{1:N})$ where for the NG model

$$p(\beta_k^{1:N}) \propto u_k^{\frac{\alpha}{K}-\frac{N}{2}} \mathcal{K}_{\frac{\alpha}{K}-\frac{N}{2}}(\gamma u_k)$$

and for the NIG model

$$p(\beta_k^{1:N}) \propto (q_k)^{-(N+1)/2} \mathcal{K}_{\frac{N+1}{2}}(\gamma q_k)$$

where

$$u_k = \sqrt{\sum\nolimits_{n=1}^{N} (\beta_k^n)^2}, \; q_k = \sqrt{\frac{\alpha^2}{K^2} + u_k^2} \tag{11}$$

3. Sparsity Properties

Further on we will also use the following notation for any random variable u

$$pen(u) \equiv \log(p(u))$$

Table 1. Penalizations and their derivatives for different prior distributions

	$pen(\beta_k^{1:N})$	$pen'(\beta_k^{1:N})$
Lasso ($N=1$)	$\gamma\lvert\beta_k\rvert$	γ
NJ	$N\log(u_k)$	N/u_k
NG	$(\frac{N}{2}-\frac{\alpha}{K})\log u_k$ $-\log \mathcal{K}_{\frac{\alpha}{K}-\frac{N}{2}}(\gamma u_k)$	$\frac{\gamma \mathcal{K}_{\frac{\alpha}{K}-\frac{N}{2}-1}(\gamma u_k)}{\mathcal{K}_{\frac{\alpha}{K}-\frac{N}{2}}(\gamma u_k)}$
NIG	$\frac{N+1}{2}\log(q_k)$ $-\log \mathcal{K}_{\frac{N+1}{2}}(\gamma q_k)$	$\frac{(N+1)u_k}{q_k^2}$ $+\frac{\gamma u_k}{q_k}\frac{\mathcal{K}_{\frac{N-1}{2}}(\gamma q_k)}{\mathcal{K}_{\frac{N+1}{2}}(\gamma q_k)}$

where '$\equiv$' denotes equal up to an additive constant independent of u. When computing the MAP/PML estimate for N data, we select

$$\widehat{\beta}^{1:N} = \arg\min_{\beta^{1:N}} \sum_{n=1}^{N} \frac{\|y_n - X\beta^n\|_2^2}{2\sigma^2} - \sum_{k=1}^{K} pen(\beta_k^{1:N}). \tag{12}$$

We give in Table 1 the penalizations $pen(\beta_k^{1:N})$ and their derivatives for different prior distributions as a function of u_k and q_k defined in Eq. (11).

When $\alpha/K = 1$, the NG prior is equal to the Laplace prior so its penalization reduces to the ℓ_1 penalization used in Lasso and basis pursuit (Tibshirani, 1996; Chen et al., 2001). When $\alpha/K \to 0$ and $c \to 0$ the prior is the NJ prior and the penalization reduces to $\log(|\beta_k|)$ which has been used in (Figueiredo, 2003). We display in Figure 5 the contours of constant value for various prior distributions when $N = 1$ and $K = 2$. For $\alpha/K < 1/2$, the MAP estimate (12) does not exist as the pdf (3) is unbounded. For other values of the parameters, a mode can dominate at zero whereas we are interested in the data driven turning point/local minimum (Griffin & Brown, 2007).

Consider now the case where the matrix X is orthogonal, $\sigma = 1$ and $N = 1$. The turning point and/or MAP/PML estimate is obtained by minimizing Eq. (12) which is equivalent to minimize componentwise

$$\frac{1}{2}(z_k - \beta_k)^2 + pen(\beta_k) \tag{13}$$

where $z = X^T y$. The first derivative of (13) is $sign(\beta_k)\left(|\beta_k| + pen'(|\beta_k|)\right) - z_k$. As stated in (Fan & Li, 2001, p. 1350), a sufficient condition for the estimate to be a thresholding rule is that the minimum of the function $|\beta_k| + pen'(|\beta_k|)$ is strictly positive. Plots of the function $|\beta_k| + pen'(|\beta_k|)$ are given in Figure 6 and the resulting thresholds corresponding to the argument minimizing (13) are presented in Figure 7. It follows that the normal-gamma prior is a thresholding rule for $\alpha/K \leq 1$ and yields sparse estimates. The normal-inverse Gaussian is not a thresholding rule as the derivative of the penalization is 0 when $\beta_k = 0$ whatever being the values of the parameters. However, from Figure 7(d), it is clear that it can yield "almost sparse" estimates; that is most components are such that $\left|\widehat{\beta}_k\right| \simeq 0$.

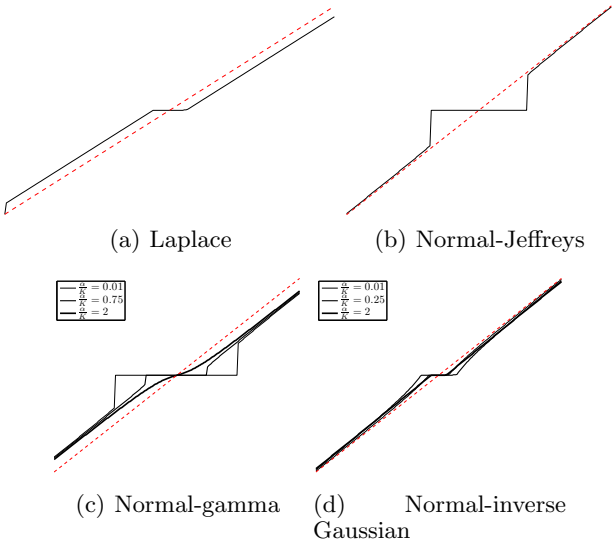
Figure 6. Plots of $|\beta_k| + pen'(|\beta_k|)$.

4. Algorithms

4.1. EM

The log-posterior in Eq. (12) is not concave but we can use the EM algorithm to find modes of it. The EM algorithm relies on the introduction of the missing data $\sigma_{1:K} = (\sigma_1, ..., \sigma_K)$. Conditional upon these missing data, the regression model is linear Gaussian and all the EM quantities can be easily computed in closed form; see for example (Figueiredo, 2003; Griffin & Brown, 2007). We have at iteration $i+1$ of the EM



(a) Laplace (b) Normal-Jeffreys

(c) Normal-gamma (d) Normal-inverse Gaussian

Figure 7. Thresholds for the different prior distributions.

$$\widehat{\beta}^{1:N}_{(i+1)} = \arg\max_{\beta_{1:N}} Q(\beta^{1:N}; \widehat{\beta}^{1:N}_{(i)})$$

where $Q(\beta^{1:N}; \widehat{\beta}^{1:N}_{(i)})$ is given by

$$\int \log(p(\beta^{1:N}|y_{1:N}, \sigma_{1:K})).p(\sigma_{1:K}|\widehat{\beta}^{1:N}_{(i)}, y_{1:N})d\sigma_{1:K}.$$

After a few calculations, we obtain

$$\widehat{\beta}^{n}_{(i+1)} = \left(\sigma^2 V_{(i)} + X^T X\right)^{-1} X^T y_n$$

with $V_{(i)} = diag(m_{1,(i)}, \ldots, m_{K,(i)})$ and $m_{k,(i)} = \left(\widehat{u}_{k,(i)}\right)^{-1} pen'(\widehat{u}_{k,(i)})$ where $\widehat{u}_{k,(i)} = \sqrt{\sum_{n=1}^{N}\left(\widehat{\beta}^{n}_{k,(i)}\right)^2}$, $pen'(\widehat{u}_{k,(i)}) = \frac{\partial pen(u_k)}{\partial u_k}\Big|_{\widehat{u}_{k,(i)}}$ (see Table 1).

4.2. MCMC

We can also easily sample from the posterior distribution $p(\beta^{1:N}|y_{1:N})$ by sampling from $p(\beta^{1:N}, \sigma^2_{1:K}|y_{1:N})$ using the Gibbs sampler. Indeed the full conditional distributions $p(\beta^{1:N}|\sigma_{1:K}, y_{1:N})$ and $p(\sigma^2_{1:K}|\beta^{1:N}, y_{1:N})$ are available in closed-form. The distribution $p(\beta^{1:N}|\sigma_{1:K}, y_{1:N})$ is a multivariate normal whereas we have $p(\sigma^2_{1:K}|\beta^{1:N}, y_{1:N}) = \prod_{k=1}^{K} p(\sigma^2_k|\beta^{1:N}_k)$. For the NG prior, we obtain

$$p(\sigma^2_k|\beta^{1:N}_k) = \frac{(\sigma^2_k)^{\frac{\alpha}{K}-\frac{N}{2}-1}\exp\left(-\frac{1}{2}\frac{u^2_k}{\sigma^2_k} - \gamma\sigma^2_k\right)}{2\left(\frac{u_k}{\gamma}\right)^{\frac{\alpha}{K}-\frac{N}{2}}\mathcal{K}_{\frac{\alpha}{K}-\frac{N}{2}}(\gamma u_k)}$$

which is a generalized inverse Gaussian distribution from which we can sample exactly. For the NIG distribution, we also obtain a generalized inverse Gaussian distribution.

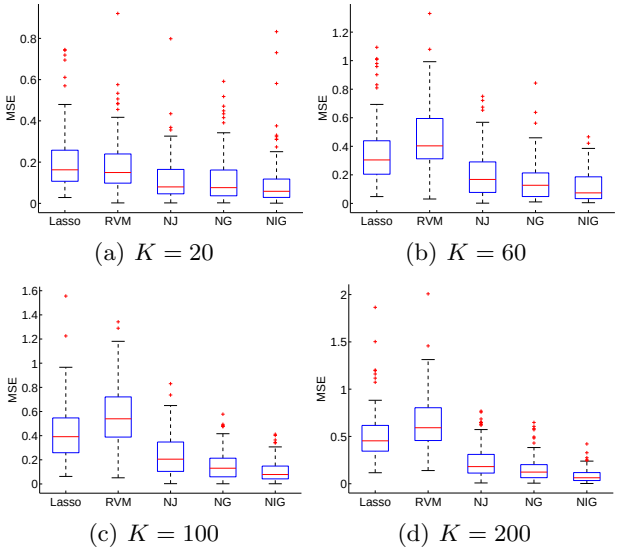
5. Applications

5.1. Simulated Data

In the following, we provide numerical comparisons between the Laplace (that is Lasso), the RVM, NJ, NG and NIG models. We simulate 100 datasets from (1) with $L = 50$ and $\sigma = 1$. The correlation between $X_{k,i}$ and $X_{k,j}$ is $\rho^{|i-j|}$ with $\rho = 0.5$. We set $\beta = (3\ 1.5\ 0\ 0\ 2\ 0\ 0\ldots)^T \in \mathbb{R}^K$ where the remaining components of the vector are set to zero. We consider the cases where $K = 20, 60, 100, 200$. Parameters of the Lasso, NG and NIG are estimated by 5-fold cross-validation, as described in (Tibshirani, 1996). The Lasso estimate is obtained with the Matlab implementation of the interior point method downloadable at http://www.stanford.edu/~boyd/l1_ls/. For the other priors, the estimate is obtained via 100 iterations of the EM algorithm. Box plots of the mean square error (MSE) are reported in Figure 8. These plots show that the performance of the estimators based on the NG and NIG priors outperform those of classical models in that case. In Figure 9 are represented the box plots of the number of estimated coefficients whose absolute value is below T, $T = 10^{-10}$ (the precision tuned for the Lasso estimate) and $T = 10^{-3}$, for $K = 200$. The true number of zeros in that case is 197. The NG outperforms the other models in identifying the zeros of the model. On the contrary, as the NIG estimate is not a thresholding rule, the median number of coefficients whose absolute value is below 10^{-10} for this model is zero. However, most of the coefficients have a very low absolute value, as the median of the coefficients with absolute value below 10^{-3} is equal to the true value 197 (see Figure 9(b)). Moreover, the estimator obtained by thresholding the coefficients whose absolute value is below 10^{-3} to zero yields very minor differences in terms of MSE.

5.2. Biscuit NIR Dataset

We consider the biscuits data which have been studied in (Griffin & Brown, 2007; West, 2003). The matrix X is composed of 300 (centered) NIR reflectance measurements from 70 biscuit dough pieces. The observations y are the percentage of fat, sucrose, flour and water associated to each piece. The objective here is to predict the level of each of the ingredients from the NIR reflectance measurements. The data are divided into a training dataset (39 measurements) and a test dataset (31 measurements). The fitted coefficients of fat and flour, using 5-fold cross-validation, are represented in Figure 10. The estimated spikes are consistent with the results obtained in (West, 2003; Griffin & Brown, 2007). In particular, both models detect



(a) $K = 20$ (b) $K = 60$

(c) $K = 100$ (d) $K = 200$

Figure 8. Box plots of the MSE associated to the simulated data.

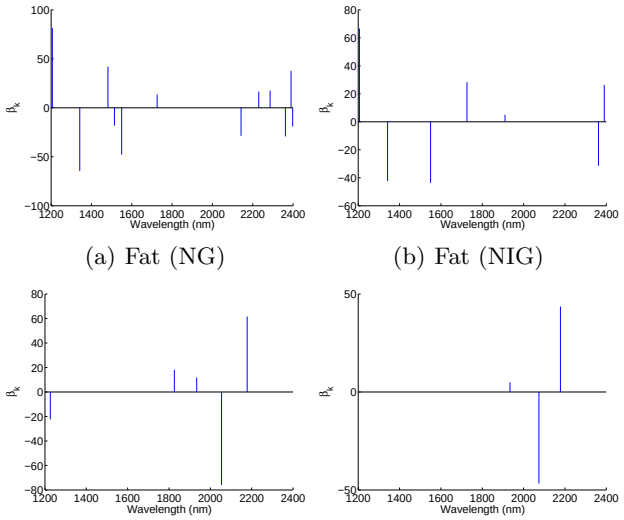
a spike at 1726nm, which lies in a region known for fat absorbance. The predicted observations versus the true observations are given in Figure 11 for the training and test datasets. The test data are well fitted by the estimated coefficients. MSE errors for the test dataset are reported in Table 2. The proposed models show better performances for flour and similar performances for fat.

6. Discussion

We have presented some flexible priors for linear regression based on the NG and NIG models. The NG prior yields sparse local maxima of the posterior distribution whereas the NIG prior yields "almost sparse" estimates; that is most of the coefficients are extremely close to zero. We have shown that asymptotically these models are closely related to the variance gamma process and the normal-inverse Gaussian process. Contrary to the NJ model or the RVM,



(a) Fat (NG) (b) Fat (NIG)

(c) Flour (NG) (d) Flour (NIG)

Figure 10. Coefficients estimated with a normal-gamma (left) and normal-inverse Gaussian (right) prior for fat (top) and flour (bottom) ingredients.

Table 2. MSE for biscuits NIR data

	Flour	Fat
NJ	9.93	0.56
RVM	6.48	0.56
NG	3.44	0.55
NIG	1.94	0.49

these models require specifying two hyperparameters. However, using a simple cross-validation procedure we have demonstrated that these models can perform significantly better that well-established procedures. In particular, the experimental performance of the NIG model are surprisingly good and deserve being further studied. The NG prior has been discussed in (Griffin & Brown, 2007). It was discarded because of its spike at zero and the flatness of the penalty for large values but no simulations were provided. They favour another model which relies on a cylinder parabolic function[1]. The NG prior has nonetheless interesting asymptotic properties in terms of Lévy processes and we have demonstrated its empirical performances. The NG, NIG and Laplace priors can also be considered as particular cases of generalized hyperbolic distributions. This class of distributions has been used in (Snoussi & Idier, 2006) for blind source separation.

The extension to (probit) classification is straightfor-

[1]The authors provide a link to a program to compute this function. Unfortunately, it is extremely slow. The resulting algorithm is at least one order of magnitude slower than our algorithms which rely on Bessel functions.

ward by adding latent variables corresponding to the regression function plus some normal noise. Computationally it only requires adding one line in the EM algorithm and one simulation step in the Gibbs sampler.

Abstract

In this paper we perform an empirical evaluation of supervised learning on high-dimensional data. We evaluate performance on three metrics: accuracy, AUC, and squared loss and study the effect of increasing dimensionality on the performance of the learning algorithms. Our findings are consistent with previous studies for problems of relatively low dimension, but suggest that as dimensionality increases the relative performance of the learning algorithms changes. To our surprise, the method that performs consistently well across all dimensions is random forests, followed by neural nets, boosted trees, and SVMs.

1. Introduction

In the last decade, the dimensionality of many machine learning problems has increased substantially. Much of this results from increased interest in learning from text and images. Some of the increase in dimensionality, however, results from the development of techniques such as SVMs and L_1 regularization that are practical and effective in high dimensions. These advances may make it unnecessary to restrict the feature set and thus promote building and learning from data sets that include as many features as possible. At the same time, memory and computational power have increased to support computing with large data sets.

Perhaps the best known empirical studies to examine the performance of different learning methods are STATLOG (King et al., 1995) and (Caruana & Niculescu-Mizil, 2006). STATLOG was a very thorough study, but did not include test problems with high dimensions and could not evaluate newer learning methods such as bagging, boosting, and kernel methods. More recently, (Caruana & Niculescu-Mizil, 2006) includes a number of new learning algorithms that emerged after the STATLOG project, but only examined performance on problems with low-to-medium dimension. One must question if the results of either of these studies apply to text data, biomedical data, link analysis data etc. where many attributes are highly correlated and there may be insufficient data to learn complex interactions among attributes. This paper attempts to address that question.

There are several limitations to the empirical study in (Caruana & Niculescu-Mizil, 2006). First, they performed all experiments using only 5000 training cases, despite the fact that much more labeled data was available for many problems. For one of the problems (COVTYPE) more than 500,000 labeled cases were available. Intentionally training using far less data than is naturally available on each problem makes the results somewhat contrived. Second, although they evaluated learning performance on eight performance metrics, examination of their results shows that there are strong correlations among the performance measures and examining this many metrics probably added little to the empirical comparison and may have led to a false impression of statistical confidence. Third, and perhaps most important, all of the data sets examined had low to medium dimensionality. The average dimensionality of the 11 data sets in their study was about 50 and the maximum dimensionality was only 200. Many modern learning problems have orders of magnitude higher dimensionality. Clearly learning methods can behave very differently when learning from high-dimensional data than when learning from low-dimensional data.

In the empirical study performed for this paper we complement the prior work by: 1) using the natural size training data that is available for each problem; 2) using just three important performance metrics: ac-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

curacy, area under the ROC curve (AUC), and squared loss; and 3) performing experiments on data with high to very high dimensionality (750-700K dimensions).

2. Methodology

2.1. Learning Algorithms

This section summarizes the algorithms and parameter settings we used. The reader should bear in mind that some learning algorithms are more efficient at handling large training sets and high-dimensional data than others. For an efficient algorithm we can afford to explore the parameter space more exhaustively than for an algorithm that does not scale well. But that's not unrealistic; a practitioner may prefer an efficient algorithm that is regarded as weak but which can be tuned well over an algorithm that might be better but where careful tuning would be intractable. Below we describe the implementations and parameter settings we used. An algorithm marked with an asterisk (e.g. **ALG***) denotes our own custom implementation designed to handle high-dimensional sparse data.

SVMs: We train linear SVMs using SVM^{perf} (Joachims, 2006) with error rate as the loss function. We vary the value of C by factors of ten from 10^{-9} to 10^5. For kernel SVMs we used LaSVM, an approximate SVM solver that uses stochastic gradient descent (Bordes et al., 2005), since traditional kernel SVM implementations simply cannot handle the amounts of data in some of our experiments. To guarantee a reasonable running time we train the SVM for 30 minutes for each parameter setting and use the gradient based strategy for the selection of examples. We use polynomial kernels of degree 2 and 3 and RBF kernels with width $\{0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1, 2\}$. We vary the value of C by factors of ten from 10^{-7} to 10^5.

ANN*: We train neural nets with gradient descent backpropagation, early stopping and no momentum (cf. section 5). We vary the number of hidden units $\{8, 16, 32\}$ and learning rate $\{10^{-4}, 10^{-3}, 10^{-2}\}$.

Logistic Regression (LR): We use the BBR package (Genkin et al., 2006) to train models with either L_1 or L_2 regularization. The regularization parameter is varied by factors of ten from 10^{-7} to 10^5.

Naive Bayes (NB*): Continuous attributes are modeled as coming from a normal distribution. We use smoothing and vary the number of unobserved values {0,0.1,0.2,0.5,1,2,5,10,20,50,100}.

KNN*: We use distance weighted KNN. We use the 1000 nearest neighbors weighted by a Gaussian kernel with 40 different kernel widths in the range $[0.1, 820]$. The distance between two points is a weighted euclidean distance where the weight of each feature is determined by its information gain.

Random Forests (RF*): We grow 500 trees and the size of the feature set considered at each split is $s/2, s, 2s, 4s$ or $8s$ where s is the square root of the number of attributes, as suggested in (Breiman, 2001).

Bagged Decision Trees(BAGDT*): We bag 100 ID3 trees. The same implementation is used for **boosted stumps (BSTST*)** and **boosted trees (BSTDT*)** but because full-size ID3 trees can't easily be boosted, we stop splitting when a node contains less than 50 examples. We do 2^{10} and 2^{15} iterations of boosting for trees and stumps respectively and use the validation set to pick the number of iterations from the set $\{2^i | i = 0, 1, ...15\}$.

Perceptrons (PRC*): We train voted perceptrons (Freund & Schapire, 1999) with 1,5,10,20 and 30 passes through the data. We also average 100 perceptrons each of which is obtained by a single pass through a permutation of the data.

With SVM, ANN, LR, KNN and PRC and datasets with continuous attributes we train both on raw and standardized data. This preprocessing can be thought of as one more parameter for these algorithms. To preserve sparsity, which is crucial for the implementations we use, we treat the mean of each feature as zero, compute the standard deviation, and divide by it.

2.2. Performance Metrics

To evaluate performance we use three metrics: accuracy (ACC), a threshold metric, squared error (RMS), a probability metric, and area under the ROC curve (AUC), an ordering metric. To standardize scores across different problems and metrics, we divide performances by the median performance observed on each problem for that metric. For squared error we also invert the scale so that larger numbers indicate better performance as with accuracy and AUC.

2.3. Calibration

The output of some learning algorithms such as ANN, logistic regression, bagged trees and random forests can be interpreted as the conditional probability of the class given the input. The common implementation of other methods such as SVM and boosting, however, are not designed to predict probabilities (Niculescu-Mizil & Caruana, 2005).

To overcome this, we use two different methods to map the predictions from each learning algorithm to

calibrated probabilities. The first is Isotonic Regression (Zadrozny & Elkan, 2002), a method which fits a non-parametric non-decreasing function to the predictions. The second calibration method is Platt's method (Platt, 1999) which fits a sigmoid to the predictions. (Niculescu-Mizil & Caruana, 2005) suggests that Platt's method outperforms isotonic regression when there is less than about 1000 points available to learn the calibration function, and that calibration can hurt predictions from methods such as ANN and logistic regression (Caruana & Niculescu-Mizil, 2006). We will revisit those findings later in the discussion. Finally, note that calibrating can affect metrics other than probability metrics such as squared loss. It can affect accuracy by changing the optimal threshold (for calibrated predictions the optimum threshold will be near 0.5) and Isotonic Regression can affect AUC by creating ties on calibration plateaus where prior to calibration there was a definite ordering.

To summarize our methodology, we optimize for each dataset and metric individually. For each algorithm and parameter setting we calibrate the predictions using isotonic regression, Platt's method, and the identity function (no calibration) and choose the parameter settings and calibration method that optimizes the performance metric on a validation set.

2.4. Data Sets

We compare the methods on 11 binary classification problems whose dimensionality ranges from 761 to 685569. The datasets are summarized in Table 1.

TIS[1] is from the Kent Ridge Bio-medical Data Repository. The problem is to find Translation Initiation Sites (TIS) at which translation from mRNA to proteins initiates. CRYST[2] is a protein crystallography diffraction pattern analysis dataset from the X6A beamline at Brookhaven National Laboratory. STURN and CALAM are ornithology datasets.[3] The task is to predict the appearance of two bird species: sturnella neglecta and calamospiza melanocorys. KDD98 is from the 1998 KDD-Cup. The task is to predict if a person donates money. This is the only dataset with missing values. We impute the mean for continuous features and treat missing nominal and boolean features as new values. DIGITS[4] is the MNIST database of handwritten digits by Cortes and LeCun. It was converted from a 10 class problem to a hard binary problem by treating digits less than 5 as one class and the rest as the other class. IMDB and CITE are link prediction datasets.[5] For IMDB each attribute represents an actor, director, etc. For CITE attributes are the authors of a paper in the CiteSeer digital library. For IMDB the task is to predict if Mel Blanc was involved in the film or television program and for CITE the task is to predict if J. Lee was a coauthor of the paper. We created SPAM from the TREC 2005 Spam Public Corpora. Features take binary values showing if a word appears in the document or not. Words that appear less than three times in the whole corpus were removed. Real-Sim (R-S) is a compilation of Usenet articles from four discussion groups: simulated auto racing, simulated aviation, real autos and real aviation.[6] The task is to distinguish real from simulated. DSE[7] is newswire text with annotated opinion expressions. The task is to find Subjective Expressions i.e. if a particular word expresses an opinion.

Table 1. Description of problems

Imdb	685569	84K	18.4K	84K	0.44

To split data into training, validation and test sets, if the data came with original splits for train and test sets (i.e. DIGITS, KDD98) we preserved those splits and created validation sets as 10% of the train set. If the data originally was split into folds, we merged some folds to create a training set, a validation set and a test set. (We did this because running these experiments is so costly that we could not afford to perform N-fold cross validation as this would make the experiments about N times more costly.) DSE came in 10 folds plus a development fold twice as big as other folds. We used the development fold as the validation set and merged the first 5 folds for the train set and the rest for the test set. CRYST came in 5 folds. One fold became the validation set, 2 folds were merged for training and the rest became the test set.

For the rest of the datasets we tried to balance be-

tween the following factors: (a) The test sets should be large enough so that differences between learning algorithms are apparent. (b) The test sets can be larger when the learning task is easy, but more data should be kept in the training set when the learning task is hard. (c) Some datasets would inevitably have more attributes than examples in the training set (IMDB, CITE, SPAM); for the rest we tried to put enough examples in the training set so that methods with small bias might learn something interesting. (d) The validation sets should be big enough so that parameter selection and calibration works well. In general we split the data so that we have around 50% in the training set and 50% in the test set. Validation data is drawn from the training set.

3. Results

Table 2 shows the performance of each learning method on each of the eleven problems. In the table, the problems are arranged left to right in order of increasing dimensionality. The table is broken into four sections. The top three sections report results for Accuracy (ACC), Squared Error (RMS), and Area under the ROC Curve (AUC). The bottom section is the average of the performance across these three metrics.

For each metric and problem, the performances have been standardized by dividing by the median performance observed for that problem and metric. Without standardization it is difficult to perform an unbiased comparison across different datasets and metrics. A score of one indicates that the method had typical performance on that problem and metric compared to the other learning methods. Scores above one indicate better than typical performance, while scores less than one indicate worse than typical performance. The scale for RMS has been reversed so that scores above one represent better than typical, i.e., lower, RMS.[8] The median performance for each problem and metric is included in the table to allow calculating raw performances from the standardized scores. The last column in the table is the average score across the eleven test problems. In each section of the table, learning algorithms are sorted by these average scores. The last column of the last section represents the average score across all problems and metrics.

Examining the results in the bottom section shows that on average across all problems and metrics, random forests have the highest overall performance. On average, they perform about 1% (1.0102) better than the typical model and about 0.6% (1.0102 vs. 1.0039) better than the next best method, ANN. The best methods overall are RF, ANN, boosted decision trees, and SVMs. The worst performing methods are Naive Bayes and perceptrons. On average, the top eight of ten methods fall within about 2% of each other. While it is not easy to achieve an additional 1% of performance at the top end of the scale, it is interesting that so many methods perform this similarly to each other on these high-dimensional problems.

If we examine the results for each of the metrics individually, we notice that the largest differences in performance among the different learning algorithms occur for AUC and the smallest differences occur for ACC. For accuracy, boosted decision trees are the best performing models followed by random forests. However, a closer examination of the table shows that boosted trees do better in accuracy mostly because of their excellent performance on the datasets with relatively low dimensionality. Comparing boosted trees with random forests in the left part of the table we see that random forests outperform boosted trees only on the TIS dataset. The situation is reversed on the right part of the table where boosted trees outperform random forests only on the CITE dataset. As dimensionality increases, we expect boosted trees to fall behind random forests.

In RMS, random forests are marginally better than boosted trees. This is confirmed by a bootstrap analysis (cf. Section 4): random forests have 33% and 35% chance of ranking 1st and 2nd respectively, while for boosted trees the corresponding probabilities are 31% and 21%. However, in AUC random forests are clear winners followed by, somewhat surprisingly, KNN.

Interestingly, although ANN is the 2nd best method overall in the bottom of the table, is does not perform 1st or 2nd for any of the individual metrics in the top of the table. It is 2nd overall only because ANNs consistently yield very good, though perhaps not exceptional, performance on all metrics.

A fact that is not apparent from the table is that calibration with isotonic regression works better than calibrating with Platt's method, or no calibration, on most problems and thus was used for almost all of the results reported in the table. Since our validation sets always are larger than 1000 examples, this confirms the findings in (Niculescu-Mizil & Caruana, 2005) that isotonic regression is preferred with large validation sets.

[8] This is different and simpler than the normalized scores used in (Caruana & Niculescu-Mizil, 2006). We have experimented with several ways of standardizing scores and the results change little with different methods. The learning methods that rank at the top (and the bottom) are least affected by the exact standardization method.

3.1. Effect of Dimensionality

In this section we attempt to show the trends in performance as a function of dimensionality. In Figure 1 the x-axis shows dimensionality on a log scale. The y-axis is the *cumulative* score of each learning method on problems of increasing dimensionality. The score is the average across the three standardized performance metrics where standardization is done by subtracting the median performance on each problem.[9] Subtracting median performance means that scores above (below) zero indicate better (worse) than typical performance. The score accumulation is done left-to-right on problems of increasing dimensionality. A line that tends to slope upwards (downwards) signifies a method that performs better (worse) on average compared to other methods as dimensionality increases. A horizontal line suggests typical performance across problems of different dimensionality. Naive Bayes is excluded from the graph because it falls far below the other methods. Caution must be used when interpreting cumulative score plots. Due to the order in which scores are aggregated, vertical displacement through much of the graph is significantly affected by the performance on problems of lower dimensionality. The end of the graph on the right, however, accumulates across all problems and thus does not favor problems of any dimensionality, The slope roughly corresponds to the average relative performance across dimensions. From the plot it is clear that boosted trees do very

[9]Here we subtract the median instead of dividing by it because we are accumulating relative performance. Standardization by subtracting the median yields similar rankings as dividing by the median.

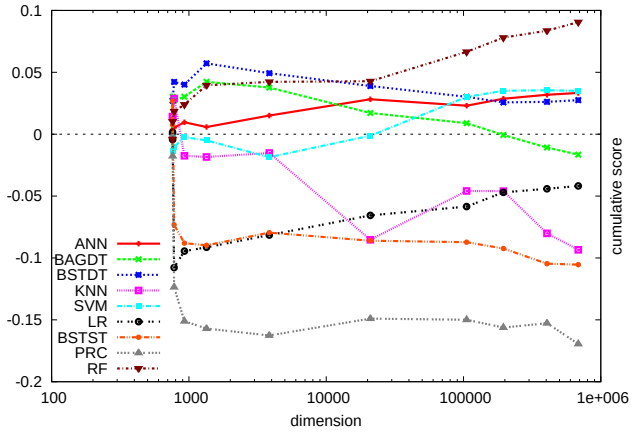

Figure 1. Cumulative standardized scores of each learning algorithm as a function of the dimension.

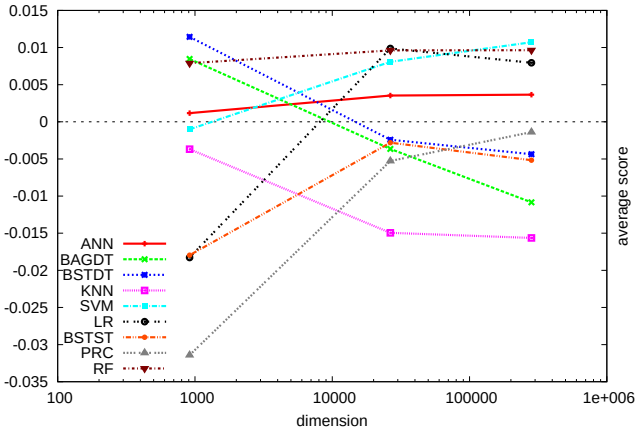

Figure 2. Moving average standardized scores of each learning algorithm as a function of the dimension.

well in modest dimensions, but lose ground to random forests, neural nets, and SVMs as dimensionality increases. Also, linear methods such as logistic regression begin to catch up as dimensionality increases.

Figure 2 shows the same results as Figure 1, but presented differently to avoid the complexity of accumulation. Here each point in the graph is the average performance of the 5 problems of lowest dimension (from 761 to 1344), the 5 problems of highest dimension (21K to 685K) and 5 problems of intermediate dimension (927 to 105K). Care must be used when interpreting this graph because each point averages over only 5 data sets. The results suggest that random forests overtake boosted trees. They are among the top performing methods for high-dimensional problems together with logistic regression and SVMs. Again we see that neural nets are consistently yielding above average performance even in very high dimension. Boosted trees, bagged trees, and KNN do not appear to cope well in very high dimensions. Boosted stumps, perceptrons, and Naive Bayes perform worse than the typical method regardless of dimension.

Figure 3 shows results similar to Figure 2 but only for different classes of SVMs: linear-only (L), kernel-only (K) and linear that can optimize accuracy or AUC (L+P) (Joachims, 2006). We also plot combinations of these (L+K and L+K+P) where the specific model that is best on the validation set is selected. The results suggest that the best overall performance with SVMs results from trying all possible SVMs (using the validation set to pick the best). Linear SVMs that can optimize accuracy or AUC outperform simple linear SVMs at modest dimensions, but have little effect when dimensionality is very high. Similarly, simple linear SVMs though not competitive with kernel SVMs at low dimensions, catch up as dimensionality increases.

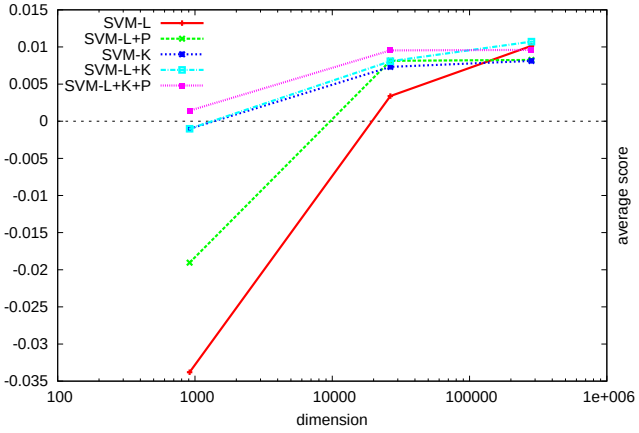

Figure 3. Moving average standardized scores for different SVM algorithms as a function of the dimension.

4. Bootstrap Analysis

We could not afford cross validation in these experiments because it would be too expensive. For some datasets and some methods, a single parameter setting can take days or weeks to run. Instead we used large test sets to make our estimates more reliable and adequately large validation sets to make sure that the parameters we select are good. However, without a statistical analysis, we cannot be sure that the differences we observe are not merely statistical fluctuation.

To help insure that our results would not change if we had selected datasets differently we did a bootstrap analysis similar to the one in (Caruana & Niculescu-Mizil, 2006). For a given metric we randomly select a bootstrap sample (sampling with replacement) from our 11 problems and then average the performance of each method across the problems in the bootstrap sample. Then we rank the methods. We repeat the bootstrap sampling 20,000 times and get 20,000 potentially different rankings of the learning methods.

Table 3 shows the results of the bootstrap analysis. Each entry in the table shows the percentage of time that each learning method ranks 1st, 2nd, 3rd, etc. on bootstrap samples of the datasets. Because of space limits, we only show results for average performance across the three metrics.

The bootstrap analysis suggests that random forests probably are the top performing method overall, with a 73% chance of ranking first, a 20% chance of ranking second, and less than a 8% chance of ranking below 2nd place. The ranks of other good methods, however, are less clear and there appears to be a three-way tie for 2nd place for boosted trees, ANNs, and SVMs.

5. Computational Challenges

Running this kind of experiment in high dimensions presents many computational challenges. In this section we outline a few of them.

In most high dimensional data features are sparse and the learning methods should take advantage of sparse vectors. For ANN, for example, when inputs are sparse, a lot of computation in the forward direction can be saved by using a matrix times sparse vector procedure. More savings happen when the weights are updated since the gradient of the error with respect to a weight going out of a unit with zero value vanishes. This is why our ANN implementation does not use momentum. If it did, all weights would have to be updated each iteration.

Another caveat is that for tree learning algorithms, indexing the data by feature instead of by example can speed up queries about which examples exhibit a particular feature. These queries are common during learning and one should consider this indexing scheme. Our random forest implementation indexes by feature.

Boosted decision trees on continuous data was the slowest of all methods. For bagged trees running times were better because we only grew 100 trees that can be grown in parallel. The same holds for random forests which have the added benefit that computation scales with the square root of dimensionality. Training ANNs was sometimes slow, mainly because applying some of the techniques in (Le Cun et al., 1998) would not preserve the sparsity of the data. For SVMs and logistic regression, we didn't have computational problems thanks to recent advances in scaling them (Genkin et al., 2006; Bordes et al., 2005; Joachims, 2006; Shalev-Shwartz et al., 2007). As a sanity check we compared the performance of the approximate kernel SVM solver with the exact SVM^{light} on some of our smallest problems and found no significant difference. Naive Bayes and perceptrons are among the fastest methods. KNN was sufficiently fast that we didn't have to use specialized data structures for nearest neighbor queries.

6. Related Work

Our work is most similar to (Caruana & Niculescu-Mizil, 2006). We already pointed out shortcomings in that study, but we also borrowed much from their methodology and tried to improve on it. STATLOG (King et al., 1995) was another comprehensive empirical study that was discussed in Section 1. A study by LeCun (LeCun et al., 1995) compares learning algorithms not only based on traditional performance metrics but also with respect to computational cost. Our study addresses this issue only qualitatively. Clearly, computational issues have to be taken into consideration in such large scale. A wide empirical comparison of voting algorithms such as bagging and boosting is conducted in (Bauer & Kohavi, 1999). The importance of evaluating performance on metrics such as AUC is discussed thoroughly in (Provost & Fawcett, 1997). The effect of different calibration methods is discussed in (Niculescu-Mizil & Caruana, 2005).

7. Discussion

Although there is substantial variability in performance across problems and metrics in our experiments, we can discern several interesting results. First, the results confirm the experiments in (Caruana & Niculescu-Mizil, 2006) where boosted decision trees perform exceptionally well when dimensionality is low. In this study boosted trees are the method of choice for up to about 4000 dimensions. Above that, random forests have the best overall performance. (Random forests were the 2nd best performing method in the previous study.) We suspect that the reason for this is that boosting trees is prone to overfitting and this becomes a serious problem in high dimensions. Random forests is better behaved in very high dimensions, it is easy to parallelize, scales efficiently to high dimensions and performs consistently well on all three metrics.

Non-linear methods do surprisingly well in high dimensions if model complexity can be controlled, e.g. by exploring the space of hypotheses from simple to complex (ANN), by margins (SVMs), or by basing some decisions on random projections (RF). Logistic regression and linear SVMs also gain in performance as dimensionality increases. Contrary to low dimensions, in high dimensions we have no evidence that linear SVMs can benefit from training procedures that directly op-

timize specific metrics such as AUC.

The results suggest that calibration never hurts and almost always helps on these problems. Even methods such as ANN and logistic regression benefit from calibration in most cases. We suspect that the reasons for this are the availability of more validation data for calibration than in previous studies and that high dimensional problems are harder in some sense.

Acknowledgments

We thank all the students who took CS678 at Cornell in the spring of 2007 and helped with this study. We especially thank Sergei Fotin, Michael Friedman, Myle Ott and Raghu Ramanujan who implemented KNN, ANNs, Random Forests and Boosted Trees respectively. We also thank Alec Berntson Eric Breck and Art Munson for providing the crystallography, DSE and ornithology datasets respectively. Art also put together the calibration procedures. Finally, we thank the 3 anonymous reviewers for their helpful comments. This work was supported in part by NSF Awards 0412930 and 0412894.

Abstract

Recent developments in programmable, highly parallel Graphics Processing Units (GPUs) have enabled high performance implementations of machine learning algorithms. We describe a solver for Support Vector Machine training running on a GPU, using the Sequential Minimal Optimization algorithm and an adaptive first and second order working set selection heuristic, which achieves speedups of 9-35× over LIBSVM running on a traditional processor. We also present a GPU-based system for SVM classification which achieves speedups of 81-138× over LIBSVM (5-24× over our own CPU based SVM classifier).

1. Introduction

Driven by the capabilities and limitations of modern semiconductor manufacturing, the computing industry is currently undergoing a massive shift towards parallel computing (Asanović et al., 2006). This shift brings dramatically enhanced performance to those algorithms which can be adapted to parallel computers.

One set of such algorithms are those used to implement Support Vector Machines (Cortes & Vapnik, 1995). Thanks to their robust generalization performance, SVMs have found use in diverse classification tasks, such as image recognition, bioinformatics, and text processing. Yet, training Support Vector Machines and using them for classification remains very computationally intensive. Much research has been done to accelerate training time, such as Osuna's decomposition approach (Osuna et al., 1997), Platt's Sequential Minimal Optimization (SMO) algorithm (Platt, 1999), Joachims' SVM^{light} (Joachims, 1999), which introduced shrinking and kernel caching, , and the working set selection heuristics used by LIBSVM (Fan et al., 2005). Despite this research, SVM training time is still significant for large training sets.

In this paper, we show how Support Vector Machine training and classification can be adapted to a highly parallel, yet widely available and affordable computing platform: the graphics processor, or more specifically, the Nvidia GeForce 8800 GTX, and detail the performance gains achieved.

The organization of the paper is as follows. Section 2 describes the SVM training and classification problems briefly. Section 3 gives an overview of the architectural and programming features of the GPU. Section 4 presents the details of implementation of the parallel SMO approach on the GPU. Section 5 explains the implementation details of the SVM classification problem. We present our results in Section 6 and conclude in Section 7.

2. Support Vector Machines

We consider the standard two-class soft-margin SVM classification problem (C-SVM), which classifies a given data point $x \in \mathbb{R}^n$ by assigning a label $y \in \{-1, 1\}$.

2.1. SVM Training

Given a labeled training set consisting of a set of data points $x_i, i \in \{1, ..., l\}$ with their accompanying labels $y_i, i \in \{1, ..., l\}$, the SVM training problem can be written as the following Quadratic Program, where α_i is a set of weights, one for each training point, which are being optimized to determine the SVM classifier, C is a parameter which trades classifier generality for accuracy on the training set, and $Q_{ij} = y_i y_j \Phi(x_i, x_j)$,

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

where $\Phi(x_i, x_j)$ is a kernel function.

$$\begin{aligned} \max_{\alpha} \; & F(\alpha) = \sum_{i=1}^{l} \alpha_i - \frac{1}{2}\alpha^T Q \alpha \\ \text{subject to} \quad & 0 \leq \alpha_i \leq C, \; \forall i \in 1 \ldots l \\ & y^T \alpha = 0 \end{aligned} \tag{1}$$

We consider the standard kernel functions shown in table 1.

Table 1. Standard Kernel Functions

LINEAR	$\Phi(x_i, x_j) = x_i \cdot x_j$
POLYNOMIAL	$\Phi(x_i, x_j; a, r, d) = (a x_i \cdot x_j + r)^d$
GAUSSIAN	$\Phi(x_i, x_j; \gamma) = \exp\left\{-\gamma \lvert\lvert x_i - x_j \rvert\rvert^2\right\}$
SIGMOID	$\Phi(x_i, x_j; a, r) = \tanh(a x_i \cdot x_j + r)$

2.1.1. SMO Algorithm

The SVM Training problem can be solved by many methods, each with different parallelism implications. We have implemented the Sequential Minimal Optimization algorithm (Platt, 1999), with a hybrid working set selection heuristic making use of the first order heuristic proposed by (Keerthi et al., 2001) as well as the second order heuristic proposed by (Fan et al., 2005).

The SMO algorithm is a specialized optimization approach for the SVM quadratic program. It takes advantage of the sparse nature of the support vector problem and the simple nature of the constraints in the SVM QP to reduce each optimization step to its minimum form: updating two α_i weights. The bulk of the computation is then to update the Karush-Kuhn-Tucker optimality conditions for the remaining set of weights and then find the next two weights to update in the next iteration. This is repeated until convergence. We state this algorithm briefly, for reference purposes.

Algorithm 1 Sequential Minimal Optimization

Input: training data x_i, labels y_i, $\forall i \in \{1..l\}$
Initialize: $\alpha_i = 0$, $f_i = -y_i$, $\forall i \in \{1..l\}$,
Initialize: b_{high}, b_{low}, i_{high}, i_{low}
Update $\alpha_{i_{high}}$ and $\alpha_{i_{low}}$
repeat
  Update f_i, $\forall i \in \{1..l\}$
  Compute: b_{high}, i_{high}, b_{low}, i_{low}
  Update $\alpha_{i_{high}}$ and $\alpha_{i_{low}}$
until $b_{low} \leq b_{high} + 2\tau$

For the first iteration, we initialize $b_{high} = -1$, $i_{high} = \min\{i : y_i = 1\}$, $b_{low} = 1$, and $i_{low} = \min\{i : y_i = -1\}$.

During each iteration, once we have chosen i_{high} and i_{low}, we take the optimization step:

$$\alpha'_{i_{low}} = \alpha_{i_{low}} + y_{i_{low}}(b_{high} - b_{low})/\eta \tag{2}$$

$$\alpha'_{i_{high}} = \alpha_{i_{high}} + y_{i_{low}} y_{i_{high}} (\alpha_{i_{low}} - \alpha'_{i_{low}}) \tag{3}$$

where $\eta = \Phi(x_{i_{high}}, x_{i_{high}}) + \Phi(x_{i_{low}}, x_{i_{low}}) - 2\Phi(x_{i_{high}}, x_{i_{low}})$. To ensure that this update is feasible, $\alpha'_{i_{low}}$ and $\alpha'_{i_{high}}$ must be clipped to the valid range $0 \leq \alpha_i \leq C$.

The optimality conditions can be tracked through the vector $f_i = \sum_{j=1}^{l} \alpha_j y_j \Phi(x_i, x_j) - y_i$, which is constructed iteratively as the algorithm progresses. After each α update, f is updated for all points. This is one of the major computational steps of the algorithm, and is done as follows:

$$\begin{aligned} f'_i = f_i &+ (\alpha'_{i_{high}} - \alpha_{i_{high}}) y_{i_{high}} \Phi(x_{i_{high}}, x_i) \\ &+ (\alpha'_{i_{low}} - \alpha_{i_{low}}) y_{i_{low}} \Phi(x_{i_{low}}, x_i) \end{aligned} \tag{4}$$

In order to evaluate the optimality conditions, we define index sets:

$$\begin{aligned} I_{high} = &\{i : 0 < \alpha_i < C\} \cup \{i : y_i > 0, \alpha_i = 0\} \\ &\cup \{i : y_i < 0, \alpha_i = C\} \end{aligned} \tag{5}$$

$$\begin{aligned} I_{low} = &\{i : 0 < \alpha_i < C\} \cup \{i : y_i > 0, \alpha_i = C\} \\ &\cup \{i : y_i < 0, \alpha_i = 0\} \end{aligned} \tag{6}$$

Because of the approximate nature of the solution process, these index sets are computed to within a tolerance ϵ, e.g. $\{i : \epsilon < \alpha_i < (C - \epsilon)\}$.

We can then measure the optimality of our current solution by checking the optimality gap, which is the difference between $b_{high} = \min\{f_i : i \in I_{high}\}$, and $b_{low} = \max\{f_i : i \in I_{low}\}$. When $b_{low} \leq b_{high} + 2\tau$, we terminate the algorithm.

2.1.2. Working set selection

During each iteration, we need to choose i_{high} and i_{low}, which index the α weights which will be changed in the following optimization step. The first order heuristic from (Keerthi et al., 2001) chooses them as follows:

$$i_{high} = \arg\min\{f_i : i \in I_{high}\} \tag{7}$$

$$i_{low} = \arg\max\{f_i : i \in I_{low}\} \tag{8}$$

The second order heuristic from (Fan et al., 2005) chooses i_{high} and i_{low} to optimize the unconstrained SVM functional. An optimal approach to this problem would require examining $\binom{l}{2}$ candidate pairs, which would be computationally intractable. To simplify the problem, i_{high} is instead chosen as in the first order

heuristic, and then i_{low} is chosen to maximally improve the objective function while still guaranteeing progress towards the constrained optimum from problem (1). More explicitly:

$$i_{high} = \arg\min\{f_i : i \in I_{high}\} \quad (9)$$

$$i_{low} = \arg\max\{\Delta F_i(\alpha) : i \in I_{low}, f_{i_{high}} < f_i\} \quad (10)$$

After choosing i_{high}, we compute for all $i \in \{1..l\}$

$$\beta_i = f_{i_{high}} - f_i \quad (11)$$

$$\eta_i = \Phi(x_{i_{high}}, x_{i_{high}}) + \Phi(x_i, x_i) - 2\Phi(x_{i_{high}}, x_i) \quad (12)$$

$$\Delta F_i(\alpha) = \beta_i^2/\eta_i \quad (13)$$

We then find the maximum ΔF_i over all valid points ($i \in I_{low}$) for which we are guaranteed to progress towards the constrained optimum ($f_{i_{high}} < f_i$).

2.1.3. Adaptive heuristic

The second order heuristic utilizes more information from the SVM training problem, and so it generally reduces the number of iterations necessary during the solution process. However, it is more costly to compute. In our GPU implementation, the geometric mean of iteration time over our benchmark set using the second order heuristic increased by 1.9× compared to the first order heuristic. On some benchmarks, the total number of iterations decreased sufficiently to provide a significant speedup overall, but on others, the second order heuristic is counterproductive for our GPU implementation.

To overcome this problem, we implemented an adaptive heuristic that chooses between the two selection heuristics dynamically, with no input or tuning from the user. The adaptive heuristic periodically samples progress towards convergence as a function of wall-clock time using both heuristics, then chooses the more productive heuristic.

This sampling occurs every $l/10$ iterations, and during each sample, the heuristic under test is executed for two phases of 64 iterations each. The average optimality gap in each of these phases is computed, and then the rate of progress is estimated by dividing the change in the optimality gap over the two phases by the time it has taken to execute them. The same sampling process is then performed with the other heuristic, and the best heuristic is then used until the next sampling period.

2.2. SVM Classification

The SVM classification problem is as follows: for each data point z which should be classified, compute

$$\hat{z} = \operatorname{sgn}\left\{b + \sum_{i=1}^{l} y_i \alpha_i \Phi(x_i, z)\right\} \quad (14)$$

where $z \in \mathbb{R}^n$ is a point which needs to be classified, and all other variables remain as previously defined.

From the classification problem definition, it follows immediately that the decision surface is defined by referencing a subset of the training data, or more specifically, those training data points for which the corresponding $\alpha_i > 0$. Such points are called support vectors.

Generally, we classify not just one point, but a set of points. We exploit this for better performance, as explained in Section 5.

3. Graphics Processors

Graphics processors are currently transitioning from their initial role as specialized accelerators for triangle rasterization to general purpose engines for high throughput floating-point computation. Because they still service the large gaming industry, they are ubiquitous and relatively inexpensive.

GPU architectures are specialized for compute-intensive, memory-intensive, highly parallel computation, and therefore are designed such that more resources are devoted to data processing than caching or control flow. State of the art GPUs provide up to an order of magnitude more peak IEEE single-precision floating-point than their CPU counterparts. Additionally, GPUs have much more aggressive memory subsystems, typically endowed with more than 10x higher memory bandwidth than a CPU. Peak performance is usually impossible to achieve on general purpose applications, yet capturing even a fraction of peak performance yields significant speedup.

GPU performance is dependent on finding high degrees of parallelism: a typical computation running on the GPU must express thousands of threads in order to effectively use the hardware capabilities. As such, we consider it an example of future "many-core" processing (Asanović et al., 2006). Algorithms for machine learning applications will need to consider such parallelism in order to utilize many-core processors. Applications which do not express parallelism will not continue improving their performance when run on newer computing platforms at the rates we have enjoyed in the past. Therefore, finding large scale par-

allelism is important for compute performance in the future. Programming for GPUs is then indicative of the future many-core programming experience.

3.1. Nvidia GeForce 8800 GTX

In this project, we employ the NVIDIA GeForce 8800 GTX GPU, which is an instance of the G80 GPU architecture, and is a standard GPU widely available on the market. Pertinent facts about the GPU platform can be found in table 2. We refer the reader to the Nvidia CUDA reference manual for more details (Nvidia, 2007).

Table 2. Nvidia GeForce 8800 GTX Characteristics

# of stream processors	128
Peak general purpose IEEE SP	346 GFlops
Multiprocessor local store size	16 kB
Clock rate	1.35 GHz
Memory capacity	768 MB
Memory bandwidth	86.4 GB/s
CPU⟷GPU bandwidth	3.2 Gbit/s

3.2. CUDA

Nvidia provides a programming environment for its GPUs called the Compute Unified Device Architecture (CUDA). The user codes in annotated C++, accelerating compute intensive portions of the application by executing them on the GPU.

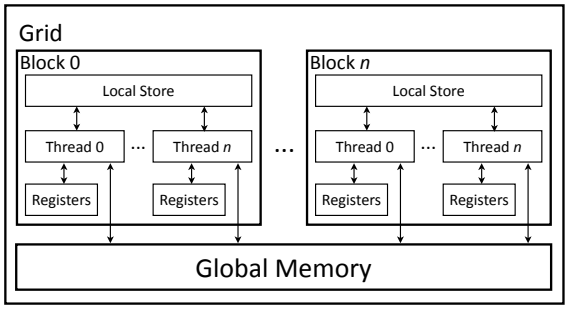

Figure 1. Logical organization of the GeForce 8800

Figure 1 illustrates how the GPU appears to the programmer. The programmer organizes the computation into grids, which are organized as a set of thread blocks. The grids run sequentially on the GPU, meaning that all computation in the grid must finish before another grid is invoked. As mentioned, grids contain thread blocks, which are batches of threads that execute together, sharing local memories and synchronizing at programmer specified barriers. A maximum of 512 threads can comprise a thread block, which puts a limit on the scope of synchronization and communication in the computation. However, enormous numbers of blocks can be launched in parallel in the grid, so that the total number of threads that can be launched in parallel is very high. In practice, we need a large number of thread blocks to ensure that the compute power of the GPU is efficiently utilized.

4. SVM Training Implementation

Since GPUs need a large number of threads to efficiently exploit parallelism, we create one thread for every data point in the training set. For the first phase of the computation, each thread computes f_i' from equation (4). We then apply a working set selection heuristic to select the next points which will be optimized. The details are explained in the following section.

4.1. Map Reduce

At least since the LISP programming language, programmers have been mapping independent computations onto partitioned data sets, using reduce operations to summarize the results. Recently, Google proposed a Map Reduce variant for processing large datasets on compute clusters (Dean & Ghemawat, 2004). This algorithmic pattern is very useful for extracting parallelism, since it is simple to understand, and maps well to parallel hardware, given the inherent parallelism in the map stage of the computation.

The Map Reduce pattern has been shown to be useful for many machine learning applications (Chu et al., 2007), and is a natural fit for our SVM training algorithm. For the first order heuristic, the computation of f_i' for all points is the map function, and the search for b_{low}, b_{high}, i_{low} and i_{high} is the reduction operation. For the second order heuristic, there are two Map Reduce stages: one to compute f_i', b_{high} and i_{high}, and another where the map stage computes ΔF_i for all points, while the reduce stage computes b_{low} and i_{low}.

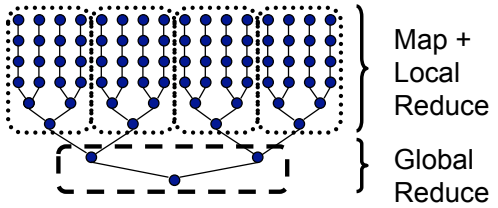

Figure 2. Structuring the Map Reduce

Because the CUDA programming model has strict lim-

itations on synchronization and communication between thread blocks, we organize the reductions in two phases, as shown in figure 2. The first phase does the map computation, as well as a local reduce within a thread block. The second phase finishes the global reduction. Each phase of this process is implemented as a separate call to the GPU.

4.2. Implementation Details

4.2.1. Caching

Since evaluating the kernel function $\Phi(\cdot)$ is the dominant part of the computation, it is useful to cache as much as possible from the matrix of kernel function evaluations $K_{ij} = \Phi(x_i, x_j)$ (Joachims, 1999). We compute rows of this matrix on the fly, as needed by the algorithm, and cache them in the available memory on the GPU.

When updating the vector f, we need access to two rows of K, since we have changed exactly two entries in α. In our system, the CPU checks to see which of these two rows, if any, are present in the cache. If a row is not present, the CPU voids the least recently used row of the cache, and assigns it to the new row which is needed. For the rows which hit in the cache, the GPU avoids doing the kernel evaluations. Otherwise, the GPU writes out the appropriate row or rows after computing the kernel values. When using the second order heuristic, the computation of ΔF references the row of K corresponding to i_{high}, which guarantees that the next update of f will have a cache hit for its access to the same row.

4.2.2. Data Movement

Programming the GPU requires manually copying data from the host computer to the GPU and vice versa, and it also requires manually copying data from the GPU's global memory to the fast local stores. As mentioned previously, if the cache does not contain a particular row of K corresponding to the point x_j, that row will need to be generated, which means that we need to compute $\Phi(x_i, x_j)\ \forall i \in 1..l$. Since the vector x_j is shared between all computations, we load it into the GPU's local store. This is key to performance, since accessing the local store is orders of magnitude faster than accessing the global memory.

4.3. Related Work

There have been previous attempts to parallelize the SVM training problem. The most similar to ours is (Cao et al., 2006), which parallelizes the SMO algorithm on a cluster of computers using MPI. Both our approach and their approach use the concurrency inherent in the KKT condition updates as the major source of parallelism. However, in terms of implementation, GPUs present a completely different model than clusters, and hence the amount of parallelism exploited, such as the number of threads, granularity of computation per thread, memory access patterns, and data partitioning are very different. We also implement more sophisticated working set selection heuristics.

Many other approaches for parallelizing SVM training have been presented. The cascade SVM (Graf et al., 2005) is another proposed method for parallelizing SVM training on clusters. It uses a method of divide and conquer to solve large SVM problems. (Zanni et al., 2006) parallelize the underlying QP solver using Parallel Gradient Projection Technique. Work has been done on using a parallel Interior Point Method for solving the SVM training problem (Wu et al., 2006). (Collobert et al., 2002) proposes a method where the several smaller SVMs are trained in a parallel fashion and their outputs weighted using a Artificial Neural Network. (Ferreira et al., 2006) implement a gradient based solution for SVM training, which relies on data parallelism in computing the gradient of the objective function for an unconstrained QP optimization at its core. Some of these techniques, for example, the training set decomposition approaches like the Cascade SVM are orthogonal to the work we describe, and could be applied to our solver. (Bottou et al., 2007) give an extensive overview of parallel SVM implementations. We implemented the parallel SMO training algorithm because of its relative simplicity, yet high performance and robust convergence characteristics.

5. SVM Classification Implementation

We approached the SVM classification problem by making use of Map Reduce computations as well as vendor supplied Basic Linear Algebra Subroutines - specifically, the Matrix Matrix Multiplication routine (SGEMM), which calculates $C' = \alpha AB + \beta C$, for matrices A, B, and C and scalars α and β. For the Linear, Polynomial, and Sigmoid kernels, calculating the classification value involves finding the dot product between all test points and the support vectors, which is done through SGEMM. For the Gaussian kernel, we use the simple identity $||x - y||^2 = x \cdot x + y \cdot y - 2x \cdot y$ to recast the computation into a Matrix Matrix multiplication, where the SGEMM computes $D_{ij} = -\gamma||z_i - x_j||^2 = 2\gamma(z_i \cdot x_j) - \gamma(z_i \cdot z_i + x_j \cdot x_j)$, for a set of unknown points z and a set of support vectors x. We then apply a map reduce computation to

combine the computed D values to get the final result.

Continuing the Gaussian example, the map function exponentiates D_{ij} element wise, multiplies each column of the resulting matrix by the appropriate $y_j\alpha_j$. The reduce function sums the rows of the matrix and adds b to obtain the final classification for each data point as given by equation (14). Other kernels require similar Map Reduce calculations to finish the classification.

6. Results

The SMO implementation on the GPU is compared with LIBSVM, as LIBSVM uses Sequential Minimal Optimization for SVM training. We used the Gaussian kernel in all of our experiments, since it is widely employed.

6.1. Training

We tested the performance of our GPU implementation versus LIBSVM on the datasets detailed in tables 3 and 4.

Table 3. Datasets - References and training parameters

Dataset	C	γ
Adult (Asuncion & Newman, 2007)	100	0.5
Web (Platt, 1999)	64	7.8125
MNIST (LeCun et al., 1998)	10	0.125
USPS (Hull, 1994)	10	2^{-8}
Forest (Asuncion & Newman, 2007)	10	0.125
Face (Rowley et al., 1998)	10	0.125

Table 4. Dataset Size

Dataset	# Points	# Dimensions
Adult	32,561	123
Web	49,749	300
MNIST	60,000	784
USPS	7,291	256
Forest	561,012	54
Face	6,977	381

The sizes of the datasets are given in table 4. References for the datasets used and the (C, γ) values used for SVM training are provided in table 3.

We ran LIBSVM on an Intel Core 2 Duo 2.66 GHz processor, and gave LIBSVM a cache size of 650 MB, which is larger than our GPU implementation was allowed. CPU-GPU communication overhead was included in the solver runtime, but file I/O time was excluded for both our solver and LIBSVM. Table 5 shows results from our solver. File I/O varies from 1.2 seconds for USPS to about 12 seconds for Forest dataset. The CPU - GPU data transfer overhead was also very low. The time taken to transfer the training data to the GPU and copy the results back was less than 0.6 seconds, even for our largest dataset (Forest).

Since any two solvers give slightly different answers on the same optimization problem, due to the inexact nature of the optimization process, we show the number of support vectors returned by the two solvers as well as how close the final values of b were for the GPU solver and LIBSVM, which were both run with the same tolerance value $\tau = 0.001$. As shown in the table, the deviation in number of support vectors between the two solvers is less than 2%, and the deviation in the offset b is always less than 0.1%. Our solver provides equivalent accuracy to the LIBSVM solver, which will be shown again in the classification results section.

Table 5. SVM Training Convergence Comparison

Dataset	Number of SVs		Difference in b (%)
	GPU Adaptive	LIBSVM	
Adult	18,674	19,058	-0.004
Web	35,220	35,232	-0.01
MNIST	43,730	43,756	-0.04
USPS	684	684	0.07
Forest	270,351	270,311	0.07
Face	3,313	3,322	0.01

Table 6 contains performance results for the two solvers. We see speedups in all cases from 9× to 35×. For reference, we have shown results for the solvers using both heuristics statically. Examining the data shows that the adaptive heuristic performs robustly, surpassing or coming close to the performance of the best static heuristic on all benchmarks.

6.2. Classification

Results for our classifier are presented in table 8. We achieve $81 - 138\times$ speedup over LibSVM on the datasets shown. As with the solver, file I/O times were excluded from overall runtime. File I/O times vary from 0.4 seconds for Adult dataset to about 6 seconds for MNIST dataset.

6.2.1. Optimizations to CPU based classifier

LIBSVM classifies data points serially. This effectively precludes data locality optimizations and produces significant slowdown. It also represents data in a sparse format, which can cause overhead as well.

To optimize the CPU classifier, we performed the following:

1. We changed the data structure used for storing

Table 6. SVM Training Results

the support vectors and test vectors from a sparse indexed set to a dense matrix.

2. To maximize performance, we used BLAS routines from the Intel Math Kernel Library to perform operations similar to those mentioned in Section 5.

3. Wherever possible, loops were parallelized (2-way for the dual-core machine) using OpenMP.

These optimizations improved the classification speed on the CPU by a factor of $3.4 - 28.3\times$. The speedup numbers for the different datasets are shown in table 8. It should be noted that the GPU version is better than the optimized CPU versions by a factor of $4.9 - 23.9\times$.

For some insight into these results, we note that the optimized CPU classifier performs best on problems with a large number of input space dimensions, which helps make the SVM classification process compute bound. For problems with a small number of input space dimensions, the SVM classification process is memory bound, meaning it is limited by memory bandwidth. Since the GPU has much higher memory bandwidth, as noted in section 3, it is even more attractive for such problems.

We tested the combined SVM training and classification process for accuracy by using the SVM classifier produced by the GPU solver with the GPU classification routine, and used the SVM classifier provided by LIBSVM's solver to perform classification with LIBSVM. Thus, the accuracy of the classification results presented in table 7 reflect the overall accuracy of the GPU solver and GPU classifier system. The results are identical, which shows that our GPU based SVM system is as accurate as traditional CPU based methods.

Table 7. Accuracy of GPU SVM classification vs. LIBSVM

Dataset	GPU Accuracy	LIBSVM Accuracy
Adult	6619/8000	6619/8000
Web	3920/4000	3920/4000
MNIST	2400/2500	2400/2500
USPS	1948/2007	1948/2007
Face	23665/24045	23665/24045

7. Conclusion

This work has demonstrated the utility of graphics processors for SVM classification and training. Training time is reduced by $9 - 35\times$, and classification time is reduced by $81 - 138\times$ compared to LIBSVM, or $5 - 24\times$ over our own CPU based SVM classifier. These kinds of performance improvements can change the scope of SVM problems which are routinely solved, increasing the applicability of SVMs to difficult classification problems. For example, training a classifier for an input data set with almost 600000 data points and 50 dimensions takes only 34 minutes on the GPU, compared with over 18 hours on the CPU.

The GPU is a very low cost way to achieve such high performance: the GeForce 8800 GTX fits into any modern desktop machine, and currently costs $300. Problems which used to require a compute cluster can now be solved on one's own desktop. New machine learning algorithms that can take advantage of this kind of performance, by expressing parallelism widely, will provide compelling benefits on future many-core platforms.

Fast Nearest Neighbor Retrieval for Bregman Divergences

Lawrence Cayton LCAYTON@CS.UCSD.EDU
Department of Computer Science and Engineering, University of California, San Diego, CA 92093

Abstract

We present a data structure enabling efficient nearest neighbor (NN) retrieval for bregman divergences. The family of bregman divergences includes many popular dissimilarity measures including KL-divergence (relative entropy), Mahalanobis distance, and Itakura-Saito divergence. These divergences present a challenge for efficient NN retrieval because they are not, in general, metrics, for which most NN data structures are designed. The data structure introduced in this work shares the same basic structure as the popular metric ball tree, but employs convexity properties of bregman divergences in place of the triangle inequality. Experiments demonstrate speedups over brute-force search of up to several orders of magnitude.

1. Introduction

Nearest neighbor (NN) search is a core primitive in machine learning, vision, signal processing, and elsewhere. Given a database X, a dissimilarity measure d, and a query q, the goal is to find the $x \in X$ minimizing $d(x, q)$. Brute-force search is often impractical given the size and dimensionality of modern data sets, so many data structures have been developed to accelerate NN retrieval.

Most retrieval data structures are for the ℓ_2 norm and, more generally, metrics. Though many dissimilarity measures are metrics, many are not. For example, the natural notion of dissimilarity between probability distributions is the KL-divergence (relative entropy), which is not a metric. It has been used to compare histograms in a wide variety of applications, including text analysis, image classification, and content-based image retrieval (Pereira et al., 1993; Puzicha et al., 1999; Rasiwasia et al., 2007). Because the KL-divergence does not satisfy the triangle inequality, very little of the research on NN retrieval structures applies.

The KL-divergence belongs to a broad family of dissimilarities called *bregman divergences*. Other examples include Mahalanobis distance, used *e.g.* in classification (Weinberger et al., 2006); the Itakura-Saito divergence, used in sound processing (Gray et al., 1980); and ℓ_2^2 distance. Bregman divergences present a challenge for fast NN retrieval since they need not be symmetric or satisfy the triangle inequality.

This paper introduces *bregman ball trees* (bbtrees), the first NN retrieval data structure for general bregman divergences. The data structure is a relative of the popular metric ball tree (Omohundro, 1989; Uhlmann, 1991; Moore, 2000). Since this data structure is built on the triangle inequality, the extension to bregman divergences is non-trivial.

A bbtree defines a hierarchical space decomposition based on bregman balls; retrieving a NN with the tree requires computing bounds on the bregman divergence from a query to these balls. We show that this divergence can be computed exactly with a simple bisection search that is very efficient. Since only bounds on the divergence are needed, we can often stop the search early using primal and dual function evaluations.

In the experiments, we show that the bbtree provides a substantial speedup—often orders of magnitude—over brute-force search.

2. Background

This section provides background on bregman divergences and nearest neighbor search.

2.1. Bregman Divergences

First we briefly overview bregman divergences.

Definition 1 (Bregman, 1967)**.** *Let f be a strictly convex differentiable function.* [1] *The bregman diver-*

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] Additional technical restrictions are typically put on

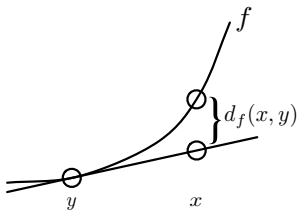

Figure 1. The bregman divergence between x and y.

gence based on f is

$$d_f(x,y) \equiv f(x) - f(y) - \langle \nabla f(y), x - y \rangle.$$

One can interpret the bregman divergence as the distance between a function and its first-order taylor expansion. In particular, $d_f(x,y)$ is the difference between $f(x)$ and the linear approximation of $f(x)$ centered at y; see figure 1. Since f is convex, $d_f(x,y)$ is always nonnegative.

Some standard bregman divergences and their base functions are listed in table 1.

A bregman divergence is typically used to assess similarity between two objects, much like a metric. But though metrics and bregman divergences are both used for similarity assessment, they do not share the same fundamental properties. Metrics satisfy three basic properties: non-negativity: $d(x,y) \geq 0$; symmetry: $d(x,y) = d(y,x)$; and, perhaps most importantly, the triangle inequality: $d(x,z) \leq d(x,y) + d(y,z)$. Bregman divergences are nonnegative, however they do not satisfy the triangle inequality (in general) and can be asymmetric.

Bregman divergences do satisfy a variety of geometric properties, a couple of which we will need later. The bregman divergence $d_f(x,y)$ is convex in x, but not necessarily in y. Define the bregman ball of radius R around μ as

$$B(\mu, R) \equiv \{x \ : \ d_f(x,\mu) \leq R\}.$$

Since $d_f(x,\mu)$ is convex in x, $B(\mu,R)$ is a convex set.

Another interesting property concerns means. For a set of points, the mean under a bregman divergence is well defined and, interestingly, is independent of the choice of divergence:

$$\mu_X \equiv \text{argmin}_\mu \sum_{x \in X} d_f(x,\mu) = \frac{1}{|X|} \sum_{x \in X} x.$$

This fact can be used to extend k-means to the family of bregman divergences (Banerjee et al., 2005).

f. In particular, f is assumed to be *Legendre*.

Table 1. Some standard bregman divergences.

	$f(x)$	$d_f(x,y)$
ℓ_2^2	$\frac{1}{2}\|x\|_2^2$	$\frac{1}{2}\|x-y\|_2^2$
KL	$\sum x_i \log x_i$	$\sum x_i \log \frac{x_i}{y_i}$
Mahalanobis	$\frac{1}{2}x^\top Q x$	$\frac{1}{2}(x-y)^\top Q (x-y)$
Itakura-Saito	$-\sum \log x_i$	$\sum \left(\frac{x_i}{y_i} - \log \frac{x_i}{y_i} - 1 \right)$

2.2. NN Search

Because of the tremendous practical and theoretical importance of nearest neighbor search in machine learning, computational geometry, databases, and elsewhere, many retrieval schemes have been developed to reduce the computational cost of finding NNs.

KD-trees (Friedman et al., 1977) are one of the earliest and most popular data structures for NN retrieval. The data structure and accompanying search algorithm provide a blueprint for a huge body of future work (including the present one). The tree defines a hierarchical space partition where each node defines an axis-aligned rectangle. The search algorithm is a simple branch and bound exploration of the tree. Though KD-trees are useful in many applications, their performance has been widely observed to degrade badly with the dimensionality of the database.

Metric ball trees (Omohundro, 1989; Uhlmann, 1991; Yianilos, 1993; Moore, 2000) extend the basic methodology behind KD-trees to metric spaces by using metric balls in place of rectangles. The search algorithm uses the triangle inequality to prune out nodes. They seem to scale with dimensionality better than KD-trees (Moore, 2000), though high-dimensional data remains very challenging. Some high-dimensional datasets are intrinsically low-dimensional; various retrieval schemes have been developed that scale with a notion of intrinsic dimensionality (Beygelzimer et al., 2006).

In many applications, an exact NN is not required; something nearby is good enough. This is especially true in machine learning applications, where there is typically a lot of noise and uncertainty. Thus many researchers have switched to the problem of *approximate* NN search. This relaxation led to some significant breakthroughs, perhaps the most important being locality sensitive hashing (Datar et al., 2004). Spill trees (Liu et al., 2004) are another data structure for approximate NN search and have exhibited very strong performance empirically.

The present paper appears to be the first to describe a general method for efficiently finding bregman NNs; however, some related problems have been examined. (Nielsen et al., 2007) explores the geometric properties of bregman voronoi diagrams. Voronoi diagrams are of course closely related to NN search, but do not lead to an efficient NN data structure beyond dimension 2. (Guha et al., 2007) contains results on *sketching* bregman (and other) divergences. Sketching is related to dimensionality reduction, which is the basis for many NN schemes.

We are aware of only one NN speedup scheme for KL-divergences (Spellman & Vemuri, 2005). The results in this paper are quite limited: experiments were conducted on only one dataset and the speedup is less than 3x. Moreover, there appears to be a significant technical flaw in the derivation of their data structure. In particular, they cite the pythagorean theorem as an *equality* for projection onto an arbitrary convex set, whereas it is actually an *inequality*.

3. Bregman Ball Trees

This section describes the bregman ball tree data structure. The data structure and search algorithms follow the same basic program used in KD-trees and metric trees; in place of rectangular cells or metric balls, the fundamental geometric object is a bregman ball.

A bbtree defines a hierarchical space partition based on bregman balls. The data structure is a binary tree where each node i is associated with a subset of the database $X_i \subset X$. Node i additionally defines a bregman ball $B(\mu_i, R_i)$ with center μ_i and radius R_i such that $X_i \subset B(\mu_i, R_i)$. Interior (non-leaf) nodes of tree have two child nodes l and r. The database points belonging to node i are split between child l and r; each point in X_i appears in exactly one of X_l or X_r.[2] Though X_l and X_r are disjoint, the balls $B(\mu_l, R_l)$ and $B(\mu_r, R_r)$ may overlap. The root node of the tree encapsulates the entire database. Each leaf covers a small fraction of the database; the set of all leaves cover the entirety.

3.1. Searching

This subsection describes how to retrieve a query's nearest neighbor with a bbtree. Throughout, $X = \{x_1, \ldots, x_n\}$ is the database, q is a query, and $d_f(\cdot, \cdot)$ is a (fixed) bregman divergence. The point we are searching for is the *left* NN

$$x_q \equiv \text{argmin}_{x \in X} d_f(x, q).$$

Finding the *right* NN ($\text{argmin}_{x \in X} d_f(q, x)$) is considered in section 5.

Branch and bound search locates x_q in the bbtree. First, the tree is descended; at each node, the search algorithm chooses the child for which $d_f(\mu, q)$ is smallest and *ignores* the sibling node (temporarily). Upon arriving at a leaf node i, the algorithm calculates $d_f(x, q)$ for all $x \in X_i$. The closest point is the candidate NN; call it x_c. Now the algorithm must traverse back up the tree and consider the previously ignored siblings. An ignored sibling j must be explored if

$$d_f(x_c, q) > \min_{x \in B(\mu_j, R_j)} d(x, q). \quad (1)$$

The algorithm computes the right side of (1); we come back that in a moment. If (1) holds, then node j and all of its children can be ignored since the NN cannot be found in that subtree. Otherwise, the subtree rooted at j must be explored. This algorithm is easily adjusted to return the k-nearest neighbors.

The algorithm hinges on the computation of (1)—the *bregman projection onto a bregman ball*. In the ℓ_2^2 (or arbitrary metric) case, the projection can be computed analytically with the triangle inequality. Since general bregman divergences do not satisfy this inequality, we need a different way to compute—or at least bound—the right side of (1). Computing this projection is the main technical contribution of this paper, so we discuss it separately in section 4.

3.2. Approximate Search

As we mentioned in section 2.2, many practical applications do not require an exact NN. This is especially true in machine learning applications, where there is typically a lot of noise and even the representation of points used is heuristic (*e.g.* selecting an appropriate kernel for an SVM often involves guesswork). This flexibility is fortunate, since exact NN retrieval methods rarely work well on high-dimensional data.

Following (Liu et al., 2004), a simple way to speed up the retrieval time of the bbtree is to simply stop after only a few leaves have been examined. This idea originates from the empirical observation that metric and KD-trees often locate a point very close to the NN quickly, then spend most of the execution time backtracking. We show empirically that the quality of the NN degrades gracefully as the number of leaves examined decreases. Even when the search procedure is stopped very early, it returns a solution that is among the nearest neighbors.

[2] The disjointedness of the two point sets is not essential.

3.3. Building

The performance of the search algorithm depends on how many nodes can be pruned; the more, the better. Intuitively, the balls of two siblings should be well-separated and compact. If the balls are well-separated, a query is likely to be much closer to one than the other. If the balls are compact, then the distance from a query to a ball will be a good approximation to the distance from a query to the nearest point within the ball. Thus at each level, we'd like to divide the points into two well-separated sets, each of which is compact. A natural way to do this is to use k-means, which has already been extended to bregman divergences (Banerjee et al., 2005).

The build algorithm proceeds from top down. Starting at the top, the algorithm runs k-means to partition the points into two clusters. This process is repeated recursively. The total build time is $O(n \log n)$. Clustering from the bottom-up might yield better results, but the $O(n^2 \log n)$ build time is impractical for large datasets.

4. Computing the Bound

Recall that the search procedure needs to determine if the bound

$$d_f(x_c, q) > \min_{x \in B(\mu, R)} d_f(x, q) \tag{2}$$

holds, where x_c is the current candidate NN. We first show that the right side can be computed to accuracy ϵ in only $O(\log \frac{1}{\epsilon})$ steps with a simple bisection search. Since we only actually need upper and lower bounds on the quantity, we then present a procedure that augments the bisection search with primal and dual bounds so that it can stop early.

The right of (2) is a convex program:

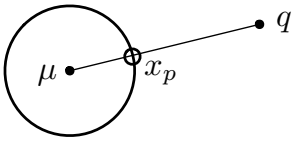
$$\begin{aligned} \min_{x} \quad & d_f(x, q) \\ \text{subject to:} \quad & d_f(x, \mu) \leq R. \end{aligned} \tag{P}$$

The search algorithm will need to solve (P) many times in the course of locating q's NN, so we need to be able to compute a solution very quickly.

Before considering the general case, let us pause to examine the ℓ_2^2 case. In this case, we can compute the projection x_p analytically:

$$x_p = \theta\mu + (1 - \theta)q,$$

where $\theta = \frac{\sqrt{2R}}{\|q - \mu\|}$.



What properties of this projection might extend to all of bregman divergences?

1. First, x_p lies on the line between q and μ; this drastically reduces the search space from a D-dimensional convex set to a one-dimensional line.
2. Second, x_p lies on the boundary of $B(\mu, R)$—*i.e* $d_f(x_p, \mu) = R$. Combined with property 1, this fact completely determines x_p: it is the point where the line between μ and q intersects the shell of $B(\mu, R)$.
3. Finally, since the ℓ_2^2 ball is spherically symmetric, we can compute this intersection analytically.

We prove that the first property is a special case of a fact that holds for all bregman divergences. Additionally, the second property generalizes to bregman divergences without change. The final property does not go through, so we will not be able to find a solution to (P) analytically.

Throughout, we use $q' \equiv \nabla f(q)$, $\mu' \equiv \nabla f(\mu)$, *etc.* to simplify notation. x_p denotes the optimal solution to (P).

Claim 2. *x_p' lies on the line between q' and μ'.*

Proof. The lagrange dual function of (P) is

$$\inf_x d_f(x, q) + \lambda(d_f(x, \mu) - R), \tag{3}$$

where $\lambda \geq 0$. Differentiating (3) with respect to x and setting it equal to 0, we get

$$\nabla f(x_p) - \nabla f(q) + \lambda \nabla f(x_p) - \lambda \nabla f(\mu) = 0.$$

We use the change of variable $\theta \equiv \frac{\lambda}{1+\lambda}$ and rearrange to arrive at

$$\nabla f(x_p) = \theta\mu' + (1 - \theta)q',$$

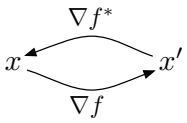
where $\theta \in [0, 1)$. □

Thus we see that property 1 of the ℓ_2^2 projection is a special case of a relationship between the gradients; it follows from claim 2 because $\nabla f(x) = x$ for the ℓ_2^2 divergence.

Since f is strictly convex, the gradient mapping is one-to-one. Moreover, the inverse mapping is given by the gradient of the *convex conjugate*, defined as

$$f^*(y) \equiv \sup_x \{\langle x, y\rangle - f(x)\}. \quad (4)$$

Symbolically:



Thus to solve (P), we can look for the optimal x' along $\theta\mu' + (1-\theta)q'$, and then apply ∇f^* to recover x_p.[3] To keep notation simple, we define

$$x'_\theta \equiv \theta\mu' + (1-\theta)q' \quad \text{and} \quad (5)$$
$$x_\theta \equiv \nabla f^*(x'_\theta). \quad (6)$$

Now onto the second property.

Claim 3. *$d_f(x_p, \mu) = R$—i.e. the projection lies on the boundary of $B(\mu, R)$.*

The claim follows from complementary slackness applied to (3). Claims 2 and 3 imply that finding the projection of q onto $B(\mu, R)$ is equivalent to

$$\begin{aligned} \text{find} \quad & \theta \\ \text{subject to:} \quad & d_f(x_\theta, \mu) = R \\ & \theta \in (0, 1] \\ & x_\theta = \nabla f^*(\theta\mu' + (1-\theta)q'). \end{aligned}$$

Fortunately, solving this program is simple.

Claim 4. *$d_f(x_\theta, \mu)$ is monotonic in θ.*

This claim follows from the convexity of f^*. Since $d_f(x_\theta, \mu)$ is monotonic, we can efficiently search for θ_p satisfying $d_f(x_{\theta_p}, \mu) = R$ using bisection search on θ. We summarize the result in the following theorem.

Theorem 5. *Suppose $\|\nabla^2 f^*\|_2$ is bounded around x'_p. Then a point x satisfying*

$$|d_f(x, q) - d_f(x_p, q)| \le \epsilon + O(\epsilon^2)$$

can be found in $O(\log 1/\epsilon)$ iterations. Each iteration requires one divergence evaluation and one gradient evaluation.

4.1. Stopping Early

Recall that the point of all this analysis is to evaluate whether

$$d_f(x_c, q) > \min_{x \in B(\mu,R)} d_f(x, q), \quad (7)$$

where x_c is the current candidate NN. If (7) holds, the node in question must be searched; otherwise it can be pruned. We can evaluate the right side of (7) exactly using the bisection method described previously, but an exact solution is not needed. Suppose we have bounds a and A satisfying

$$A \ge \min_{x \in B(\mu,R)} d_f(x, q) \ge a.$$

If $d_f(x_c, q) < a$, the node can be pruned; if $d_f(x_c, q) > A$, the node must be explored. We now describe upper and lower bounds that are computed at each step of the bisection search; the search proceeds until one of the two stopping conditions is met.

A lower bound is given by weak duality. The lagrange dual function is

$$\mathcal{L}(\theta) \equiv d_f(x_\theta, q) + \frac{\theta}{1-\theta}\Big(d_f(x_\theta, \mu) - R\Big). \quad (8)$$

By weak duality, for any $\theta \in [0, 1)$,

$$\mathcal{L}(\theta) \le \min_{x \in B(\mu,R)} d_f(x, q). \quad (9)$$

For the upper bound, we use the primal. At any θ satisfying $d_f(x_\theta, \mu) \le R$, we have

$$d_f(x_\theta, q) \ge \min_{x \in B(\mu,R)} d_f(x, q). \quad (10)$$

Let us now put all of the pieces together. We wish to evaluate whether (7) holds. The algorithm performs bisection search on θ, attempting to locate the θ satisfying $d_f(x_\theta, \mu) = R$. At step i the algorithm evaluates θ_i on two functions. First, it checks the lower bound bound given by the dual function $\mathcal{L}(\theta_i)$ defined in (8). If $\mathcal{L}(\theta_i) > d_f(x_c, q)$, then the node can be pruned. Otherwise, if $x_{\theta_i} \in B(\mu, R)$, we can update the upper bound. If $d_f(x_{\theta_i}, q) < d_f(x_c, q)$, then the node must be searched. Otherwise, neither bound holds, so the bisection search continues. See Algorithm 1 for pseudocode.

5. Left and Right NN

Since a bregman divergence can be asymmetric, it defines two NN problems:

- (lNN) return $\text{argmin}_{x \in X} d_f(x, q)$ and
- (rNN) return $\text{argmin}_{x \in X} d_f(q, x)$.

The bbtree data structure finds the left NN . We show that it can also be used to find the right NN.

[3] All of the base functions in table 1 have closed form conjugates.

Algorithm 1 CanPrune

Input: $\theta_l, \theta_r \in (0,1]$, $q, x_c, \mu \in \mathbb{R}^D$, $R \in \mathbb{R}$.
Set $\theta = \frac{\theta_l + \theta_r}{2}$.
Set $x_\theta = \nabla f^*(\theta\mu' + (1-\theta)q')$
if $\mathcal{L}(\theta) > d_f(x_c, q)$ **then**
  return YES
else if $x_\theta \in B(\mu, R)$ and $d_f(x_\theta, q) < d_f(x_c, q)$ **then**
  return NO
else if $d_f(x_\theta, \mu) > R$ **then**
  return CanPrune$(\theta_l, \theta, q, x_c, \mu)$
else if $d_f(x_\theta, \mu) < R$ **then**
  return CanPrune$(\theta, \theta_r, q, x_c, \mu)$
end if

Recall that the convex conjugate of f is defined as $f^*(y) \equiv \sup_x\{\langle x, y\rangle - f(x)\}$. The supremum is realized at a point x satisfying $\nabla f(x) = y$; thus

$$f^*(y') = \langle y, y'\rangle - f(y).$$

We use this identity to rewrite $d_f(\cdot,\cdot)$:

$$\begin{aligned} d_f(x,y) &= f(x) - f(y) - \langle y', x - y\rangle \\ &= f(x) + f^*(y') - \langle y', x\rangle \\ &= d_{f^*}(y', x'). \end{aligned}$$

This relationship provides a simple prescription for adapting the bbtree to the rNN problem: build a bbtree for the divergence d_{f^*} and the database $X' \equiv \{\nabla f(x_1), \ldots, \nabla f(x_n)\}$. On query q, $q' \equiv \nabla f(q)$ is computed and the bbtree finds $x' \in X'$ minimizing $d_{f^*}(x', q')$. The point x whose gradient is x' is then the rNN to q.

6. Experiments

We examine the performance benefit of using bbtrees for approximate and exact NN search. All experiments were conducted with a simple C implementation that is available from the author's website.

The results are for the KL-divergence. We chose to evaluate the bbtree for the KL-divergence because it is used widely in machine learning, text mining, and computer vision; moreover, very little is known about efficient NN retrieval for it. In contrast, there has been a tremendous amount of work for speeding up the ℓ_2^2 and Mahalanobis divergences—they both may be handled by standard metric trees and many other methods. Other bregman divergences appear much less often in applications. Still, examining the practical performance of bbtrees for these other bregman divergences is an interesting direction for future work.

We ran experiments on several challenging datasets.

- **rcv-D**. We used latent dirichlet allocation (LDA) (Blei et al., 2003) to generate topic histograms for 500k documents in the rcv1 corpus (Lewis et al., 2004). These histograms were generated by building a LDA model on a training set and then performing inference on 500k documents to generate their posterior dirichlet parameters. Suitably scaled, these parameters give a representation of the documents in the topic simplex (Blei et al., 2003). We generated data using this process for $D = 8, 16, \ldots, 256$ topics.
- **Corel histograms**. This dataset contains 60k color histograms generated from the Corel image dataset. Each histogram is 64-dimensional.
- **Semantic space**. This dataset is a 371-dimensional representation of 5000 images from the Corel Stock photo collection. Each image is represented as a distribution over 371 description keywords (Rasiwasia et al., 2007).
- **SIFT signatures**. This dataset contains 1111-dimensional representations of 10k images from the PASCAL 2007 dataset (Everingham et al., 2007). Each point is a histogram of quantized SIFT features as suggested in (Nowak et al., 2006).

Notice that most of these datasets are fairly high-dimensional.

We are mostly interested in approximate NN retrieval, since that is likely sufficient for machine learning applications. If the bbtree is stopped early, it is not guaranteed to return an exact NN, so we need a way to evaluate the quality of the point it returns. One natural evaluation metric is this: How many points from the database are closer to the query than the returned point? Call this value NC for "number closer". If NC is small compared to the size of the database, say 10 versus 100k, then it will likely share many properties with the true NN (*e.g.* class label).[4]

The results are shown in figure 2. These are strong results; it is shown that the bbtree is often orders of magnitude faster than brute-force search without a substantial degradation of quality. More analysis appears in the caption.

[4] A different evaluation criteria is the approximation ratio ϵ satisfying $d_f(x,q) \leq (1+\epsilon)d_f(x_q, q)$, where x_q is q's true NN. We did not use this measure because it is difficult to interpret. For example, suppose we find $\epsilon = .3$ approximate NNs from two different databases A and B. It could easily be the case that *all* points in A are 1.3-approximate NNs, whereas only the exact NN in database B is 1.3-approximate.

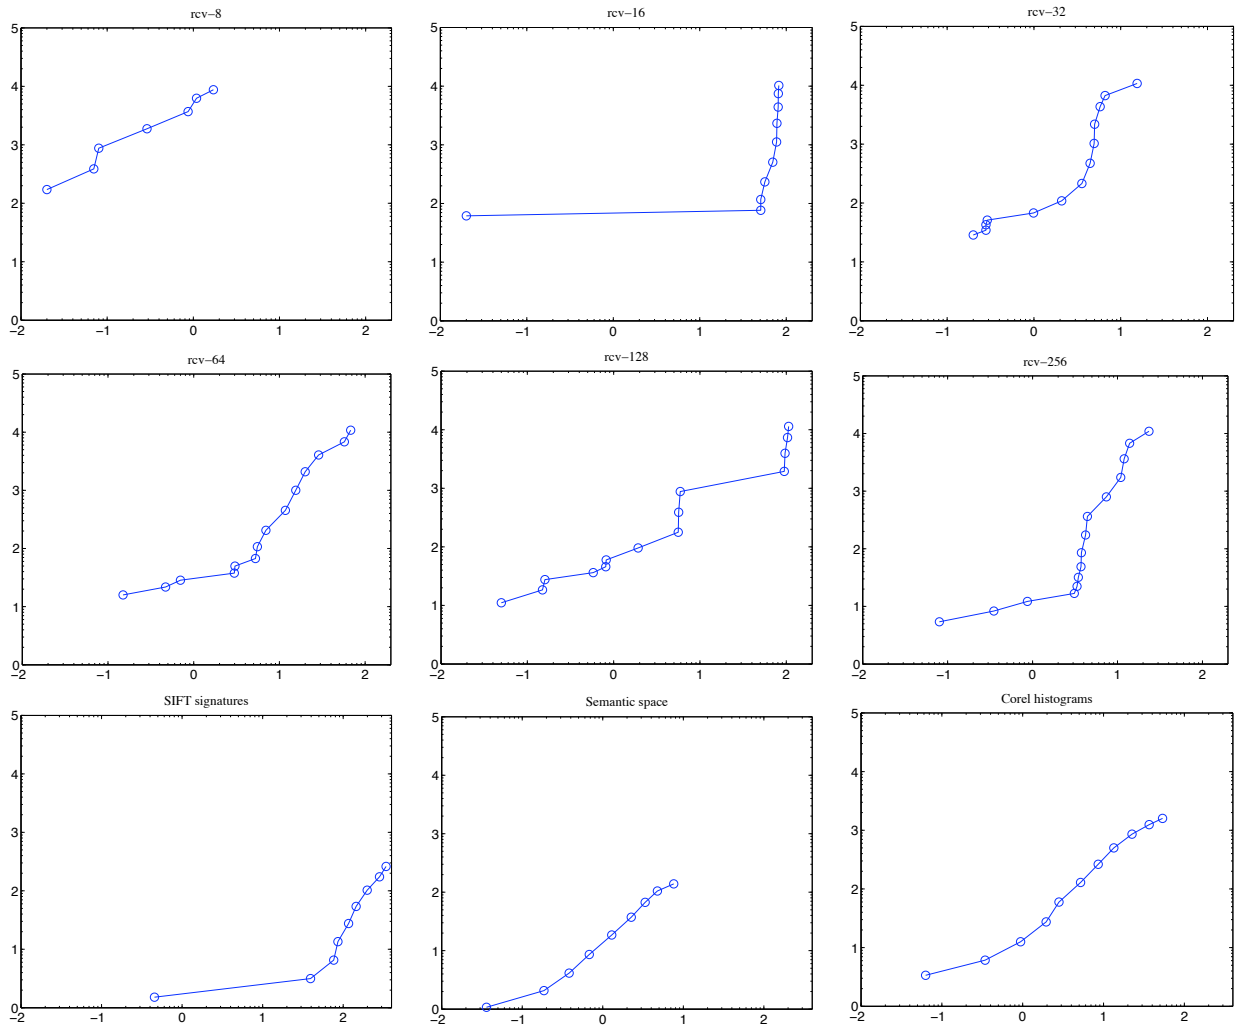


Figure 2. Log-log plots (base 10): y-axis is the exponent of the speedup over brute force search, x-axis is the exponent of the number of database points closer to the query than the reported NN. The y-axis ranges from 10^0 (no speedup) to 10^5. The x-axis ranges from 10^{-2} to 10^2. All results are averages over queries not in the database.

Consider the plot for rcv-128 (center). At $x = 10^0$, the bbtree is returning one of the two nearest neighbors (on average) out of 500k points at a 100x speedup over brute force search. At $x = 10^1$, the bbtree is returning one of the eleven nearest neighbors (again, out of 500k points) and yields three orders of magnitude speedup over brute force search.

The best results are achieved on the rcv-D datasets and the Corel histogram dataset. The improvements are less pronounced for the SIFT signature and Semantic space data, which may be a result of both the high dimensionality and small size of these two datasets. Even so, we are getting useful speedups on the semantic space dataset (10-100x speedup with small error). For the SIFT signatures, we are getting a 10x speedup while receiving NNs in the top 1%.

Table 2. Exact search

dataset	dimensionality	speedup
rcv-8	8	64.5
rcv-16	16	36.7
rcv-32	32	21.9
rcv-64	64	12.0
corel histograms	64	2.4
rcv-128	128	5.3
rcv-256	256	3.3
semantic space	371	1.0
SIFT signatures	1111	0.9

Finally, we consider exact NN retrieval. It is well known that finding a (guaranteed) exact NN in moderate to high-dimensional databases is very challenging. In particular, metric trees, KD-trees, and relatives typically afford a reasonable speedup in moderate dimensions, but the speedup diminishes with increasing dimensionality (Moore, 2000; Liu et al., 2004). When used for exact search, the bbtree reflects this basic pattern. Table 2 shows the results. The bbtree provides a substantial speedup on the moderate-dimensional databases (up through $D = 256$), but no speedup on the two databases of highest dimensionality.

7. Conclusion

In this paper, we introduced bregman ball trees and demonstrated their efficacy in NN search. The experiments demonstrated that bbtrees can speed up approximate NN retrieval for the KL-divergence by orders of magnitude over brute force search. There are many possible directions for future research. On the practical side, which ideas behind the many variants of metric trees might be useful for bbtrees? On the theoretical side, what is a good notion of intrinsic dimensionality for bregman divergences and can a practical data structure be designed around it?

Abstract

In high-dimensional classification problems it is infeasible to include enough training samples to cover the class regions densely. Irregularities in the resulting sparse sample distributions cause local classifiers such as Nearest Neighbors (NN) and kernel methods to have irregular decision boundaries. One solution is to "fill in the holes" by building a convex model of the region spanned by the training samples of each class and classifying examples based on their distances to these approximate models. Methods of this kind based on affine and convex hulls and bounding hyperspheres have already been studied. Here we propose a method based on the *bounding hyperdisk* of each class – the intersection of the affine hull and the smallest bounding hypersphere of its training samples. We argue that in many cases hyperdisks are preferable to affine and convex hulls and hyperspheres: they bound the classes more tightly than affine hulls or hyperspheres while avoiding much of the sample overfitting and computational complexity that is inherent in high-dimensional convex hulls. We show that the hyperdisk method can be kernelized to provide nonlinear classifiers based on non-Euclidean distance metrics. Experiments on several classification problems show promising results.

1. Introduction

Nearest neighbours (NN) – assigning the query to the class with the nearest training sample(s) under some suitable distance metric – is one of the simplest methods for multi-class classification. Asymptotically it makes at most twice as many errors as the optimal Bayes rule classifier, but this result assumes dense sampling which requires training sets that are exponentially large in the dimensionality of the underlying feature space class distributions. In high-dimensional problems such as text, gene or visual object classification, tractable training sets are necessarily much smaller than this, and the performance of NN can often be poor. The main problem is the sparse and irregular distribution of the training samples, which often leaves "holes" in the input space – regions that have few or no nearby training samples from the relevant class. Equivalently, local density estimates in high dimensions are intrinsically noisy because any region with a radius significantly smaller than that of the class has such a small volume relative to that of the class that it typically contains few or no samples. These effects make the inter-class decision boundaries of high dimensional NN and local kernel based methods erratic, thus leading to classification errors.

One way to circumvent this problem is to approximate each class with a point set that "fills in the holes" between the examples. In particular, any convex set containing the examples has this property. Several approximations of this kind have already been studied including the affine hulls, convex hulls, bounding hyperspheres and bounding hyperellipsoids of the examples (Gulmezoglu et al., 2001, Laaksonen, 1997, Nalbantov et al., 2007, Vincent & Bengio, 2001). Despite the simplicity of their geometry, such approximations are useful in high dimensions because in any case fine local details can not be resolved with practical numbers of samples. Queries are classified to the class whose convex approximation is closest to the query point – a convex nearest-point problem that can be solved reasonably efficiently with standard methods. This is equivalent to NN in which additional points are fantasized to fill in the set of each class.

Affine hulls (*i.e.* spanning linear subspaces that have

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

been shifted to pass through the centroid of the class) were first used for global classifiers of isolated words and hand-written digits in (Gulmezoglu et al., 2001, Laaksonen, 1997), giving good classification performance. Similarly, (Nalbantov et al., 2007) used convex hulls for global classifiers on some of the UCI and SlatLog problems, comparing these to Support Vector Machines (SVMs) both theoretically and empirically. Such global convex approximations may fail to capture the decision boundaries of classes with nonlinear boundaries and one can also build more local approximations, or even build a separate approximation for each query sample based on convex approximations of its k nearest neighbours from each class. Again the query is classified to the (locally) nearest hull. Although this is not immune to the hole problem, (Vincent & Bengio, 2001) reported significant improvements over traditional NN for affine and convex hull methods of this kind in handwritten digit classification. Another way to handle complex boundaries is via nonlinear mapping to a high-dimensional feature space (*e.g*. via a kernel) followed by a global convex set approximation of the kind described below.

Besides classification, approximations based on affine or convex hulls have also been used for dimensionality reduction. Mixtures of Principal Component Analyzers can be used to approximate nonlinear data manifolds under local linearity assumptions (Hinton et al., 1997). Locally Linear Embedding (Roweis & Saul, 2000) approximates the nonlinear structure of high-dimensional data by exploiting local affine/convex reconstructions. (Verbeek, 2006) combined several locally valid linear manifolds to obtain a global nonlinear mapping between the high-dimensional sample space and a low-dimensional manifold. In (Cevikalp et al., 2008), we proposed a margin based discriminative dimensionality reduction method based on convex models of classes.

The current paper presents a new convex approximation based classifier that models each class with its bounding hyperdisk – the intersection of the affine hull and the minimal bounding hypersphere of its training examples. Hyperdisks are attractive primitives because they maintain the stability of the affine hull and hypersphere methods while providing better localization of the training samples and hence potentially better discrimination. Convex hull approximations tend to be unrealistically tight (for practical training set sizes, classes typically extend considerably beyond the convex hull of the training samples) while affine hull and hypersphere ones tend to be too loose in complementary senses (one too "broad", the other too "deep"). The hyperdisk approach to some extent captures the best aspects of each method. It can be applied both globally and locally and it is simple enough to be expressible in terms of dot products and hence to allow kernelization.

The paper is organized as follows. In section 2 we recall the affine and convex hull based methods. Section 3 introduces the hyperdisk method. Section 4 describes our experiments and data sets. Finally, section 5 presents conclusions and future directions.

2. Background on Related Methods

2.1. Nearest Affine Hull (NAH) Classification

Let the training samples be $\mathbf{x}_{ci} \in \mathbb{R}^d$, where $c = 1, \ldots, C$ indexes the C classes and $i = 1, \ldots, N_c$ indexes the N_c samples of class c. We suppose that the affine hull of the samples from each class is a proper subset of $\mathbb{R}^d$ of dimension less than d (which certainly holds when $N_c \ll d$). The affine hull is the affine span of the training samples, *i.e*. the smallest affine subspace containing them

$$H_c^{\text{aff}} = \left\{ \mathbf{x} = \textstyle\sum_{i=1}^{N_c} \alpha_i \, \mathbf{x}_{ci} \;\middle|\; \sum_i \alpha_i = 1 \right\}. \qquad (1)$$

The affine hull gives a rather loose approximation to the class region because it does not constrain the position of the training points within the affine subspace. The distance from a query point $\mathbf{x}_q$ to an affine hull H_c^{aff} is the norm of the displacement from $\mathbf{x}_q$ to the closest point on the hull, which can be expressed as the orthogonal projection of $\mathbf{x}_q$ normal to the subspace (see, *e.g*., (Cevikalp et al., 2007) for derivations):

$$d(\mathbf{x}_q, H_c^{\text{aff}}) = \|(\mathbf{I} - \mathbf{P}_c)(\mathbf{x}_q - \boldsymbol{\mu}_c)\| = \|\mathbf{P}_c^{\perp} \mathbf{x}_q - \boldsymbol{\mu}_c^{\perp}\|. \quad (2)$$

Here: $\mathbf{I}$ is the identity matrix, $\mathbf{P}_c$ is the orthogonal projection onto the spanning subspace (the range of the covariance matrix) of the class-c training samples, and $\mathbf{P}_c^{\perp} = \mathbf{I} - \mathbf{P}_c$ is the orthogonal projection onto the null space of the covariance – *i.e*. the orthogonal complement of the spanning subspace, called the *indifference subspace* in (Gulmezoglu et al., 2001, Cevikalp et al., 2005). $\boldsymbol{\mu}_c$ can be any reference point in H_c^{aff} – *e.g*. one of the samples $\mathbf{x}_{ci}$, or their mean – and $\boldsymbol{\mu}_c^{\perp} = \mathbf{P}_c^{\perp} \boldsymbol{\mu}_c$, the residual of $\boldsymbol{\mu}_c$ under the projection, encodes the orthogonal displacement of H_c^{aff} from the origin.

As its name suggests, the NAH classifier assigns the query to the class whose affine hull is the closest:

$$g(\mathbf{x}_q) = \min_{c=1,\ldots,C} (d(\mathbf{x}_q, H_c^{\text{aff}})). \qquad (3)$$

Equivalently, NAH chooses the class that provides the best (smallest $\|\text{error}\|$) reconstruction of the query using an affine combination of training samples. The decision boundaries of NAH are piecewise quadratic. Numerically, point projections can be computed on the fly without explicitly evaluating and storing the $d \times d$ projection matrices $\mathbf{P}_c$ and $\mathbf{P}_c^{\perp}$ by using $\mathbf{P}_c = \mathbf{Q}_c \, \mathbf{Q}_c^{\top}$ where $\mathbf{Q}_c$ is the U matrix of the thin SVD (or equivalently the Q matrix of the

thin QR decomposition) of the matrix of centred class-c training examples $[\mathbf{x}_{c1} - \boldsymbol{\mu}_c, \ldots, \mathbf{x}_{cN_c} - \boldsymbol{\mu}_c]$.

In practice the training data is often somewhat noisy. This can harm the classification performance owing to the inclusion of spurious 'noise' dimensions in the affine hulls. To reduce this we suppress dimensions of the SVD (and hence of $\mathbf{Q}_c$) that correspond to overly small singular values.

For nonlinear classes that lie on smooth manifolds, NAH can also be applied locally by finding the k-nearest samples to the query from each class, building local affine hulls using these nearest neighbors, and assigning the query to the class with the closest hull (Vincent & Bengio, 2001). This can reproduce complex nonlinear decision boundaries.

2.2. Nearest Convex Hull (NCH) Classification

The affine hull gives a rather loose approximation to the class region. Alternatively, we can take a maximally tight bound by approximating the class with the convex hull of its training samples. For this, we include non-negativity constraints $\alpha_i \geq 0$, $i = 1, \ldots, N_c$ in (1) and replace all of the affine hull distance computations with convex hull ones. The distance from a query $\mathbf{x}_q$ to the convex hull of class c is the norm of the displacement from $\mathbf{x}_q$ to the closest point on the hull. This reduces to solving the following quadratic programming problem

$$\begin{aligned} &\min_{\boldsymbol{\alpha}_c} \ \frac{1}{2}||\mathbf{x}_q - \mathbf{X}_c\,\boldsymbol{\alpha}_c||^2 \\ &s.t. \ \sum_{i=1}^{N_c} \alpha_{ci} = 1, \ \ \alpha_{ci} \geq 0, \ \ i = 1, \ldots, N_c, \end{aligned} \tag{4}$$

where $\mathbf{X}_c$ is a matrix whose columns are the class-c training samples. Given the optimal α^*_{ci} coefficients, the distance from $\mathbf{x}_q$ to the convex hull of the class c is $||\mathbf{x}_q - \mathbf{X}_c\,\boldsymbol{\alpha}^*_c||$. This is repeated for each class and the query is assigned to the class with the closest convex hull.

Finding the maximum margin between two classes is equivalent to finding the closest points on their convex hulls (Bennett & Bredensteiner, 2000) so convex distances can also be computed by using a classical hard-margin SVM algorithm to find the margin (convex distance) separating each class from the given query point.

NAH and NCH are "one class" methods in the sense that we do not explicitly calculate the decision boundaries during the training phase. Instead they remain implicit and the decisions are made on-line for each test sample. However both approaches can be viewed as large margin classifiers closely related to hard-margin linear SVM's. In particular, the piecewise linear/quadratic decision boundary of NCH contains the SVM boundary as one facet, and generalizes it to use distance to the convex hull rather than linear separation as the decision criterion.

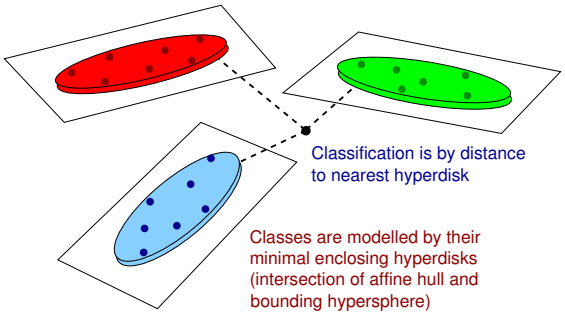

Figure 1. The principle of the proposed nearest bounding hyperdisk method. Classes are modelled by the bounding hyperdisk of their training examples and new examples are classified to the class with the closest hyperdisk.

3. Nearest Bounding Hyperdisk (NHD) Classification

In high-dimensional spaces, classes often extend well beyond the convex hulls of their training samples. For example, any individual simplex spanned by points sampled from a high-dimensional hypersphere can include only a negligible fraction of the volume of the sphere even if the vertices themselves are well spaced and close to the surface of the sphere. Conversely, affine hulls often give a rather loose approximation to the class as they do not constrain the positions of the training points within the affine subspace. This is problematic if the classes have similar or intersecting affine hulls but very different distributions of samples within their hulls. In such cases the classification performance will be poor if the affine projections of the queries onto the affine hulls are too far from training samples (*e.g.* as indicated by large values of the α_i coefficients for the constructed affine projections). The "soft margin" approach to handling this is to allow negative weights in (4) but to penalize over-large values by including upper and lower bounds in the quadratic program. However this deteriorates the run-time efficiency of NAH because the affine hull parameters of classes can no longer be computed in advance.

Instead, we can keep both a simpler geometric interpretation and good run-time efficiency by approximating the class samples with their bounding hyperdisk, *i.e.* the intersection of their affine hull and their minimal bounding hypersphere.

3.1. Global Nearest Hyperdisk Method

We will only describe the basic global Nearest Hyperdisk (NHD) classifier, but local application is also possible in the same way as for NAH and NCH. NHD approximates each class with the smallest bounding hyperdisk of its training samples – the set formed by inter-

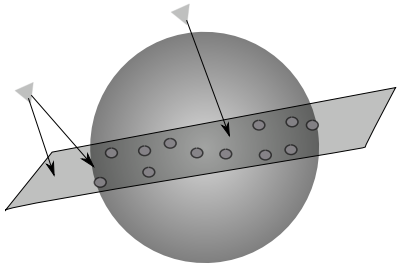

Figure 2. Computing distances from queries to a hyperdisk. The affine projection of the query on the left lies outside the hypersphere so it needs to be projected along the affine hull onto the hypersphere before the query-hyperdisk distance can be calculated. The affine projection of the query at the top already lies within the hypersphere so no adjustment is necessary.

secting their affine hull and their smallest bounding hypersphere. Such hyperdisks can be computed economically and they support rapid nearest point computations. There are already a number of methods based on affine hulls or bounding hyperspheres – for example hyperspheres have been used for outlier detection (Tax & Duin, 2004, Shawe-Taylor & Cristianini, 2004) and binary classification (Wang et al., 2005) – but we are not aware of any previous machine learning method based on hyperdisks. The bounding hypersphere of class c is characterized by its center $\mathbf{s}_c$ and radius r_c. These can be found by solving the following quadratic program

$$\begin{aligned} &\min_{\gamma, r_c, \xi} \; r_c^2 + \gamma \sum_{i=1}^{N_c} \xi_i \\ &\quad s.t. \;\; ||\mathbf{x}_{ci} - \mathbf{s}_c||^2 \leq r_c^2 + \xi_i, \;\; i = 1, \ldots, N_c, \end{aligned} \tag{5}$$

or its dual

$$\begin{aligned} &\min_{\alpha} \;\; \sum_{i,j} \alpha_i \alpha_j \langle \mathbf{x}_{ci}, \mathbf{x}_{cj} \rangle - \sum_i \alpha_i \langle \mathbf{x}_{ci}, \mathbf{x}_{ci} \rangle \\ &s.t. \;\; \sum_{i=1}^{N_c} \alpha_i = 1, \;\; 0 \leq \alpha_i \leq \gamma, \;\; i = 1, \ldots, N_c. \end{aligned} \tag{6}$$

Here α_i are Lagrange multipliers and $\gamma \in [0, 1]$ is a ceiling parameter that can be set to a finite value to eliminate overdistant points as outliers. Given the solution, the center of the hypersphere is $\mathbf{s}_c = \sum_{i=1}^{N_c} \alpha_i \mathbf{x}_{ci}$ and the radius is $r_c = ||\mathbf{x}_{ci} - \mathbf{s}_c||$ for any $\mathbf{x}_{ci}$ with $0 < \alpha_i < \gamma$.

To compute the distance from a query to the hyperdisk of a class, we find the affine projection of the query onto the affine hull by $\mathbf{x}_q^{\text{aff}} = \mathbf{P}_c(\mathbf{x}_q - \boldsymbol{\mu}_c) + \boldsymbol{\mu}_c = \mathbf{P}_c \mathbf{x}_q + \boldsymbol{\mu}_c^{\perp}$. If the projection lies outside the bounding hypersphere we move it along the line joining it to the center of the sphere until it touches the sphere. The distance from the query to the disk is the distance from it to the (possibly moved) projection – see fig. 2. Formally, the distance is

$$d(\mathbf{x}_q, H_c^{\text{disk}}) = \sqrt{\max(\|\mathbf{x}_q^{\text{aff}} - \mathbf{s}_c\| - r_c, 0)^2 + \|\mathbf{x}_q - \mathbf{x}_q^{\text{aff}}\|^2}.$$

3.2. Kernelization of the Hyperdisk Method

We now show that the hyperdisk method can be kernelized, allowing it to be used in implicit high dimensional feature spaces induced by Mercer kernels. This brings all of the usual advantages and disadvantages of kernelization, notably scope for a richer choice of distance functions and highly nonlinear decision boundaries that can aid data separability in return for the need to work with an implicit model defined by a large set of training samples.

The kernel trick can be used to map the data into an implicit feature space as in Kernel PCA (Schölkopf et al., 1998). Let $\boldsymbol{\phi}(\cdot)$ be the implicit feature space embedding and $k(\mathbf{x}, \mathbf{y}) = \boldsymbol{\phi}^\top(\mathbf{x})\boldsymbol{\phi}(\mathbf{y})$ be the corresponding kernel function. Suppose that we want to project a sample $\mathbf{x}$ onto the affine hull of a given set of samples $\{\mathbf{x}_i | i = 1, \ldots, m\}$. Let $\boldsymbol{\Phi} = [\boldsymbol{\phi}(\mathbf{x}_1), \ldots, \boldsymbol{\phi}(\mathbf{x}_m)]$ be their feature space embedding matrix, $\mathbf{K} = \boldsymbol{\Phi}^\top \boldsymbol{\Phi} = [k(\mathbf{x}_i, \mathbf{x}_j)]$ be their $m \times m$ kernel matrix and $\mathbf{k}_{\mathbf{x}} = \boldsymbol{\Phi}^\top \boldsymbol{\phi}(\mathbf{x}) = [k(\mathbf{x}_i, \mathbf{x})]$ be the $m \times 1$ kernel vector of $\mathbf{x}$ against the samples. The feature space mean of the samples is $\boldsymbol{\mu} = \frac{1}{m} \boldsymbol{\Phi}\, \mathbf{1}_m$ where $\mathbf{1}_m$ is an m-vector of 1's. The explicit approach detailed below (3) is based on the thin SVD $\mathbf{U}\mathbf{D}\mathbf{V}^\top$ of the matrix of centered sample features $[\boldsymbol{\phi}(\mathbf{x}_1) - \boldsymbol{\mu}, \ldots, \boldsymbol{\phi}(\mathbf{x}_m) - \boldsymbol{\mu}] = \boldsymbol{\Phi}\,\boldsymbol{\Pi}$, where $\boldsymbol{\Pi} = \mathbf{I} - \frac{1}{m} \mathbf{1}_m \mathbf{1}_m^\top$ is an orthogonal projection in sample space that implements subtraction of the mean on $\boldsymbol{\Phi}$. Given this, the projection of $\mathbf{x}$ onto the affine hull of the mapped samples is then $\mathbf{U}\,\mathbf{U}^\top(\boldsymbol{\phi}(\mathbf{x}) - \boldsymbol{\mu}) + \boldsymbol{\mu}$, and the squared residual of this projection is $\|\boldsymbol{\phi}(\mathbf{x}) - \boldsymbol{\mu}\|^2 - \|\mathbf{U}^\top(\boldsymbol{\phi}(\mathbf{x}) - \boldsymbol{\mu})\|^2$. Also, we are free to use any origin and linear basis that we choose for computations within the affine hull so long as we do so consistently. In particular, if we choose the orthogonal basis given by $\mathbf{U}$ centred at $\boldsymbol{\mu}^\perp = (\mathbf{I} - \mathbf{U}\mathbf{U}^\top)\boldsymbol{\mu}$, the projection of $\mathbf{x}$ onto the affine hull is represented simply by $\mathbf{U}^\top \boldsymbol{\phi}(\mathbf{x})$.

Noting that the $\mathbf{D}$ matrices of thin SVDs (*i.e.* taking only the significantly non-zero singular values) are invertible, we have $\mathbf{U} = \boldsymbol{\Phi}\,\boldsymbol{\Pi}\,\mathbf{V}\,\mathbf{D}^{-1} = \boldsymbol{\Phi}\,\mathbf{A}^\top$ where $\mathbf{A} = \mathbf{D}^{-1}\mathbf{V}^\top\boldsymbol{\Pi}$. In the kernelized case we can not evaluate the SVD of $\boldsymbol{\Phi}\,\boldsymbol{\Pi}$ explicitly because this would require numerical computations in feature space, but we can work implicitly in sample-space in terms of the eigendecomposition $\mathbf{V}\boldsymbol{\Lambda}\mathbf{V}^\top$ of the centred kernel matrix $\tilde{\mathbf{K}} = (\boldsymbol{\Phi}\,\boldsymbol{\Pi})^\top(\boldsymbol{\Phi}\,\boldsymbol{\Pi}) = \boldsymbol{\Pi}\,\mathbf{K}\,\boldsymbol{\Pi}$. Here, $\mathbf{V}$ is the same matrix as in the SVD of $\boldsymbol{\Phi}\,\boldsymbol{\Pi}$ and $\boldsymbol{\Lambda} = \mathbf{D}^2$ so that $\mathbf{A} = \boldsymbol{\Lambda}^{-1/2}\,\mathbf{V}^\top\,\boldsymbol{\Pi}$.

Putting all of these pieces together and noting that $\|\boldsymbol{\phi}(\mathbf{x})\|^2 = k(\mathbf{x}, \mathbf{x})$, we find that the squared residual error of the projection of $\mathbf{x}$ onto the affine hull of the examples

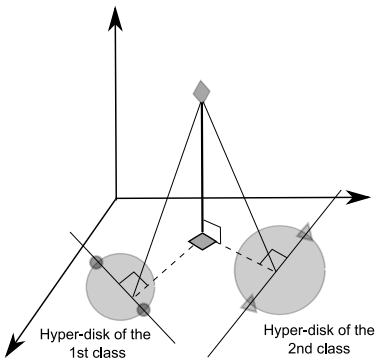

Figure 3. The kernelized NAH/NCH/NHD classifiers are based on distances between query samples and affine, *etc*., hulls of classes within the subspace spanned by the complete training data. These distances produce the same class assignments as the original classifiers.

is

$$k(\mathbf{x},\mathbf{x}) - \mathbf{k}_\mathbf{x}^\top \mathbf{A}^\top \mathbf{A} \mathbf{k}_\mathbf{x} - (2\,\mathbf{k}_\mathbf{x} - \mathbf{K}\tfrac{\mathbf{1}_m}{m})^\top (\mathbf{I} - \mathbf{A}^\top \mathbf{A} \mathbf{K}) \tfrac{\mathbf{1}_m}{m} \quad (7)$$

and the sample-space representative of the feature-space projection of $\mathbf{x}$ into the affine hull of the samples is simply $\mathbf{A}\,\mathbf{k}_\mathbf{x}$. We can use the representation vectors $\mathbf{A}\,\mathbf{k}_\mathbf{x}$ for any affine computation within the feature space affine hull, including calculations of hyperspheres and convex hulls, projections of new samples onto these, and within-hull distance computations. To calculate the overall squared distance from the example to the desired convex set within the hull, the squared residual error of the projection onto the hull (7) needs to be added to the squared within-hull distance.

In retrospect the obvious way to perform the above computations would be to use a separate feature subspace ($\mathbf{\Phi}$, $\mathbf{K}$, $\mathbf{k}_\mathbf{x}$, $\mathbf{A}$, *etc*.) for each class, but in the experiments below we actually worked in a global feature subspace based on the combined training samples of all classes. This subspace contains the affine hulls of all of the classes so the projections of test samples onto classes can be done in two stages, first projecting the sample onto the global affine hull, then projecting the result onto the class hull within the global one. The first projection is class-independent so it simply adds a sample-dependent constant residual to all of the sample-class distances. For decisions based on relative sample-class distances, these constants can be ignored. As a result, it suffices to perform all computations with the global $\mathbf{A}\,\mathbf{k}_\mathbf{x}$ vectors as though they were the original affine input points. In particular, the kernelized versions of NAH, NHD and NCH simply apply the corresponding linear method to the $\mathbf{A}\,\mathbf{k}_\mathbf{x}$ vectors of the global feature subspace. This process is illustrated in fig. 3. It only provides relative distances, so $k(\mathbf{x},\mathbf{x})$ is never needed.

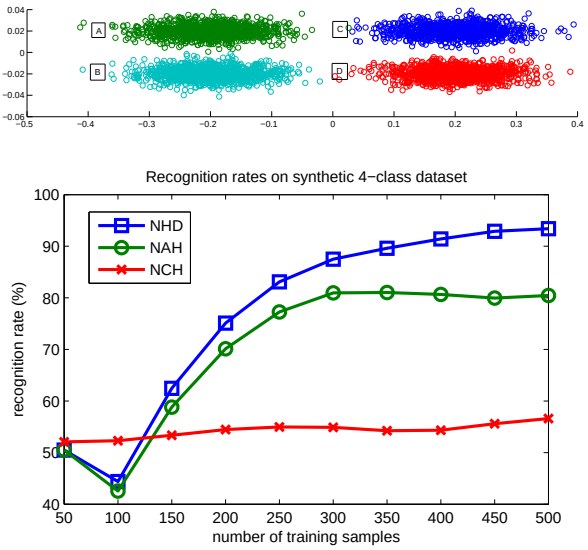

Figure 4. Top: the first two dimensions of the four disk dataset. Bottom: overall test-set recognition rates for NHD, NAH and NCH on this dataset for varying numbers of training points.

4. Experiments

We compared the proposed hyperdisk method (NHD) to Nearest Neighbour (NN), Nearest Affine Hull (NAH), Nearest Convex Hull (NCH) and Nearest Sphere Center[1] (NSC) classifiers in two regimes: high-dimensional problems where the dimensionality of the input space is much larger than the size of the training sets and the native (unkernelized) classifier is used; and low-dimensional problems where the training sets are larger than the dimensionality of the input space and a kernelized classifier is needed. We tested the methods on three tasks from multi-class visual recognition in the high-dimensional regime, and on five tasks from the UCI collection in the low-dimensional one. In each case, we optimized the algorithm parameters using global coarse-to-fine search, with random partitions of the training data into training and validation sets.

4.1. Experiments on Synthetic Data

Before starting, we illustrate some properties of the methods on a simple synthetic data set with four classes. This was produced by creating four unit-radius spheres (one for each class) in 300 dimensions with centres $(\pm 0.2, \pm 0.2, 0, \ldots, 0)$, sampling test and training points uniformly within each sphere, then compressing 200 of the dimensions including the second one by a factor of 10 – see

[1]NSC computes bounding hyperspheres for each class and assigns the query to the class whose sphere *center* is nearest.

fig. 4 (top). This produces a high dimensional data set with 100D-disk like classes and many irrelevant variables. The classes are fairly well separable but the data has somewhat suboptimal scaling. For the NAH and NHD methods we estimated the affine dimension using an eigenvalue gap detector that reliably gave the correct result (100) for all runs with more than about 120 training points.

Fig. 4 (bottom) shows the resulting recognition rates for NAH, NHD and NCH with varying numbers of training samples. The hyperdisk method predominates, particularly for larger numbers of training samples. The example is somewhat idealized – the data is quite clean and the classes have a form that is well adapted to the hyperdisk model – but it illustrates several advantages of the hyperdisk method. Firstly, NCH performs poorly. It separates classes $\{A, B\}$ from $\{C, D\}$ almost perfectly, but it is not much better than random (around 55-60% correct) at separating A from B and C from D. This happens because the interclass spacing is small and the convex hulls of the training samples fill so little of the volume of the 100-D class disks that test samples are almost as likely to lie close to the hull of the wrong class as to that of the right one – *i.e.* even though the hulls "fill in the gaps" between the training samples, they are still very poor estimates of the actual class boundaries. NCH is also much slower than NAH and NHD at run time because it needs to solve a quadratic program for each test sample to find the nearest point on the hull. Both problems are endemic to the convex hull formulation.

Secondly, NAH does surprisingly well, especially when one considers that it has an asymptotic error rate of 50%: for exact estimates of the 100-D affine hulls of the classes, A and C (and similarly, B and D) are indistinguishable because they have identical affine hulls. Empirically NAH does much better than this because the estimates of the affine hulls are noisy: being estimated from examples of class A, the hull for class A always passes close to the centre of class A, but its random tilt typically makes it pass somewhat further from the centre of class C, and vice versa. Hence, empirical NAH estimates indirectly incorporate some information about the relative positions of the classes within their affine hyperplanes. This may explain why the performances of NAH and NHD are often similar in the below experiments on real data. However, as the above results suggest, it is often advisable to incorporate the position information explicitly by using NHD.

4.2. Experiments on Image Datasets

ORL Face Dataset.[2] The Olivetti-Oracle Research Lab face dataset contains 10 upright 92×112 frontal face images per person of $C = 40$ individuals, taken at different times with slightly different lighting conditions, image positions, facial expressions and facial details. For this experiment we used the raw image pixels as input features without applying any visual preprocessing. For training we randomly selected $N = 3, 5, 7$ images of each individual, keeping the remaining $10 - N$ for testing. The results are summarized in table 4.1 (top left). The NHD and NAH classifiers were equal best among the methods tested, followed by NCH, then NN, with NSC coming last.

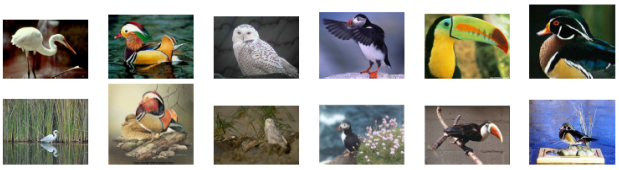

Figure 5. Some examples from the Birds dataset.

Coil100 Objects Dataset.[3] The Coil100 dataset includes 72 views each of 100 different objects taken on a turntable at orientations spaced at 5 degree intervals. We chose 40 objects randomly for the experiments. We used the raw grayscale pixels of the 128×128 images as input features, without applying any further visual preprocessing. For training we randomly selected $N = 18, 36, 54$ images of each object, keeping the remaining $72 - N$ for testing. The results are given in table 4.1 (top right). NHD and NAH again give very similar results with NHD having a slight edge. NHD achieves the best accuracy for $N = 18, 54$ while for $N = 36$ NCH is preferred to NHD and NAH. NSC again produced the worst results.

Birds Dataset. This contains six categories, each with 100 images (Lazebnik et al., 2005). It is a challenging visual object recognition task with the birds appearing against highly cluttered backgrounds and the images having large intra-class, scale, and viewpoint variability. Some example images are shown in fig. 5. We use a "bag of features" representation for the images as they are too diverse to allow simple geometric alignment of their objects. In this method, patches are sampled from the image at many different positions and scales, either densely, randomly or based on the output of some kind of salient region detector. Here we used a dense grid of patches. Each patch was described using the robust visual descriptor SIFT (Lowe, 2004) and vector quantized using nearest neighbor assignment against a 2000 word visual dictionary learned from the complete set of training patches. For training we randomly selected $N = 25, 50, 75$ images of each class, keeping the remaining $100 - N$ for testing.

The results are given in table 4.1 (bottom left). For $N = 50, 75$, NCH achieves the best recognition rates whereas

Data set	# Classes	# Examples	Dim.
Iris	3	150	4
IS	7	2310	19
MF	10	2000	256
Wine	3	178	13
WDBC	2	569	30

NHD and NAH are equal best for $N = 25$. All of the convex approximation based methods significantly outperform Nearest Neighbours.

4.3. Experiments with UCI Datasets

In the second group of experiments we tested the kernelized versions of the methods on five lower-dimensional datasets from the UCI repository: Iris, Image Segmentation (IS), Multiple Features (MF) - pixel averages, Wine, and Wisconsin Diagnostic Breast Cancer (WDBC). The key parameters of the datasets are summarized in table 2 and the results are presented in table 4.1 (bottom right).

In each case the dimensionality of the input space is smaller than the number of samples in each class. It follows that the native NAH classifier cannot be used directly because the affine hull of each class typically spans the entire input space. However kernelized versions of all of the classifiers can still be applied. The NCH and NSC formulations directly support kernelization while for NAH and NHD we used the Kernel PCA projection method described in section 3.2. We used Gaussian kernels and 5-fold cross-validation for all experiments.

NHD and NAH were the equal best classifiers for the Iris and MF databases while NCH came first for Wine and WDBC, and NN for IS. In all of the cases tested the proposed NHD classifier either matches or outperforms the NAH classifier. The convex approximation based approaches typically outperformed NN, but the difference was not as high as in the Birds database.

4.4. Discussion

The NHD and NAH classifiers often had almost identical performance but when there were differences NHD usually dominated. This suggests that NHD's tighter bounds on the classes are sometimes useful, but that they are often inactive, either because the affine hull projections of most queries already lie within the class hyperspheres or because the additional projections onto the hyperspheres do not add useful new discriminant information.

NHD and NAH often outperformed NCH in both the high-dimensional native experiments and the low-dimensional kernelized ones. As mentioned above, in high dimensions the convex hulls of the training samples typically significantly underestimate the extents of the classes unless the number of samples is exponential in the dimension of the class. Thus, despite the simplicity of their underlying approximations, the affine hulls and hyperdisks may often turn out to be better guides to the region spanned by the class than the convex hulls.

In the low-dimensional problems, NN (and related kernel methods) often perform relatively well, perhaps because hole artifacts are not so prevalent in low dimensions. Similarly, as the dimension decreases, NCH progressively improves relative to NAH because it provides tighter bounds on the class regions. NHD seems to offer a useful compro-

mise here.

In terms of run-time efficiency NAH and NHD are to be preferred as the affine hull and bounding hyperdisk parameters can be computed off-line. When there are large numbers of training samples, NCH often becomes prohibitively slow at run-time because it needs to solve a quadratic program for each sample-hull distance computation.

5. Summary and Conclusions

We have introduced a new method for high-dimensional classification based on approximating each class with the minimal bounding hyperdisk of its training samples – the intersection of their affine hull and their bounding hypersphere – and assigning test samples to the class with the nearest hyperdisk. For robustness, the algorithm uses PCA to suppress over-small "noise" dimensions in the affine hull and it removes outliers from the hypersphere calculation by bounding their Lagrange multipliers. In practice the hyperdisk approximation offers a useful middle ground between the loose approximation provided by the affine hull of the samples and the over-tight one given by their convex hull. It can also be kernelized to allow it to be used in lower-dimensional problems that require complex decision boundaries.

Future work. We are currently working on large-margin classifiers that calculate explicit decision boundaries during the training phase by maximizing the separation between the affine hull or hyperdisk approximations of the classes. These may be useful alternatives to SVMs, which maximize the separation between the convex hulls of the classes. Given that the affine hull and hyperdisk methods were often more accurate than the convex hull ones in the experiments, the new methods may yield more efficient classifiers than SVM in terms of both accuracy and computational complexity.

Learning to Sportscast: A Test of Grounded Language Acquisition

David L. Chen DLCC@CS.UTEXAS.EDU
Raymond J. Mooney MOONEY@CS.UTEXAS.EDU

Abstract

We present a novel commentator system that learns language from sportscasts of simulated soccer games. The system learns to parse and generate commentaries without any engineered knowledge about the English language. Training is done using only ambiguous supervision in the form of textual human commentaries and simulation states of the soccer games. The system simultaneously tries to establish correspondences between the commentaries and the simulation states as well as build a translation model. We also present a novel algorithm, Iterative Generation Strategy Learning (IGSL), for deciding which events to comment on. Human evaluations of the generated commentaries indicate they are of reasonable quality compared to human commentaries.

Figure 1. Screenshot of our commentator system

1. Introduction

Children acquire language through exposure to linguistic input in the context of a rich, relevant, perceptual environment. By connecting words and phrases to objects and events in the world, the semantics of language is grounded in perceptual experience (Harnad, 1990). Ideally, a machine learning system would be able to acquire language in a similar manner without human supervision. As a step in this direction, we present a commentator system that can describe events in a simulated soccer game by learning from sample human commentaries paired with the simulation states. A screenshot of our system with generated commentaries is shown in Figure 1.

Although there has been some interesting computational work in grounded language learning (Roy, 2002; Bailey et al., 1997; Yu & Ballard, 2004), most of the focus has been on dealing with raw perceptual data and the complexity of the language involved has been very modest. To help make progress, we study the problem in a simulated environment that retains many of the important properties of a dynamic world with multiple agents and actions while avoiding many of the complexities of robotics and vision. Specifically, we use the Robocup simulator (Chen et al., 2003) which provides a fairly detailed physical simulation of robot soccer. While several groups have constructed Robocup commentator systems (André et al., 2000) that provide a textual natural-language (NL) transcript of the simulated game, their systems use manually-developed templates and are incapable of learning.

Our commentator learns to semantically interpret and generate language in the Robocup soccer domain by observing an on-going commentary of the game paired with the dynamic simulator state. By exploiting existing techniques for abstracting a symbolic description of the activity on the field from the detailed state of the physical simulator (André et al., 2000), we obtain a pairing of natural language with a symbolic description of the perceptual context in which it was uttered. However, such training data is highly ambiguous because each comment usually co-occurs with several events in the game. We integrate and enhance existing methods for learning semantic parsers and NL gen-

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

erators (Kate & Mooney, 2007; Wong & Mooney, 2007a) in order to learn to understand and produce grounded language from such ambiguous training data.

2. Background

Systems for learning semantic parsers induce a function that maps NL sentences to *meaning representations* (MRs) in some formal logical language. Existing work has focused on learning from a supervised corpus in which each sentence is manually annotated with its correct MR (Mooney, 2007). Such human annotated corpora are expensive and difficult to produce, limiting the utility of this approach. The systems described below assume they have access to a formal context-free grammar, called the *meaning representation grammar* (MRG), that defines the MR language (MRL).

2.1. KRISP and KRISPER

KRISP (Kate & Mooney, 2006) uses SVMs with string kernels (Lodhi et al., 2002) to learn semantic parsers. For each production in the MRG, the system learns an SVM string classifier that recognizes the associated NL words or phrases. The resulting suite of classifiers is then used to construct the most probable MR for a complete NL sentence. Given the partial matching provided by string kernels and the over-fitting prevention provided by SVMs, KRISP has been experimentally shown to be robust to noisy training data.

KRISPER (Kate & Mooney, 2007) is an extension to KRISP that handles ambiguous training data, in which each sentence is annotated only with a *set* of potential MRs, only one of which is correct. It employs an iterative approach analogous to EM that improves upon the selection of the correct NL–MR pairs in each iteration. In the first iteration, it assumes that all of the MRs paired with a sentence are correct and trains KRISP with the resulting noisy supervision. In subsequent iterations, KRISPER uses the currently trained parser to score each potential NL–MR pair, selects the most likely MR for each sentence, and retrains the parser. In this manner, KRISPER is able to learn from the type of weak supervision expected for a grounded language learner exposed only to sentences in ambiguous contexts. However, the system has previously only been tested on artificially corrupted or generated data.

2.2. WASP

WASP learns semantic parsers using *statistical machine translation* (SMT) techniques (we use the Wong & Mooney (2007b) version). It induces a *probabilistic synchronous context-free grammar* (PSCFG) (Wu, 1997) to translate NL sentences into logical MRs using a modification of recent

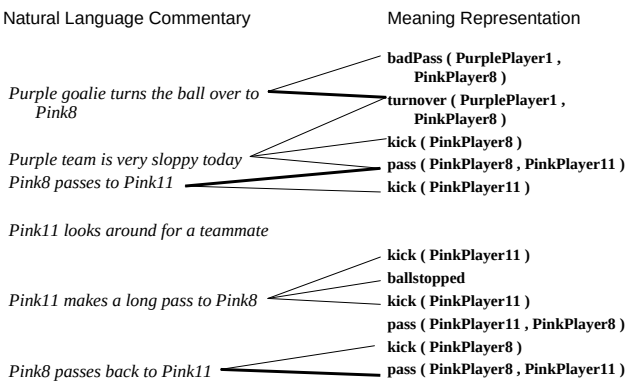

Figure 2. Sample trace of ambiguous training data

methods in syntax-based SMT (Chiang, 2005). Since a PSCFG is symmetric with respect to input/output, the same learned model can also be used to *generate* NL sentences from formal MRs. Thus, WASP learns a PSCFG that supports both semantic parsing and natural language generation. Since it does not have a formal grammar for the NL, the generator also learns an n-gram language model for the NL and uses it to choose the overall most probable NL translation of a given MR using a noisy-channel model (Wong & Mooney, 2007a).

3. Sportscasting Data

To train and test our system, we assembled human-commentated soccer games from the Robocup simulation league (www.robocup.org). Since our focus is language learning not computer vision, we chose to use simulated games instead of real game video to simplify the extraction of perceptual information. Symbolic representations of game events were automatically extracted from the simulator traces by a rule-based system. The extracted events mainly involve actions with the ball, such as kicking and passing, but also include other game information such as whether the current playmode is kickoff, offside, or corner kick. The events are represented as atomic formulas in predicate logic with timestamps. These logical facts constitute the requisite MRs, and we manually developed a simple MRG for this formal semantic language.

For the NL portion of the data, we had humans commentate games while watching them on the simulator. The commentators typed their comments into a text box, which were recorded with a timestamp. To construct the final ambiguous training data, we paired each comment with all of the events that occurred five seconds or less before the comment was made. A sample set of ambiguous training data is shown in Figure 2. Note that the use of English words for predicates and constants in the MR is for human read-

	Number of events	Number of comments			Events per comment		
		Total	Have MRs	Have Correct MR	Max	Average	Std. Dev.
2001 final	3992	722	671	520	9	2.235	1.641
2002 final	2125	514	458	376	10	2.403	1.653
2003 final	2112	410	397	320	12	2.849	2.051
2004 final	2223	390	342	323	9	2.729	1.697

Table 1. Statistics about the dataset

ability only, the system treats these as arbitrary conceptual tokens and must learn their connection to English words.

We annotated a total of four games, namely, the finals for the Robocup simulation league for each year from 2001 to 2004. Summary statistics about the data are shown in Table 1. The 2001 final has almost twice the number of events as the other games because it went into double overtime. For evaluation purposes only, a gold-standard matching was produced by examining each comment manually and selecting the correct MR if it exists. The bold lines in Figure 2 indicate the correct matches. Notice some sentences do not have correct matches (about one fifth of our data). For example, the sentence "Purple team is very sloppy today" cannot be represented in our MRL and consequently does not have a corresponding correct MR. On the other hand, in the case of the sentence "Pink11 makes a long pass to Pink8", the correct MR falls outside the 5-second window. For each game, Table 1 shows the total number of NL sentences, the number of these that have at least one recent extracted event to which it *could* refer, and the number of these that actually *do* refer to one of these recent extracted events. The maximum, average, and standard deviation for the number of recent events paired with each comment is also given.

4. New Algorithms

While existing systems are capable of solving parts of the sportscasting problem, none of them are able to perform the whole task on their own. We introduce three new end-to-end systems below which are able to learn from the ambiguous supervision in our training data and generate commentaries on unseen games.

4.1. WASPER

Since our primary goal is to learn a sportscaster rather than a parser, we use WASP to learn a system that can also generate NL from MRs produced by the perceptual system. However, WASP requires unambiguous training data which is not available for our domain. Therefore, we extend WASP using EM-like retraining similar to KRISPER to handle ambiguously annotated data, resulting in a system we call WASPER. In general, any system that learns semantic parsers can be extended to handle ambiguous data as long as it can produce confidence levels for given NL–MR pairs.

4.2. KRISPER-WASP

KRISP has been shown to be superior to WASP at handling noisy training data (Kate & Mooney, 2006). Consequently, we can expect KRISPER's parser to outperform WASPER's because EM-like training on ambiguous data initially creates a lot of noisy, incorrect supervision. Even if the average number of possible MRs per sentence is only 2, it still results in at least 50% noise in the training data in the first iteration. However, KRISPER cannot learn a language generator, which is necessary for our sportscasting task. As a result, we create a new system called KRISPER-WASP that is both good at disambiguating the training data and capable of generation. We first use KRISPER to train on the ambiguous data and produce a disambiguated training set by using its prediction for the most likely MR for each sentence. This unambiguous training set is then used to train WASP to produce both a parser and a generator.

4.3. WASPER-GEN

In both KRISPER and WASPER, the criterion for selecting the best NL–MR pairs during retraining is based on maximizing the probability of parsing a sentence into a particular MR. However, since WASPER is capable of both parsing and generation, we could alternatively select the best NL–MR pairs by evaluating how likely it is to *generate* the sentence from a particular MR. Thus, we built another version of WASPER (WASPER-GEN) that disambiguates the training data in order to maximize the performance of *generation* rather than parsing. It uses a generation-based score rather than a parsing-based score to select the best NL–MR pairs. Specifically, an NL–MR pair (n, m) is scored by using the current trained generator to generate an NL sentence for m and then comparing the generated sentence to n to compute the NIST score. NIST score is a machine translation (MT) metric that measures the precision of a translation in terms of the proportion of n-grams it shares with a human translation (Doddington, 2002). It is also used to evaluate NL generation. Another popular MT metric is BLEU score (Papineni et al., 2002) but we found it inadequate for our domain because it overly penalizes

translations shorter than the target sentences. Most of our generated commentaries are shorter than the human commentaries due to the fact that humans are more verbose and many details of the human descriptions are not represented by our MRL.

4.4. Learning for Strategic Generation

A language generator alone is not enough to produce a sportscast. In addition to knowing *how* to say something, one must also know *what* to say. A sportscaster must also choose which events to describe. In NLP, deciding what to say is called *strategic generation*.

We developed a simple method for learning which events to describe. For each event type (i.e. for each predicate like `pass`, or `goal`), the system uses the training data to estimate a probability that it is mentioned by the sportscaster. Given the gold-standard NL–MR matches, this probability is easy to estimate; however, the learner does not know the correct matching. Instead, the system must estimate the probabilities from the ambiguous training data. We compare two basic methods for estimating these probabilities.

The first method uses the *inferred* NL–MR matching produced by the language-learning system. The probability of commenting on each event type, E_i, is estimated as the percentage of events of type E_i that have been matched to *some* NL sentence.

The second method, which we call Iterative Generation Strategy Learning (IGSL), uses a variant of EM, treating the matching assignments as hidden variables, initializing each match with a prior probability, and iterating to improve the probability estimates of commenting on each event type. Unlike the first method, IGSL uses MRs not associated with any sentences explicitly in training. Algorithm 1 shows the pseudocode. Each sentence accounts for at most one occurrence of an event being commented (some comments do not correspond to any MRs), so we enforce that the counts associated with a sentence add up to exactly one. In the initial iteration, every possible match gets assigned a weight inversely proportional to its amount of ambiguity. Thus, a sentence associated with five possible MRs will assign each match a weight of $\frac{1}{5}$. In the subsequent iterations, we use the learned estimates for each event type to assign weights to the edges, again normalizing to make sure that the weights of the edges coming out of each sentence sum to one.

To generate a sportscast, we first use the learned probabilities to determine which events to describe. For each time step, we only consider commenting on the event with the highest probability. The system then generates a comment for this event stochastically based on the estimated probability for its event type.

Algorithm 1 Iterative Generation Strategy Learning

input event types $E = \{E_1, ..., E_i, ..., E_n\}$, the number of occurrences of each event type $totalCount(E_i)$, sentences S and their associated sets of meaning representations $MR(s)$,

5. Experimental Evaluation

This section presents experimental results on the Robocup data for four systems: KRISPER, WASPER, KRISPER-WASP, and WASPER-GEN. To better gauge the effect of accurate ambiguity resolution, we also include results of unmodified WASP. Since WASP requires unambiguous training data, we randomly pick a meaning for each sentence from its set of potential MRs. Finally, we also include the result of WASP trained using *gold matching* which consists of the correct NL–MR pairs annotated by a human. This represents an upper-bound on what our systems could achieve if they disambiguated the training data perfectly.

We evaluate each system on three tasks: matching, parsing, and generation. The matching task measures how well the systems can disambiguate the training data. The parsing and generation tasks measure how well the systems can translate from NL to MR, and from MR to NL, respectively.

Since there are four games in total, we trained using all possible combinations of one to three games, and in each case, tested on the games not used for training. Results were averaged over all train/test combinations. We evalu-

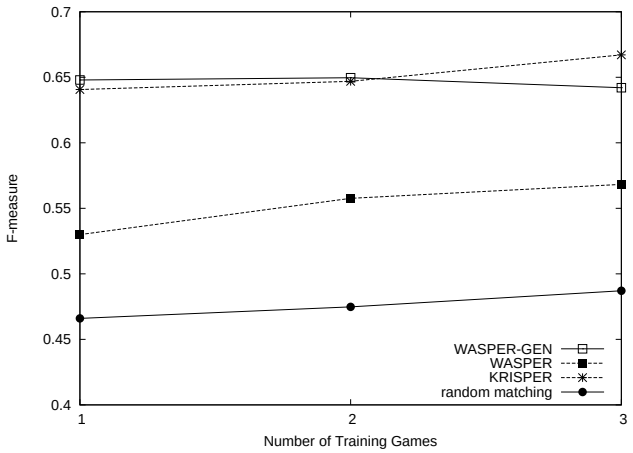

Figure 3. Matching Results

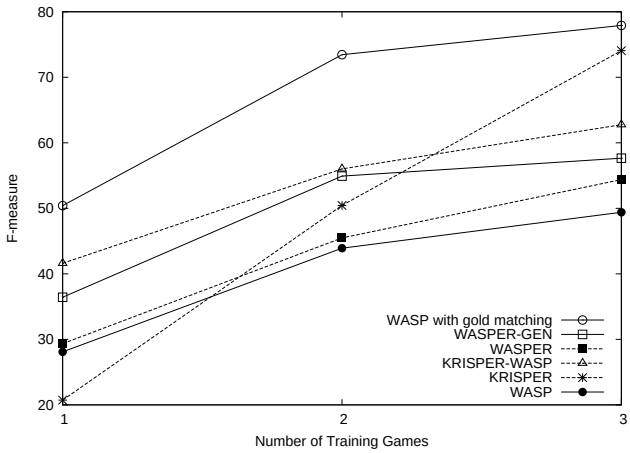

Figure 4. Semantic Parsing Results

ated matching and parsing using F-measure, the harmonic mean of recall and precision. Precision is the fraction of the system's annotations that are correct. Recall is the fraction of the annotations from the gold-standard that the system correctly produces. Generation is evaluated using NIST scores which roughly estimates how well the produced sentences match with the target sentences.

5.1. Matching NL and MR

Since handling ambiguous training data is an important aspect of grounded language learning, we first evaluate how well the various systems pick the correct NL–MR pairs. Figure 3 shows the F-measure for identifying the correct set of pairs for the various systems. WASPER does better than random matching, but worse than the other two systems. While we expected KRISPER to perform better since it is more adept at handling noisy data, it is somewhat surprising that WASPER-GEN does about the same. A potential explanation is that WASPER-GEN avoids making certain systematic errors typical of the other systems. This is discussed further in section 5.3.

5.2. Semantic Parsing

Next, we present results on the accuracy of the learned semantic parsers. Each trained system is used to parse and produce an MR for each sentence in the test set that has a correct MR in the gold-standard matching. A parse is considered correct if and only if it matches the gold standard exactly. Parsing is a fairly difficult task because there is usually more than one way to describe the same event. For example, "Player1 passes to player2" can refer to the same event as "Player1 kicks to player2." Thus, accurate parsing requires learning all the different ways people describe an event. Synonymy is not limited to verbs. In our data, "Pink1", "PinkG" and "pink goalie" all refer to player1 on the pink team. Since we are not providing the systems with any prior knowledge, parsers have to learn all these different ways of referring to the same entity.

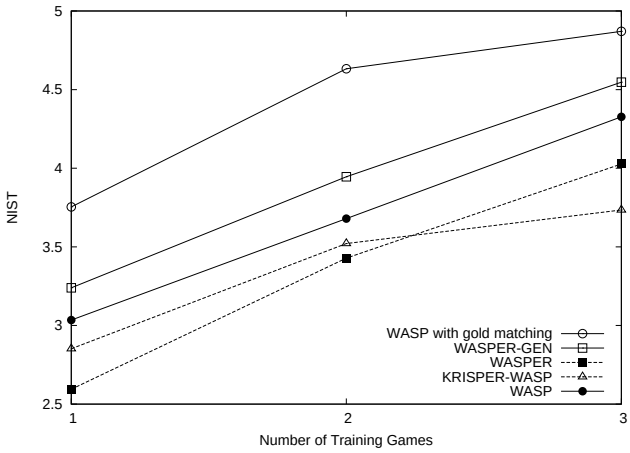

Figure 5. Generation results

Results are shown in Figure 4, and, as expected, follow the matching results. Systems that did better at disambiguating the training data also did better on parsing since their supervised training data is less noisy. When trained on 3 games, KRISPER does the best since it is most effective at handling the noise in the final supervised data. However, it tends to do worse than the other systems when given less training data.

5.3. Generation

The third evaluation task is generation. All of the WASP-based systems are given each MR in the test set that has a gold-standard matching NL sentence and asked to generate an NL description. The quality of the generated sentence is measured by comparing it to the gold-standard using NIST scoring.

This task is easier than parsing because the system only needs to learn *one way* to accurately describe an event. This property is reflected in the results, shown in Figure 5, where even the baseline system WASP does fairly well, outperforming WASPER and KRISPER-WASP. As the number of event types is fairly small, only a relatively small number of correct matchings is required to perform this task well as long as each event type is associated with a correct sentence pattern more often than any other sentence patterns. Consequently, it is far more costly to make systematic errors as is the case for WASPER and KRISPER-WASP.

Even though systems such as WASPER and KRISPER-WASP do fairly well at disambiguating the training data, the mistakes they make in selecting the NL–MR pairs often repeat the same basic error. For example, a bad pass event is often followed by a turnover event. If initially the system incorrectly determines that the comment "Player1 turns the ball over to the other team" refers to a bad pass, it will parse the sentence "Player2 turns the ball over to the other team" as a bad pass as well since it just reinforced that connection. Even if the system trains on a correct example where a bad pass is paired with the linguistic input "Player1 made a bad pass", it does not affect the parsing of the first two sentences and does not correct the mistakes. As a result, a bad pass becomes incorrectly associated with the sentence pattern "Someone turns the ball over to the other team."

On the other hand, WASPER-GEN does the best due to the imbalance between the variability of natural language comments and the MRs. While the same MR will typically occur many times in a game, the exact same comments are almost never uttered again. This leads to two performance advantages for WASPER-GEN.

WASPER-GEN avoids making the same kind of systematic mistakes as WASPER and KRISPER-WASP. Following the previous example, when WASPER-GEN encounters the correct matching for bad pass, it learns to associate bad passes with the correct sentence pattern. When it goes back to those first two incorrect pairings, it will likely correct its mistakes. This is because the same MR bad pass is present in all three examples. Thus, it will slowly move away from the incorrect connections. Of course, parsing and generation are symmetrical processes, so using generation to disambiguate data has its own problems. Namely, it is possible to converge to a point where many events generates the same natural language description. However, since there is much more variability in natural language, it is very unlikely that the same sentence pattern will occur repeatedly, each time associated with different events.

Another performance advantage of WASPER-GEN can be found by looking at the objective differences. Systems such as WASPER and KRISPER-WASP which use parsing

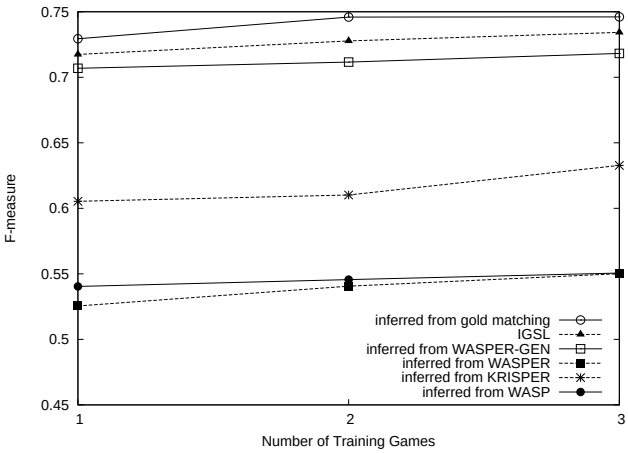

Figure 6. Strategic Generation Results

IGSL		WASPER-GEN

pass	0.983	badPass	0.708
badPass	0.970	corner_kick	0.438
goal	0.970	block	0.429
block	0.955	turnover	0.377

Table 2. Top scoring predicates with their estimated probabilities of being described

scores, try to learn a good translation model for each sentence pattern. On the other hand, WASPER-GEN only tries to learn a good translation model for each MR pattern. Thus, WASPER-GEN is more likely to converge on a good model as there are fewer MR patterns than sentence patterns. However, it can be argued that learning good translation models for each sentence pattern will help in producing more varied commentaries, a quality that is not captured by the NIST score.

5.4. Strategic Generation

The different methods for learning strategic generation are evaluated based on how often the events they describe coincide with those the human decided to describe in the test data. For the first method, results from using the inferred matchings produced by KRISPER, WASPER, KRISPER-WASP, and WASPER-GEN as well as the gold and random matching for establishing baselines are all presented in Figure 6. From the graph, it is clear that IGSL outperforms learning from the inferred matchings and actually performs at a level close to using the gold matching. However, it is important to note that we are limiting the potential of learning from the gold matching by using only the predicates to decide whether to talk about an event.

The top scoring predicates from IGSL as well as the best result from using inferred matchings, WASPER-GEN, are

	English Fluency	*Semantic Correctness*	*Sportscasting Ability*
Human	3.938	4.25	3.625
Machine	3.438	3.563	2.938

Table 3. Human evaluation of overall sportscast

shown in Table 2. While both systems learn to talk about frequent events such as passing, WASPER-GEN does poorly on rare, but significant events such as goal scoring. This is because WASPER-GEN saw those events very rarely in training and did not learn to correctly match them to sentences. It is worth noting that IGSL learns a higher probability for events in general. This improves its recall and hurts its precision. However, since many of its top-ranked events such as goals are rare, the overall quality is maintained without becoming overly verbose. Therefore, we used IGSL for the human evaluations below.

5.5. Human Evaluation

Automatic evaluation of generation is an imperfect approximation of human assessment at best. Moreover, automatically evaluating the quality of an entire generated sportscast is even more difficult. Consequently, we recruited four fluent English speakers with no previous experience with Robocup or any of our systems to serve as human judges. We compared their subjective evaluations of human and machine generated sportscasts. Each judge was given 8 clips of simulated game video along with subtitled commentaries. The 8 clips use 4 game segments of 2 minutes each, one from each of the four games. Each of the 4 game segments is shown twice, once with human commentary and once with generated commentary. We use IGSL to determine the events to comment on and use WASPER-GEN (our best performing system for generation) to produce the commentaries. The system was always trained on three games, leaving out the one from which the test segment was extracted. The videos are shown in random order with the human and machine commentaries of a segment flipped between judges to ensure no consistent bias toward segments being shown earlier or later. We asked the judges to score the commentaries using the following metrics:

Score	*English Fluency*	*Semantic Correctness*	*Sportscasting Ability*
5	Flawless	Always	Excellent
4	Good	Usually	Good
3	Non-native	Sometimes	Average
2	Disfluent	Rarely	Bad
1	Gibberish	Never	Terrible

Fluency and semantic correctness, or adequacy, are standard metrics in human evaluations of NL translations and generations. Fluency measures how well the commentaries are structured, including syntax and grammar. Semantic correctness indicates whether the commentaries actually describe what is happening in the game. Finally, sportscasting ability measures the overall quality of the sportscast. This includes whether the sportscasts are interesting and flow well. The scores are averaged over all four games and across all the judges. Table 3 shows the results.

While human commentaries are clearly superior to the machine's, the largest difference between the average scores is only 0.7. Moreover, the judges indicated that they were able to understand and follow the generated commentaries without trouble. Part of the reason for the lower scores actually result from our impoverished MRL. Semantic correctness scores were deducted when the machine misses commenting on certain facts not represented in our MRL such as the location of the ball and the players. The lack of temporal or locality information also results in dry and repetitive comments which hurt the sportscasting score. This is an important point that is not captured by the NIST score. In our NIST score evaluation, each sentence is treated separately and no attempt was made at measuring how well the individual comments fit together. However, it is clear from the human evaluations that variability of sentence pattern is vital to a good sportscast. The machine can correctly comment on all the factual events in a game and still produce a bad sportscast that no one wants to listen to.

6. Related Work

Robotics and vision researchers have worked on inferring a grounded meaning of individual words or short referring expressions from visual perceptual context, e.g. (Roy, 2002; Bailey et al., 1997; Barnard et al., 2003; Yu & Ballard, 2004). However, the complexity of the natural language used in this existing work is very restrictive, many of the systems use pre-coded knowledge of the language, and almost all use static images to learn language describing objects and their relations, and cannot use dynamic video to learn language describing actions. Some recent work on video retrieval has focused on learning to recognize events in sports videos and connect them to English words (Fleischman & Roy, 2007). There has also been recent work on grounded language learning in simulated computer-game environments (Gorniak & Roy, 2005). However, none of this prior work makes use of modern statistical-NLP parsing techniques, learns to build formal meaning representations for complete sentences, or learns to generate natural language.

There has been some recent work on learning generation strategies using reinforcement learning (Zaragoza & Li, 2005). In contrast, our domain does not include interaction with the users and no feedback is available.

7. Future Work

The current system is limited by its simple MRL. For example, the location of players or the ball is not represented. Moreover, we do not keep contextual information which makes it difficult to generate interesting, non-repetitive sportscasts. Contextual information would also help us provide comments not directly induced by the events happening now, such as the current score. Finally, it is clear that we need a more hierarchical representation that captures the relationships between events in order to avoid making systematic matching errors on frequently co-occurring events.

With respect to algorithms, using learned strategic-generation knowledge (information about what events are likely to illicit comments) could improve the resolution of ambiguities. We would also like to eventually apply our methods to real captioned video input using the latest methods in computer vision.

8. Conclusion

We have presented an end-to-end system that learns from sample commentaries and generates sportscasts for novel games. Dealing with the ambiguity inherent in the training environment is a critical issue in learning language from perceptual context. We have evaluated various methods for disambiguating the training data in order to build a language generator. Using a generation evaluation metric as the criterion for selecting the best NL–MR pairs produced the best results overall. Our system also learns a simple model of strategic generation from the ambiguous training data by estimating the probability that each event type invokes a comment. Experimental evaluation verified that the system learns to accurately parse and generate comments and to generate sportscasts that are competitive with those produced by humans.

Training SVM with Indefinite Kernels

Abstract

Similarity matrices generated from many applications may not be positive semidefinite, and hence can't fit into the kernel machine framework. In this paper, we study the problem of training support vector machines with an indefinite kernel. We consider a regularized SVM formulation, in which the indefinite kernel matrix is treated as a noisy observation of some unknown positive semidefinite one (proxy kernel) and the support vectors and the proxy kernel can be computed simultaneously. We propose a semi-infinite quadratically constrained linear program formulation for the optimization, which can be solved iteratively to find a global optimum solution. We further propose to employ an additional pruning strategy, which significantly improves the efficiency of the algorithm, while retaining the convergence property of the algorithm. In addition, we show the close relationship between the proposed formulation and multiple kernel learning. Experiments on a collection of benchmark data sets demonstrate the efficiency and effectiveness of the proposed algorithm.

1. Introduction

Kernel methods work by embedding the data into a high-dimensional (possibly infinite-dimensional) feature space, where the embedding is defined implicitly through a kernel function. Evaluating the kernel function on all pairs of data points produces a symmetric and positive semidefinite (PSD) kernel matrix. Support Vector Machine (SVM) with a positive semidefinite kernel matrix has been applied successfully in numerous classification tasks including face recognition, image retrieval, and micro-array gene expression data analysis (Cristianini & Shawe-Taylor, 2000; Schölkopf & Smola, 2001; Tong & Chang, 2001). The PSD property of the kernel matrix ensures the existence of a Reproducing Kernel Hilbert Space (RKHS) and results in a convex formulation for SVM. Thus, a global optimal solution exists.

In practice, however, similarity matrices generated from many applications may not be PSD (Qamra et al., 2005; Roth et al., 2003a; Shimodaira et al., 2001). The problem of learning with a non-PSD similarity matrix (indefinite kernel) has been addressed by many researchers (Wu et al., 2005; Haasdonk, 2005; Lin & Lin, 2003). One simple and popular approach is to generate a PSD kernel matrix by transforming the spectrum of the indefinite kernel matrix (Wu et al., 2005). Several representative transformation methods include *denoise* which neglects the negative eigenvalues (Graepel et al., 1998; Pekalska et al., 2002), *flip* which flips the sign of the negative eigenvalues (Graepel et al., 1998), *diffusion* which applies matrix diffusion on the indefinite kernel (Kondor & Lafferty, 2002), and *shift* which shifts all the eigenvalues by a positive constant (Roth et al., 2003b). One common limitation of these approaches is that the transformation may lead to the loss of valuable information in the data.

Several other works use the non-PSD similarity matrix as a kernel, but they change the formulation of SVM. In (Lin & Lin, 2003), an SMO-type method is proposed to find stationary points for the non-convex dual formulation of SVM with a non-PSD sigmoid kernel. However, this method is based on the assumption that a corresponding RKHS still exists such that SVM formulations are valid. Haasdonk (2005) interprets learning with an indefinite kernel as the minimization of distance between two convex hulls in some pseudo-Euclidean (pE) space. However, it assumes that the representer theorem holds in such a pE space. Ong et al. (2004) associate the indefinite kernels with a Reproducing Kernel Kreĭn Space (RKKS), in which a general representer theorem exists and a regularized risk functional can be defined.

Recently, Luss and d'Aspremont (2007) propose a regularized SVM formulation, in which the indefinite kernel matrix is considered as a noisy observation of some unknown PSD one (proxy kernel). One attractive property

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

of this formulation is that the support vectors as well as the proxy kernel can be found simultaneously. However, the convex reformulation in (Luss & d'Aspremont, 2007) involves a nondifferentiable objective function. To facilitate the calculation of the gradient, Luss and d'Aspremont (2007) quadratically smoothed the objective function, resulting in two algorithms including the projected gradient method and the analytic center cutting plan method.

In this paper, we study the problem of training SVM with an indefinite kernel matrix following the formulation in (Luss & d'Aspremont, 2007). We show that this problem can be reformulated as a semi-infinite quadratically constrained linear program (SIQCLP), which includes a finite number of optimization variables with an infinite number of constraints. We then propose an iterative algorithm to solve this SIQCLP problem, which consists of two key steps: computing an intermediate SVM solution by solving a quadratically constraint linear program with a restricted subset of constraints, and updating the subset of constraints based on the obtained intermediate SVM solution. We further show the convergence property of the proposed iterative algorithm.

One limitation of the proposed algorithm is that the computational cost for solving the quadratically constraint linear program depends on the number of constraints, which gradually increases during the iteration. We propose to improve the efficiency of the iterative algorithm by pruning inactive constraints at each iteration. We show that such pruning will not affect the convergence property of the algorithm. In addition, we show the close relationship between the proposed SIQCLP formulation and multiple kernel learning (MKL). More specifically, the intermediate quadratically constraint linear program with a restricted subset of constraints is shown to be equivalent to a regularized version of the multiple kernel learning formulation in (Lanckriet et al., 2004). Thus, efficient algorithms for MKL (Lanckriet et al., 2004; Rakotomamonjy et al., 2007; Sonnenburg et al., 2006) can be applied to solve the SIQCLP problem. We have performed experiments on a collection of benchmark data sets. The presented experimental results demonstrate the efficiency and effectiveness of the proposed algorithm.

2. Background

Assume $K \in \mathbb{R}^{n\times n}$ is a valid kernel matrix, that is, K is positive semidefinite (PSD). Let $y = [y_1, \cdots, y_n] \in \mathbb{R}^n$ be the vector of class labels, where $y_i \in \{-1, +1\}$. The dual formulation of 1-norm soft margin SVM classification is given by (Schölkopf & Smola, 2001):

$$\begin{aligned} \max_{\alpha\in\mathbb{R}^d} \quad & \alpha^T e - \tfrac{1}{2}\alpha^T Y K Y \alpha \\ \text{subject to} \quad & \alpha^T y = 0,\ 0 \le \alpha \le C, \end{aligned} \tag{1}$$

where α is the vector of Lagrange dual variables, $Y = \text{diag}(y)$, C is a pre-specified parameter, and e is a vector of all ones of length n.

Since K is PSD, the optimization problem in Eq. (1) is a convex Quadratic Program (QP) (Boyd & Vandenberghe, 2004); hence a global optimal solution can be found via standard optimization techniques such as primal-dual interior point methods (Nocedal & Wright, 1999). In practice, however, many similarity matrices may be non-PSD (indefinite kernels), including sigmoid kernels (Vapnik, 1995) for various values of its parameters and hyperbolic tangent kernels (Smola et al., 2000). Additional examples include the protein sequence similarity measures based on Smith-Waterman and BLAST scores.

In (Luss & d'Aspremont, 2007), the indefinite kernel is considered as a noisy observation of some unknown PSD kernel (proxy kernel), and the following max-min optimization problem is proposed for simultaneous proxy kernel learning and SVM classification:

$$\begin{aligned} \max_{\alpha\in\mathbb{R}^d} \min_{K\in\mathbb{R}^{d\times d}} \quad & \alpha^T e - \tfrac{1}{2}\alpha^T Y K Y \alpha + \rho\|K - K_0\|_F^2 \\ \text{subject to} \quad & \alpha^T y = 0,\ 0 \le \alpha \le C,\ K \succeq 0, \end{aligned} \tag{2}$$

where K_0 is a pre-specified indefinite kernel matrix, K is the unknown proxy kernel matrix, and $\rho > 0$ is the pre-specified parameter, and $||\cdot||_F$ denotes the Frobenius norm of a matrix (Golub & Van Loan, 1996).

The objective function in Eq. (2) is convex in K and concave in α, thus a global optimal solution exists. However, direct optimization of Eq. (2) in terms of both α and K leads to a complex optimization problem involving nondifferentiable objective function (Luss & d'Aspremont, 2007). To facilitate the calculation of the gradient, Luss and d'Aspremont (2007) quadratically smoothed the objective function. Two algorithms including the projected gradient method and the analytic center cutting plan method are proposed for the proposed formulation.

3. Problem Formulation

We propose to solve the optimization problem in Eq. (2) by first reformulating it as a semi-infinite program (SIP) (Hettich & Kortanek, 1993a). The SIP problem refers to optimization problems that maximizes the functional $F(z)$ subject to a system of constraints on z, expressed as $g(z, t) \le 0$ for all t in some set B. When the objective is linear and the constraints are quadratic, the optimization problem is known as semi-infinite quadratically constrained linear program (SIQCLP).

For notational simplicity, we denote the objective function

in Eq. (2) as:

$$S(\alpha, K) = \alpha^T e - \frac{1}{2}\alpha^T YKY\alpha + \rho\|K - K_0\|_F^2. \quad (3)$$

The optimal solution to the max-min problem in Eq. (2) is a saddle-point for the function $S(\alpha, K)$ subject to the constraints in Eq. (2). Let (α^*, K^*) be optimal to Eq. (2). For any feasible α and K in Eq. (2), we have

$$S(\alpha, K^*) \le S(\alpha^*, K^*) \le S(\alpha^*, K); \quad (4)$$

moreover, it can be verified that

$$S(\alpha, K^*) = \min_{\tilde{K}\succeq 0} S(\alpha, \tilde{K}) \le S(\alpha, K). \quad (5)$$

By adding an additional variable $t \in \mathbb{R}$, the max-min optimization problem in Eq. (2) can be reformulated into a SIQCLP problem as follows:

$$\begin{aligned} \max_{\alpha\in\mathbb{R}^d,\, t\in\mathbb{R}} \quad & t \\ \text{subject to} \quad & \alpha^T y = 0,\ 0 \le \alpha \le C \\ & t \le S(\alpha, K),\ \forall\ K \succeq 0. \end{aligned} \quad (6)$$

The optimization problem in Eq. (6) has two optimization variables (t and α) with an infinite number of (quadratic) constraints, i.e., one quadratic constraint $t \le S(\alpha, K)$ for each kernel matrix K. When there is only one (fixed) kernel matrix K involved in Eq. (6), this optimization problem reduces to a standard SVM problem.

4. Algorithm

We propose an iterative algorithm to solve Eq. (6), which is guaranteed to converge to a global optimum. The algorithm is closely related to the *bundle method* (Hiriart-Urruty & Lemarechal, 1993; Teo et al., 2007).

The optimization problem in Eq. (6) maximizes its objective function with respect to two variables t and α with an infinite number of (quadratic) constraints. We approach the optimum by optimizing the variables t and α with a restricted subset of the infinite number of constraints, and then updating the constraint subset based on the obtained suboptimal t and α in an iterative manner. It is similar to the strategy presented in (Sonnenburg et al., 2006). The algorithm belongs to a family of algorithms for solving general SIP problems called the *exchange methods*, in which the constraints are exchanged at each iteration. The global optimality property of the final solution after convergence is guaranteed (Hettich & Kortanek, 1993b).

For a restricted subset of constraints, called a *localization* set of kernel matrices $\mathbf{K} = \{K_i\}_{i=1}^p$, the intermediate suboptimal t and α can be computed by solving the following optimization problem:

$$\begin{aligned} \max_{\alpha\in\mathbb{R}^d,\, t\in\mathbb{R}} \quad & t \\ \text{subject to} \quad & \alpha^T y = 0,\ 0 \le \alpha \le C \\ & t \le S(\alpha, K_i),\ i = 1, \cdots, p. \end{aligned} \quad (7)$$

This corresponds to a quadratically constrained linear program (QCLP) with p quadratic constraints. The optimization problem is often called the *restricted master problem*, and the obtained suboptimal solution pair (α, t) is called *intermediate solution*. Note that this QCLP problem can be solved efficiently using general optimization solvers.

To approach the optimum of the SIQCLP problem from a given intermediate solution pair (t, α), we find the next constraint with the maximum violation, i.e., the kernel matrix K that minimizes $S(\alpha, K)$. The optimal K can be computed by solving the following minimization problem:

$$\min_K S(\alpha, K) = \min_K \rho\|K - K_0\|_F^2 - \frac{1}{2}\alpha^T YKY\alpha. \quad (8)$$

If the optimal K^* to Eq. (8) satisfies $t \le S(\alpha, K^*)$, then the current intermediate solution pair (t, α) is optimal for the optimization problem in Eq. (6). Otherwise, K^* is added into the localization set $\mathbf{K}$. The intermediate solution pair (t, α) is updated by solving the restricted master problem based on the updated $\mathbf{K}$. We repeat this iterative process until convergence. The final solution is guaranteed to be globally optimal (Sonnenburg et al., 2006).

It can be shown (Luss & d'Aspremont, 2007) that the optimal K^* to the optimization problem in Eq. (8) for a fixed α is given by:

$$K^* = \left(K_0 + Y\alpha\alpha^T Y/(4\rho)\right)_+. \quad (9)$$

Here X_+ refers to the positive part of a symmetric matrix X, i.e., $X_+ = \sum_i \max(0, \lambda_i) x_i x_i^T$, where λ_i and x_i are the i-th eigenvalue and eigenvector of X.

Based on the discussions above, we propose an iterative algorithm to solve the optimization in Eq. (6). The pseudocode is presented in Algorithm 1. Note that the algorithm searches for a quadratic constraint (specified by K^*) with the maximum violation in step 1, then updates the intermediate solution (t, α), which is repeated iteratively until convergence. When no more constraints with violation can be found, i.e., all constraints are satisfied, Algorithm 1 converges. In practice, we determine the convergence by comparing an upper and lower bound of the objective as described in the next section.

4.1. Convergence Analysis

We analyze the convergence property of Algorithm 1. Recall that Algorithm 1 alternates between the updating of the

Algorithm 1 Proposed Algorithm

Input: Indefinite kernel K_0 and class label vector y;
Output: α and $\mathbf{K}$;
Initialization: $(t_0, \alpha_0) \leftarrow \max_\alpha S(\alpha, (K_0)_+)$;
Initialization: $i \leftarrow 1, \mathbf{K} = \varnothing$;
Do
  Step 1: compute K^* from Eq. (9) and $K_i \leftarrow K^*$;
  if $S(\alpha_{i-1}, K_i) \geq t_{i-1}$ **then** exit the loop;
    else update localization set $\mathbf{K} \leftarrow \mathbf{K} \cup \{K_i\}$;
  end if
  Step 2: compute (t_i, α_i) by solving Eq. (7);
  $i \leftarrow i + 1$;
until convergence

localization set $\mathbf{K}$ (step 1) and the updating of the intermediate solution pair (t, α) (step 2). At the i-th iteration, a new kernel matrix K_i is computed from Eq. (9) based on α_{i-1}. That is,

$$S(\alpha_{i-1}, K_i) = \min_{K \succeq 0} S(\alpha_{i-1}, K). \tag{10}$$

With the addition of K_i, the localization set is updated as $\mathbf{K} = \{K_j\}_{j=1}^i$. We denote

$$l_i^- = \max_{j \leq i} S(\alpha_{j-1}, K_j). \tag{11}$$

Let (t_i, α_i) be the solution pair to the optimization problem in Eq. (7) after the i-th iteration. Denote $u_i^+ = t_i$. That is,

$$\alpha_i = \arg\max_\alpha \left(\min_{K \in \mathbf{K}} S(\alpha, K) \right), \tag{12}$$

$$u_i^+ \equiv t_i = \min_{K \in \mathbf{K}} S(\alpha_i, K) = \max_\alpha \min_{K \in \mathbf{K}} S(\alpha, K), \tag{13}$$

where $\mathbf{K}$ is the updated restricted localization set.

The following theorem shows that Algorithm 1 makes continuous progress towards the optimal solution:

Theorem 4.1. *Let l_i^- and u_i^+ be defined in Eq. (11) and Eq. (13), respectively. Let (α^*, t^*) be the optimal solution pair to the optimization problem in Eq. (6). Then*

$$u_i^+ \geq t^* \geq l_i^-. \tag{14}$$

Moreover, the sequence $\{u_i^+\}$ is monotonically decreasing, and the sequences $\{l_i^-\}$ is monotonically increasing.

Proof. For any feasible α in Eq. (6), we have

$$\min_{K \in \mathbf{K}} S(\alpha, K) \geq \min_{K \succeq 0} S(\alpha, K). \tag{15}$$

It follows that the inequality above also holds for their corresponding pointwise maximum with respect to α. From Eq. (13) and the equality below

$$t^* = \max_{\alpha \in \mathbb{R}^d} \min_{K \succeq 0} S(\alpha, K), \tag{16}$$

we have $u_i^+ \geq t^*$. On the other hand, it follows from Eq. (10) that

$$K_j = \arg\min_{K \succeq 0} S(\alpha_{j-1}, K), \;\; j = 1, \cdots, i. \tag{17}$$

Thus $\{(\alpha_{j-1}, S(\alpha_{j-1}, K_j)), j = 1, \cdots, i\}$ is a set of feasible solution pairs to the optimization problem in Eq. (6). Since (α^*, t^*) is the optimal solution pair to Eq. (6), we have $t^* \geq S(\alpha_{j-1}, K_j)$, for $j = 1, \cdots, i$. If follows from Eq. (11) that $t^* \geq l_i^-$.

From Eq. (13), we have

$$u_i^+ = \max_\alpha \min_{K \in \mathbf{K}} S(\alpha, K). \tag{18}$$

Thus, the sequence $\{u_i^+\}$ is monotonically decreasing, as the size of localization set $\mathbf{K}$ monotonically increases. It follows from Eq. (11) that $\{l_i^-\}$ is monotonically increasing. This completes the proof of the theorem. □

Based on the result in Theorem 4.1, we can use the gap between u_i^+ and l_i^- to trace the convergence of Algorithm 1. When this gap is smaller that a pre-specified tolerance, we stop the algorithm.

4.2. Pruning Inactive Constraints

In Algorithm 1, a quadratically constraint linear program (QCLP) is involved at each iteration (step 2). The computational cost for solving QCLP grows with the number of quadratic constraints, which increases by one after each iteration. We show that at each iteration, many (inactive) quadratic constraints can be pruned, while retaining the convergence property of the algorithm.

Assume that (α_i, t_i) is the optimal solution pair at the i-th iteration with $\mathbf{K}^i = \{K_j\}_{j=1}^p$ as the localization set. We further partition $\mathbf{K}^i$ into two subsets as $\mathbf{K}^i = \mathbf{K}_{act}^i \cup \mathbf{K}_{ina}^i$ such that

$$t_i = S(\alpha_i, K), \;\; \forall \; K \in \mathbf{K}_{act}^i, \tag{19}$$

and

$$t_i < S(\alpha_i, K), \;\; \forall \; K \in \mathbf{K}_{ina}^i, \tag{20}$$

where the equalities in Eq. (19) and inequalities in Eq. (20) are called *active* and *inactive* constraints (Nocedal & Wright, 1999), respectively. Let K^* be the optimal matrix given in Eq. (9) with $\alpha = \alpha_i$. In Algorithm 1, we use $\mathbf{K}^i \cup K^*$ as the new localization set. We propose to improve the efficiency by removing the inactive constraints from the optimization and updating the new localization set $\mathbf{K}^{i+1}$ as $\mathbf{K}^{i+1} = \mathbf{K}_{act}^i \cup K^*$. Let (α_{i+1}, t_{i+1}) be the optimal solution pair at the $(i+1)$-th iteration with the updated $\mathbf{K}^{i+1}$ as the localization set. To show the convergence, we need to prove $t_{i+1} \leq t_i$, as summarized below:

Lemma 4.1. *Let t_i and t_{i+1} be defined as above. Then $t_{i+1} \leq t_i$.*

Proof. Prove by contradiction. Assume that $t_{i+1} \leq t_i$ doesn't hold, i.e., $t_{i+1} > t_i$.

Let $(\tilde{\alpha}, \tilde{t})$ be the optimal solution pair to the optimization problem in Eq. (7) with $\mathbf{K}^i_{act}$ as the localization set. It is clear that $t_{i+1} \leq \tilde{t}$, as $\mathbf{K}^i_{act} \subset \mathbf{K}^{i+1} = \mathbf{K}^i_{act} \cup K^*$. Thus $\tilde{t} \geq t_{i+1} > t_i$.

For any $K \in \mathbf{K}^i_{act}$, we have $S(\tilde{\alpha}, K) \geq \tilde{t}$. Since $\tilde{t} > t_i$, the following holds for any $K \in \mathbf{K}^i_{act}$:

$$S(\tilde{\alpha}, K) \geq \tilde{t} > t_i = S(\alpha_i, K). \tag{21}$$

For any $\eta \in (0, 1)$, let $\beta = \eta\tilde{\alpha} + (1-\eta)\alpha_i$. Since $S(\alpha, K)$ is concave on α and $t_i = S(\alpha_i, K)$ for any $K \in \mathbf{K}^i_{act}$ from Eq. (19), the following holds for any $K \in \mathbf{K}^i_{act}$:

$$S(\beta, K) \geq \eta S(\tilde{\alpha}, K) + (1-\eta) S(\alpha_i, K) > t_i. \tag{22}$$

Recall that for any $K \in \mathbf{K}^i_{ina}$, we have $S(\alpha_i, K) > t_i$. Since $S(\alpha, K)$ is continuous on α, and $\mathbf{K}^i_{ina}$ is a finite set, there exists an $\epsilon \in (0, 1)$ sufficiently close to zero such that

$$S(\beta_\epsilon, K) > t_i, \ \ \forall\ K \in \mathbf{K}^i_{ina}, \tag{23}$$

where $\beta_\epsilon = \epsilon\tilde{\alpha} + (1-\epsilon)\alpha_i$.

It follows from Eqs. (22) and (23) that

$$\hat{t} = \min_{K \in \mathbf{K}^i} S(\beta_\epsilon, K) > t_i. \tag{24}$$

Since $(\beta_\epsilon, \hat{t})$ is a feasible solution pair to Eq. (7) with $\mathbf{K}^i$ as the localization set, Eq. (24) contradicts with our assumption that (α_i, t_i) is the optimal solution pair to Eq. (7). This completes the proof of the lemma. □

Lemma 4.1 shows that the upper bound defined in Eq. (13) with the inactive constraints pruned as above decreases monotonically. As the lower bound defined in Eq. (11) always increases monotonically, the proposed pruning strategy retains the convergence property in Theorem 4.1.

5. Relationship with Multiple Kernel Learning

We show the close relationship between the proposed SIQCLP formulation in Eq. (6) and the multiple kernel learning formulation in (Lanckriet et al., 2004).

For a given set of kernel matrices $\{K_i\}_{i=1}^p$ and a class label vector y, Lanckriet et al. (2004) propose to learn an optimal convex combination of the p pre-specified kernel matrices by solving the following optimization problem:

$$\begin{aligned} \min_{\{\theta_i\}} \max_{\alpha \in \mathbb{R}^d} \quad & \alpha^T e - \frac{1}{2}\alpha^T Y \left(\sum_{i=1}^p \theta_i K_i\right) Y\alpha \\ \text{subject to} \quad & \sum_{i=1}^p \theta_i \ \text{tr}(K_i) = 1, \\ & \alpha^T y = 0, \ \ 0 \leq \alpha \leq C, \end{aligned} \tag{25}$$

where $Y = \text{diag}(y)$, and C is the pre-specified parameter.

Recall that K_0 is a indefinite kernel matrix. For each of the given PSD kernel matrix K_i, we denote

$$\mu_i = \|K_i - K_0\|_F^2, \ \ i = 1, \cdots, p, \tag{26}$$

where μ_i measures the distance between K_i and K_0 in terms of Frobenius norm. Consider a regularized version of the optimization problem in Eq. (25) given by:

$$\begin{aligned} \min_{\{\theta_i\}} \max_{\alpha \in \mathbb{R}^d} \quad & \alpha^T e - \frac{1}{2}\alpha^T Y \left(\sum_{i=1}^p \theta_i K_i\right) Y\alpha + \rho \sum_{i=1}^p \theta_i \mu_i \\ \text{subject to} \quad & \sum_{i=1}^p \theta_i = 1, \ \ \alpha^T y = 0, \ \ 0 \leq \alpha \leq C, \end{aligned} \tag{27}$$

where ρ is the pre-specified parameter as in Eq. (6). The optimization problem in Eq. (27) computes an optimal linear combination of the p pre-specified kernel matrices by maximizing the margin for SVM classification, while penalizing kernels with a large deviation from K_0.

The following theorem shows the equivalence relationship between the regularized MKL problem in Eq. (27) and the SIQCLP formulation in Eq. (7).

Theorem 5.1. *Let $\{K_i\}_{i=1}^p$ be a set of pre-specified PSD kernel matrices. Then the optimization problem in Eq. (7) is equivalent to the one in Eq. (27).*

Proof. Since all constraints in Eq. (27) are linear and the objective is convex on $\{\theta_i\}$ and concave on α, the minimization and the maximization in Eq. (27) can be exchanges. This leads to the following optimization problem:

$$\begin{aligned} & \max_{\alpha \in \mathbb{R}^d} \min_{K \succeq 0} \alpha^T e - \frac{1}{2}\alpha^T YKY\alpha + \rho \sum_{i=1}^p \theta_i \mu_i \\ = \ & \max_{\alpha \in \mathbb{R}^d} \min_{\sum \theta_i = 1} \alpha^T e - \frac{1}{2}\alpha^T Y \sum_{i=1}^p \theta_i K_i Y\alpha + \rho \sum_{i=1}^p \theta_i \mu_i \\ = \ & \max_{\alpha \in \mathbb{R}^d} \min_{\sum \theta_i = 1} \left(\sum_{i=1}^p \theta_i t_i\right), \end{aligned} \tag{28}$$

where t_i is defined as

$$t_i = \left(\alpha^T e - \frac{1}{2}\alpha^T Y K_i Y\alpha + \rho\mu_i\right). \tag{29}$$

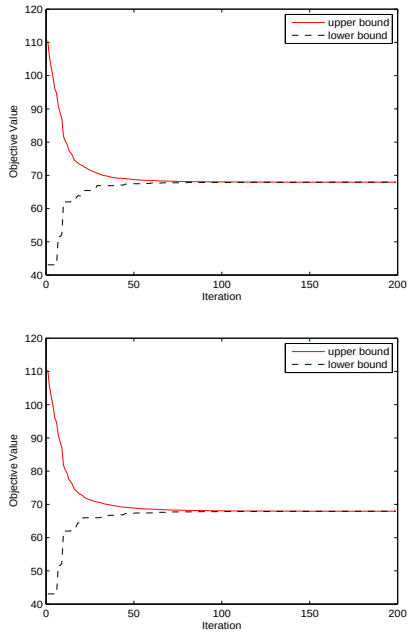

Figure 1. Convergence of the proposed algorithms without the pruning strategy applied (top graph) and with the pruning strategy applied (bottom graph).

From Eq. (28) and Eq. (29), the optimization problem in Eq. (27) can be reformulated as:

$$\begin{aligned} \max_{\alpha\in\mathbb{R}^d,\ t\in\mathbb{R}} \quad & t \\ \text{subject to} \quad & \alpha^T y = 0,\ \ 0 \le \alpha \le C, \\ & t \le \alpha^T e - \frac{1}{2}\alpha^T Y K_i Y \alpha + \rho\mu_i, \\ & i = 1, \cdots, p, \end{aligned}$$

which is equivalent to the SIQCLP formulation given in Eq. (7). We complete the proof of this theorem. □

The equivalent result in Theorem 5.1 implies that our proposed SIQCLP formulation in Eq. (6) can be solved by recycling existing efficient MKL implementations (Rakotomamonjy et al., 2007; Sonnenburg et al., 2006).

6. Experiments

We experimentally evaluate the convergence property of the proposed algorithms. We also compare the proposed algorithms with other representative ones using a collection of benchmark data sets.

6.1. Experimental Setup

We use several benchmark data sets from the UCI repository (Newman et al., 1998) including Sonar, Ionosphere, Breast Cancer, and Diabetes, as well as USPS (Hull, 1994) and Heart[1]. For USPS, we select two classes corresponding to two digits 3 and 5, and randomly select 600 samples for each digit.

In our simulation study, we first generate Gaussian kernels from the data with the parameter value estimated via cross-validation and then construct indefinite kernels through perturbation. More specifically, we randomly generate a matrix E with zero mean and identity covariance matrix, and then apply $\xi\hat{E}$ as the perturbation, where $\hat{E} = (E + E^T)/2$ and $\xi > 0$ is small constant. We set $C = 1$ in SVM. The value of ρ is estimated via cross-validation.

6.2. Convergence

In this experiment, we empirically evaluate the convergence property of the proposed algorithms with and without pruning. We also investigate the number of kernel matrices involved when the pruning strategy is employed. We use the sonar data set for this study, and the perturbation matrix is set to be $0.1\hat{E}$.

The results are presented in Figure 1. The top graph in Figure 1 shows the convergence of the upper bound as well as the lower bound of the objective value when the algorithm without the pruning strategy is applied. The bottom graph shows the convergence result for the case when the pruning strategy is applied. We can observe from the figure that the upper bound and lower bound curves approach each other gradually during the iteration. More specifically, the upper bound monotonically decreases, while the lower bound monotonically increases, both approaching the optimal objective value. This is consistent with our convergence results in Section 4.1. Interestingly, our results show that the proposed algorithms with or without the pruning strategy applied result in a similar convergent rate. We further observe that the gap between the upper and lower bound is less that 10^{-2} after about 150 iterations, and it takes about 600 iterations to attain a gap smaller than 10^{-5}.

Figure 2 shows the number of kernels (the size of the localization set) involved at each iteration. We can observe from the figure that with the pruning strategy, the number of kernels involved in the algorithm stabilizes around a small constant. In contrast, this number increases gradually when the pruning strategy is not applied. These results demonstrate the advantage of the proposed pruning strategy.

We show in Figure 3 the generalization performance (measured by classification accuracy) of the proposed algorithm with pruning at each of the first 70 iterations. We observe a large variation at the first few iterations, while the accuracy becomes more stable after about 40 iterations. We further run the algorithm until convergence and the resulting accu-

Table 1. Comparison of the proposed algorithm with other representative algorithms in terms of classification accuracy (in percentage). All values shown in the table are the averaged ones over 10 partitions of the data into training and test sets with a ratio $4:1$. λ^- num (λ^+ num) denotes the number of negative (positive) eigenvalues; λ_{min} (λ_{max}) denotes the minimum (maximum) eigenvalue; $|\lambda_{max}/\lambda_{min}|$ denotes the ratio of the absolute values of λ_{max} and λ_{min}. SVM refers to applying indefinite kernel in the SVM formulation directly, while indefinite SVM refers to our proposed algorithm with the pruning strategy applied.

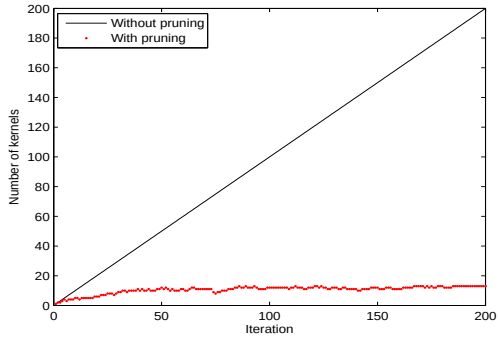

Figure 2. The number of kernel matrices involved for the proposed algorithms with and without the pruning.

racy is about 76%. We obtain a similar observation from other data sets. This implies that an early-stopping strategy could be employed for the proposed algorithm.

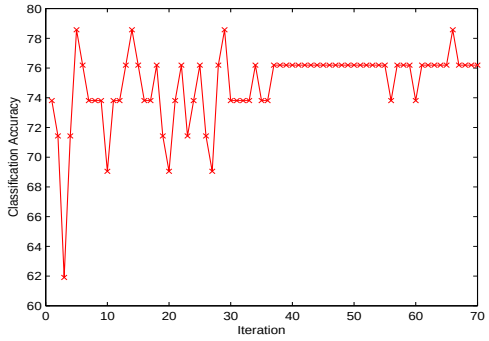

Figure 3. Generalization performance (measured by classification accuracy in percentage) of the proposed algorithm with pruning.

6.3. Classification Performance

In this experiment, we compare our proposed algorithms (Indefinite SVM) with other representative ones including Denoise, Flip, Shift, and SVM using indefinite kernels in terms of classification accuracy. The presented experimental results are averaged over 10 random partitions of the data into a training and a test set with a ratio $4:1$.

The experimental results are summarized in Table 1. We also report the maximum and minimum eigenvalues of the indefinite kernel matrix in the table. We can observe from the table that Indefinite SVM is competitive with all other algorithms in most cases. It outperforms all other algorithms on the Sonar, Ionosphere, Heart, and Diabetes data sets, where the perturbed kernel matrix has a relatively small ratio $|\lambda_{max}/\lambda_{min}|$. For the other two data sets including Breast Cancer and USPS-3-5, where the perturbed kernel matrix has a relatively large ratio $|\lambda_{max}/\lambda_{min}|$, Indefinite SVM is comparable to the best among all other algorithms. These results demonstrate the effectiveness of the proposed learning algorithm, especially when the indefinite kernel matrix is highly non-PSD. A similar trend has been observed in (Luss & d'Aspremont, 2007).

7. Conclusion

In this paper, we study the problem of training SVM with an indefinite kernel matrix following the formulation in (Luss & d'Aspremont, 2007). We propose a semi-infinite quadratically constrained linear program formulation, which can be solved iteratively. The algorithm alternates between the computation of an intermediate SVM solution by solving a quadratically constraint linear program with a subset of constraints, and the computation of the new constraint set based on the obtained intermediate SVM solution. We further propose to improve the efficiency of the iterative algorithm by pruning inactive constraints at each iteration. We show that such pruning will not affect the convergence property of the algorithm. In addition, we show the close relationship between the proposed SIQCLP formulation and multiple kernel learning. The presented analysis provides new insights into the nature of this learning formulation.

We have performed a simulation study using a collection of benchmark data sets. Our results verify the convergence property of the proposed algorithms. Our empirical results show that the proposed algorithms with or with-

out the pruning strategy applied result in a similar convergent rate, while a much smaller number of kernel matrices are involved when the pruning strategy is applied. Our results also demonstrate the favorable performance of the proposed algorithms in terms of classification accuracy in comparison with several other representative algorithms. Our future works include the analysis of the convergence rate of the proposed algorithms similar to the analysis conducted in (Teo et al., 2007), the estimation of the regularization parameter ρ, and the application of the proposed algorithms to real-world applications involving indefinite kernels such as protein sequence and structure analysis based on various sequence/structure alignment measures.

Abstract

We consider the problem of learning to follow a desired trajectory when given a small number of demonstrations from a sub-optimal expert. We present an algorithm that (i) extracts the—initially unknown—desired trajectory from the sub-optimal expert's demonstrations and (ii) learns a local model suitable for control along the learned trajectory. We apply our algorithm to the problem of autonomous helicopter flight. In all cases, the autonomous helicopter's performance exceeds that of our expert helicopter pilot's demonstrations. Even stronger, our results significantly extend the state-of-the-art in autonomous helicopter aerobatics. In particular, our results include the first autonomous tic-tocs, loops and hurricane, vastly superior performance on previously performed aerobatic maneuvers (such as in-place flips and rolls), and a complete airshow, which requires autonomous transitions between these and various other maneuvers.

1. Introduction

Many tasks in robotics can be described as a trajectory that the robot should follow. Unfortunately, specifying the desired trajectory and building an appropriate model for the robot dynamics along that trajectory are often non-trivial tasks. For example, when asked to describe the trajectory that a helicopter should follow to perform an aerobatic flip, one would have to specify a trajectory that (i) corresponds to the aerobatic flip task, and (ii) is consistent with the helicopter's dynamics. The latter requires (iii) an accurate helicopter dynamics model for all of the flight regimes encountered in the vicinity of the trajectory. These coupled tasks are non-trivial for systems with complex dynamics, such as helicopters. Failing to adequately address these points leads to a significantly more difficult control problem.

In the apprenticeship learning setting, where an expert is available, rather than relying on a hand-engineered target trajectory, one can instead have the expert demonstrate the desired trajectory. The expert demonstration yields both a desired trajectory for the robot to follow, as well as data to build a dynamics model in the vicinity of this trajectory. Unfortunately, perfect demonstrations can be hard (if not impossible) to obtain. However, repeated expert demonstrations are often suboptimal in different ways, suggesting that a large number of suboptimal expert demonstrations could implicitly encode the ideal trajectory the suboptimal expert is trying to demonstrate.

In this paper we propose an algorithm that approximately extracts this implicitly encoded optimal demonstration from multiple suboptimal expert demonstrations, and then builds a model of the dynamics in the vicinity of this trajectory suitable for high-performance control. In doing so, the algorithm learns a target trajectory and a model that allows the robot to not only mimic the behavior of the expert but even perform significantly better.

Properly extracting the underlying ideal trajectory from a set of suboptimal trajectories requires a significantly more sophisticated approach than merely averaging the states observed at each time-step. A simple arithmetic average of the states would result in a trajectory that does not even obey the constraints of the dynamics model. Also, in practice, each of the demonstrations will occur at different rates so that attempting to combine states from the same time-step in each trajectory will not work properly.

We propose a generative model that describes the expert demonstrations as noisy observations of the unobserved, intended target trajectory, where each demonstration is possibly warped along the time axis. We present an EM algorithm—which uses a (extended) Kalman smoother and an efficient dynamic programming algorithm to perform the E-step—to both infer the unobserved, intended target trajectory and a time-alignment of all the demonstrations. The time-aligned demonstrations provide the appropriate data to learn

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

good local models in the vicinity of the trajectory—such trajectory-specific local models tend to greatly improve control performance.

Our algorithm allows one to easily incorporate prior knowledge to further improve the quality of the learned trajectory. For example, for a helicopter performing in-place flips, it is known that the helicopter can be roughly centered around the same position over the entire sequence of flips. Our algorithm incorporates this prior knowledge, and successfully factors out the position drift in the expert demonstrations.

We apply our algorithm to learn trajectories and dynamics models for aerobatic flight with a remote controlled helicopter. Our experimental results show that (i) our algorithm successfully extracts a good trajectory from the multiple sub-optimal demonstrations, and (ii) the resulting flight performance significantly extends the state of the art in aerobatic helicopter flight (Abbeel et al., 2007; Gavrilets et al., 2002). Most importantly, our resulting controllers are the first to perform as well, and often even better, than our expert pilot.

We posted movies of our autonomous helicopter flights at:

`http://heli.stanford.edu`

The remainder of this paper is organized as follows: Section 2 presents our generative model for (multiple) suboptimal demonstrations; Section 3 describes our trajectory learning algorithm in detail; Section 4 describes our local model learning algorithm; Section 5 describes our helicopter platform and experimental results; Section 6 discusses related work.

2. Generative Model

2.1. Basic Generative Model

We are given M demonstration trajectories of length N^k, for $k = 0..M-1$. Each trajectory is a sequence of states, s_j^k, and control inputs, u_j^k, composed into a single state vector:

$$y_j^k = \begin{bmatrix} s_j^k \\ u_j^k \end{bmatrix}, \text{ for } j = 0..N^k - 1, k = 0..M-1.$$

Our goal is to estimate a "hidden" target trajectory of length T, denoted similarly:

$$z_t = \begin{bmatrix} s_t^\star \\ u_t^\star \end{bmatrix}, \text{ for } t = 0..T-1.$$

We use the following notation: $\mathbf{y} = \{y_j^k \mid j = 0..N^k - 1, k = 0..M-1\}$, $\mathbf{z} = \{z_t \mid t = 0..T-1\}$, and similarly for other indexed variables.

The generative model for the ideal trajectory is given by an initial state distribution $z_0 \sim \mathcal{N}(\mu_0, \Sigma_0)$ and an approximate model of the dynamics

$$z_{t+1} = f(z_t) + \omega_t^{(z)}, \quad \omega_t^{(z)} \sim \mathcal{N}(0, \Sigma^{(z)}). \tag{1}$$

The dynamics model does not need to be particularly accurate—in our experiments, we use a single generic model learned from a large corpus of data that is not specific to the trajectory we want to perform. In our experiments (Section 5) we provide some concrete examples showing how accurately the generic model captures the true dynamics for our helicopter.[1]

Our generative model represents each demonstration as a set of independent "observations" of the hidden, ideal trajectory $\mathbf{z}$. Specifically, our model assumes

$$y_j^k = z_{\tau_j^k} + \omega_j^{(y)}, \quad \omega_j^{(y)} \sim \mathcal{N}(0, \Sigma^{(y)}). \tag{2}$$

Here τ_j^k is the time index in the hidden trajectory to which the observation y_j^k is mapped. The noise term in the observation equation captures both inaccuracy in estimating the observed trajectories from sensor data, as well as errors in the maneuver that are the result of the human pilot's imperfect demonstration.[2]

The time indices τ_j^k are unobserved, and our model assumes the following distribution with parameters d_i^k:

$$\mathbb{P}(\tau_{j+1}^k | \tau_j^k) = \begin{cases} d_1^k & \text{if } \tau_{j+1}^k - \tau_j^k = 1 \\ d_2^k & \text{if } \tau_{j+1}^k - \tau_j^k = 2 \\ d_3^k & \text{if } \tau_{j+1}^k - \tau_j^k = 3 \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

$$\tau_0^k \equiv 0. \tag{4}$$

To accommodate small, gradual shifts in time between the hidden and observed trajectories, our model assumes the observed trajectories are subsampled versions of the hidden trajectory. We found that having a hidden trajectory length equal to twice the average length of the demonstrations, i.e., $T = 2(\frac{1}{M}\sum_{k=1}^{M} N^k)$, gives sufficient resolution.

Figure 1 depicts the graphical model corresponding to our basic generative model. Note that each observation y_j^k depends on the hidden trajectory's state at time τ_j^k, which means that for τ_j^k unobserved, y_j^k depends on all states in the hidden trajectory that it could be associated with.

2.2. Extensions to the Generative Model

Thus far we have assumed that the expert demonstrations are misaligned copies of the ideal trajectory

[1] The state transition model also predicts the controls as a function of the previous state and controls. In our experiments we predict $u_{t+1}^\star$ as $u_t^\star$ plus Gaussian noise.

[2] Even though our observations, $\mathbf{y}$, are correlated over time with each other due to the dynamics governing the observed trajectory, our model assumes that the observations y_j^k are independent for all $j = 0..N^k - 1$ and $k = 0..M-1$.

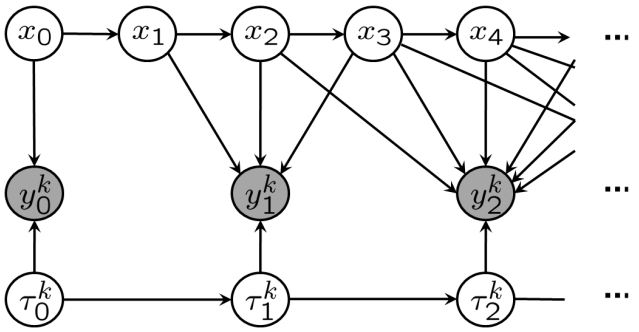

Figure 1. Graphical model representing our trajectory assumptions. (Shaded nodes are observed.)

merely corrupted by Gaussian noise. Listgarten et al. have used this same basic generative model (for the case where $f(\cdot)$ is the identity function) to align speech signals and biological data (Listgarten, 2006; Listgarten et al., 2005). We now augment the basic model to account for other sources of error which are important for modeling and control.

2.2.1. Learning Local Model Parameters

For many systems, we can substantially improve our modeling accuracy by using a time-varying model $f_t(\cdot)$ that is specific to the vicinity of the intended trajectory at each time t. We express f_t as our "crude" model, f, augmented with a bias term[3], $\beta_t^\star$:

$$z_{t+1} = f_t(z_t) + \omega_t^{(z)} \equiv f(z_t) + \beta_t^\star + \omega_t^{(z)}.$$

To regularize our model, we assume that $\beta_t^\star$ changes only slowly over time. We have $\beta_{t+1}^\star \sim \mathcal{N}(\beta_t^\star, \Sigma^{(\beta)})$.

We incorporate the bias into our observation model by computing the observed bias $\beta_j^k = y_j^k - f(y_{j-1}^k)$ for each of the observed state transitions, and modeling this as a direct observation of the "true" model bias corrupted by Gaussian noise. The result of this modification is that the ideal trajectory must not only look similar to the demonstration trajectories, but it must also obey a dynamics model which includes those errors consistently observed in the demonstrations.

2.2.2. Factoring out Demonstration Drift

It is often difficult, even for an expert pilot, during aerobatic maneuvers to keep the helicopter centered around a fixed position. The recorded position trajectory will often drift around unintentionally. Since these position errors are highly correlated, they are not explained well by the Gaussian noise term in our observation model.

To capture such slow drift in the demonstrated trajectories, we augment the latent trajectory's state with a "drift" vector δ_t^k for each time t and each demonstrated trajectory k. We model the drift as a zero-mean random walk with (relatively) small variance. The state observations are now noisy measurements of $z_t + \delta_t^k$ rather than merely z_t.

2.2.3. Incorporating Prior Knowledge

Even though it might be hard to specify the complete ideal trajectory in state space, we might still have prior knowledge about the trajectory. Hence, we introduce additional observations $\rho_t = \rho(z_t)$ corresponding to our prior knowledge about the ideal trajectory at time t. The function $\rho(z_t)$ computes some features of the hidden state z_t and our expert supplies the value ρ_t that this feature should take. For example, for the case of a helicopter performing an in-place flip, we use an observation that corresponds to our expert pilot's knowledge that the helicopter should stay at a fixed position while it is flipping. We assume that these observations may be corrupted by Gaussian noise, where the variance of the noise expresses our confidence in the accuracy of the expert's advice. In the case of the flip, the variance expresses our knowledge that it is, in fact, impossible to flip perfectly in-place and that the actual position of the helicopter may vary slightly from the position given by the expert.

Incorporating prior knowledge of this kind can greatly enhance the learned ideal trajectory. We give more detailed examples in Section 5.

2.2.4. Model Summary

In summary, we have the following generative model:

$$\begin{aligned}
z_{t+1} &= f(z_t) + \beta_t^\star + \omega_t^{(z)}, && (5)\\
\beta_{t+1}^\star &= \beta_t^\star + \omega_t^{(\beta)}, && (6)\\
\delta_{t+1}^k &= \delta_t^k + \omega_t^{(\delta)}, && (7)\\
\rho_t &= \rho(z_t) + \omega_t^{(\rho)}, && (8)\\
y_j^k &= z_{\tau_j^k} + \delta_j^k + \omega_j^{(y)}, && (9)\\
\tau_j^k &\sim \mathbb{P}(\tau_{j+1}^k | \tau_j^k) && (10)
\end{aligned}$$

Here $\omega_t^{(z)}, \omega_t^{(\beta)}, \omega_t^{(\delta)}, \omega_t^{(\rho)}, \omega_j^{(y)}$ are zero mean Gaussian random variables with respective covariance matrices $\Sigma^{(z)}, \Sigma^{(\beta)}, \Sigma^{(\delta)}, \Sigma^{(\rho)}, \Sigma^{(y)}$. The transition probabilities for τ_j^k are defined by Eqs. (3, 4) with parameters d_1^k, d_2^k, d_3^k (collectively denoted $\mathbf{d}$).

3. Trajectory Learning Algorithm

Our learning algorithm automatically finds the time-alignment indexes $\boldsymbol{\tau}$, the time-index transition probabilities $\mathbf{d}$, and the covariance matrices $\Sigma^{(\cdot)}$ by (approximately) maximizing the joint likelihood of the observed trajectories $\mathbf{y}$ and the observed prior knowl-

[3]Our generative model can incorporate richer local models. We discuss our choice of merely using biases in our generative trajectory model in more detail in Section 4.

edge about the ideal trajectory $\boldsymbol{\rho}$, while marginalizing out over the unobserved, intended trajectory $\mathbf{z}$. Concretely, our algorithm (approximately) solves

$$\max_{\boldsymbol{\tau},\Sigma^{(\cdot)},\mathbf{d}} \log \mathbb{P}(\mathbf{y}, \boldsymbol{\rho}, \boldsymbol{\tau} \; ; \; \Sigma^{(\cdot)}, \mathbf{d}). \tag{11}$$

Then, once our algorithm has found $\boldsymbol{\tau}, \mathbf{d}, \Sigma^{(\cdot)}$, it finds the most likely hidden trajectory, namely the trajectory $\mathbf{z}$ that maximizes the joint likelihood of the observed trajectories $\mathbf{y}$ and the observed prior knowledge about the ideal trajectory $\boldsymbol{\rho}$ for the learned parameters $\boldsymbol{\tau}, \mathbf{d}, \Sigma^{(\cdot)}$.[4]

The joint optimization in Eq. (11) is difficult because (as can be seen in Figure 1) the lack of knowledge of the time-alignment index variables $\boldsymbol{\tau}$ introduces a very large set of dependencies between all the variables. However, when $\boldsymbol{\tau}$ is known, the optimization problem in Eq. (11) greatly simplifies thanks to context specific independencies (Boutilier et al., 1996). When $\boldsymbol{\tau}$ is fixed, we obtain a model such as the one shown in Figure 2. In this model we can directly estimate the multinomial parameters $\mathbf{d}$ in closed form; and we have a standard HMM parameter learning problem for the covariances $\Sigma^{(\cdot)}$, which can be solved using the EM algorithm (Dempster et al., 1977)—often referred to as Baum-Welch in the context of HMMs. Concretely, for our setting, the EM algorithm's E-step computes the pairwise marginals over sequential hidden state variables by running a (extended) Kalman smoother; the M-step then uses these marginals to update the covariances $\Sigma^{(\cdot)}$.

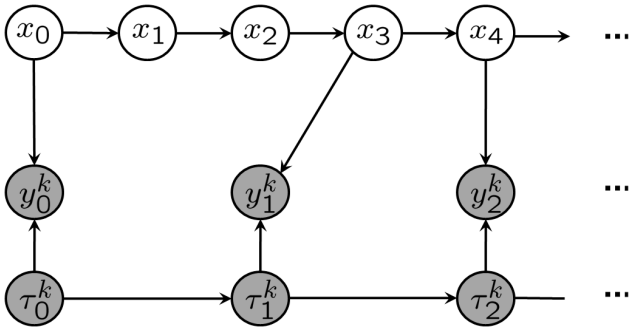

Figure 2. Example of graphical model when $\boldsymbol{\tau}$ is known. (Shaded nodes are observed.)

To also optimize over the time-indexing variables $\boldsymbol{\tau}$, we propose an alternating optimization procedure. For fixed $\Sigma^{(\cdot)}$ and $\mathbf{d}$, and for fixed $\mathbf{z}$, we can find the optimal time-indexing variables $\boldsymbol{\tau}$ using dynamic programming over the time-index assignments for each demonstration independently. The dynamic programming algorithm to find $\boldsymbol{\tau}$ is known in the speech recognition literature as dynamic time warping (Sakoe & Chiba, 1978) and in the biological sequence alignment literature as the Needleman-Wunsch algorithm (Needleman & Wunsch, 1970). The fixed $\mathbf{z}$ we use, is the one that maximizes the likelihood of the observations for the current setting of parameters $\boldsymbol{\tau}, \mathbf{d}, \Sigma^{(\cdot)}$.[5]

In practice, rather than alternating between complete optimizations over $\Sigma^{(\cdot)}, \mathbf{d}$ and $\boldsymbol{\tau}$, we only partially optimize over $\Sigma^{(\cdot)}$, running only one iteration of the EM algorithm.

We provide the complete details of our algorithm in the full paper (Coates et al., 2008).

4. Local Model Learning

For complex dynamical systems, the state z_t used in the dynamics model often does not correspond to the "complete state" of the system, since the latter could involve large numbers of previous states or unobserved variables that make modeling difficult.[6] However, when we only seek to model the system dynamics along a specific trajectory, knowledge of both z_t and how far we are along that trajectory is often sufficient to accurately predict the next state z_{t+1}.

Once the alignments between the demonstrations are computed by our trajectory learning algorithm, we can use the time aligned demonstration data to learn a sequence of trajectory-specific models. The time indices of the aligned demonstrations now accurately associate the demonstration data points with locations along the learned trajectory, allowing us to build models for the state at time t using the appropriate corresponding data from the demonstration trajectories.[7]

[4]Note maximizing over the hidden trajectory and the covariance parameters simultaneously introduces undesirable local maxima: the likelihood score would be highest (namely infinity) for a hidden trajectory with a sequence of states exactly corresponding to the (crude) dynamics model $f(\cdot)$ and state-transition covariance matrices equal to all-zeros as long as the observation covariances are nonzero. Hence we marginalize out the hidden trajectory to find $\boldsymbol{\tau}, \mathbf{d}, \Sigma^{(\cdot)}$.

[5]Fixing $\mathbf{z}$ means the dynamic time warping step only approximately optimizes the original objective. Unfortunately, without fixing $\mathbf{z}$, the independencies required to obtain an efficient dynamic programming algorithm do not hold. In practice we find our approximation works very well.

[6]This is particularly true for helicopters. Whereas the state of the helicopter is very crudely captured by the 12D rigid-body state representation we use for our controllers, the "true" physical state of the system includes, among others, the airflow around the helicopter, the rotor head speed, and the actuator dynamics.

[7]We could learn the richer local model within the trajectory alignment algorithm, updating the dynamics model during the M-step. We chose not to do so since these models are more computationally expensive to estimate. The richer local models have minimal influence on the alignment because the biases capture the average model error—the richer models capture the derivatives around it. Given the limited influence on the alignment, we chose to save computational time and only estimate the richer models

Figure 3. Our XCell Tempest autonomous helicopter.

To construct an accurate nonlinear model to predict z_{t+1} from z_t, using the aligned data, one could use locally weighted linear regression (Atkeson et al., 1997), where a linear model is learned based on a weighted dataset. Data points from our aligned demonstrations that are nearer to the current time index along the trajectory, t, and nearer the current state, z_t, would be weighted more highly than data far away. While this allows us to build a more accurate model from our time-aligned data, the weighted regression must be done online, since the weights depend on the current state, z_t. For performance reasons[8] this may often be impractical. Thus, we weight data only based on the time index, and learn a parametric model in the remaining variables (which, in our experiments, has the same form as the global "crude" model, $f(\cdot)$). Concretely, when estimating the model for the dynamics at time t, we weight a data point at time t' by:[9]

$$W(t') = \exp\left(-\frac{(t-t')^2}{\sigma^2}\right),$$

where σ is a bandwidth parameter. Typical values for σ are between one and two seconds in our experiments. Since the weights for the data points now only depend on the time index, we can precompute all models $f_t(\cdot)$ along the entire trajectory. The ability to precompute the models is a feature crucial to our control algorithm, which relies heavily on fast simulation.

5. Experimental Results

5.1. Experimental Setup

To test our algorithm, we had our expert helicopter pilot fly our XCell Tempest helicopter (Figure 3), which can perform professional, competition-level maneuvers.[10]

We collected multiple demonstrations from our expert for a variety of aerobatic trajectories: continuous in-place flips and rolls, a continuous tail-down "tic toc," and an airshow, which consists of the following maneuvers in rapid sequence: split-S, snap roll, stall-turn, loop, loop with pirouette, stall-turn with pirouette, "hurricane" (fast backward funnel), knife-edge, flips and rolls, tic-toc and inverted hover.

The (crude) helicopter dynamics $f(\cdot)$ is constructed using the method of Abbeel et al. (2006a).[11] The helicopter dynamics model predicts linear and angular accelerations as a function of current state and inputs. The next state is then obtained by integrating forward in time using the standard rigid-body equations.

In the trajectory learning algorithm, we have bias terms $\beta_t^\star$ for each of the predicted accelerations. We use the state-drift variables, δ_t^k, for position only.

For the flips, rolls, and tic-tocs we incorporated our prior knowledge that the helicopter should stay in place. We added a measurement of the form:

$$0 = p(z_t) + \omega^{(\rho_0)}, \quad \omega^{(\rho_0)} \sim \mathcal{N}(0, \Sigma^{(\rho_0)})$$

where $p(\cdot)$ is a function that returns the position coordinates of z_t, and $\Sigma^{(\rho_0)}$ is a diagonal covariance matrix. This measurement—which is a direct observation of the pilot's intended trajectory—is similar to advice given to a novice human pilot to describe the desired maneuver: A good flip, roll, or tic-toc trajectory stays close to the same position.

We also used additional advice in the airshow to indicate that the vertical loops, stall-turns and split-S should all lie in a single vertical plane; that the hurricanes should lie in a horizontal plane and that a good knife-edge stays in a vertical plane. These measurements take the form:

$$c = N^\top p(z_t) + \omega^{(\rho_1)}, \quad \omega^{(\rho_1)} \sim \mathcal{N}(0, \Sigma^{(\rho_1)})$$

where, again, $p(z_t)$ returns the position coordinates of z_t. N is a vector normal to the plane of the maneuver, c is a constant, and $\Sigma^{(\rho_1)}$ is a diagonal covariance matrix.

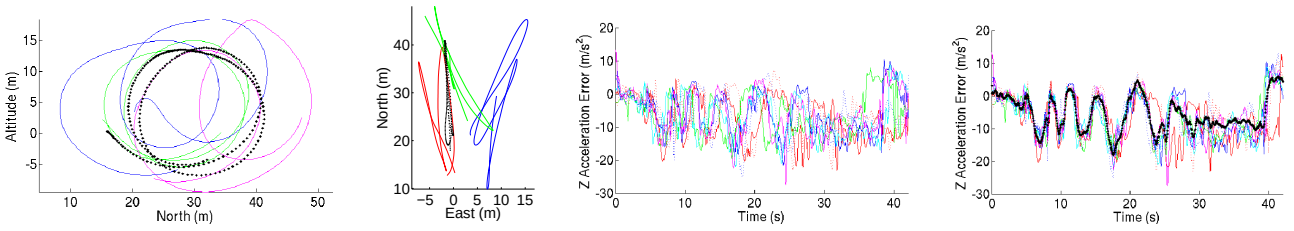
after alignment.

[8]During real-time control execution, our model is queried roughly 52000 times per second. Even with KD-tree or cover-tree data structures a full locally weighted model would be much too slow.

[9]In practice, the data points along a short segment of the trajectory lie in a low-dimensional subspace of the state space. This sometimes leads to an ill-conditioned parameter estimation problem. To mitigate this problem, we regularize our models toward the "crude" model $f(\cdot)$.

[10]We instrumented the helicopter with a Microstrain 3DM-GX1 orientation sensor. A ground-based camera system measures the helicopter's position. A Kalman filter uses these measurements to track the helicopter's position, velocity, orientation and angular rate.

[11]The model of Abbeel et al. (2006a) naturally generalizes to any orientation of the helicopter regardless of the flight regime from which data is collected. Hence, even without collecting data from aerobatic flight, we can reasonably attempt to use such a model for aerobatic flying, though we expect it to be relatively inaccurate.



(a) (b) (c) (d)

Figure 4. Colored lines: demonstrations. Black dotted line: trajectory inferred by our algorithm. (See text for details.)

5.2. Trajectory Learning Results

Figure 4(a) shows the horizontal and vertical position of the helicopter during the two loops flown during the airshow. The colored lines show the expert pilot's demonstrations. The black dotted line shows the inferred ideal path produced by our algorithm. The loops are more rounded and more consistent in the inferred ideal path. We did not incorporate any prior knowledge to this extent. Figure 4(b) shows a top-down view of the same demonstrations and inferred trajectory. The prior successfully encouraged the inferred trajectory to lie in a vertical plane, while obeying the system dynamics.

Figure 4(c) shows one of the bias terms, namely the model prediction errors for the Z-axis acceleration of the helicopter computed from the demonstrations, before time-alignment. Figure 4(d) shows the result after alignment (in color) as well as the inferred acceleration error (black dotted). We see that the unaligned bias measurements allude to errors approximately in the -1G to -2G range for the first 40 seconds of the airshow (a period that involves high-G maneuvering that is not predicted accurately by the "crude" model). However, only the aligned biases precisely show the magnitudes and locations of these errors along the trajectory. The alignment allows us to build our ideal trajectory based upon a much more accurate model that is tailored to match the dynamics observed in the demonstrations.

Results for other maneuvers and state variables are similar. At the URL provided in the introduction we posted movies which simultaneously replay the different demonstrations, before alignment and after alignment. The movies visualize the alignment results in many state dimensions simultaneously.

5.3. Flight Results

After constructing the idealized trajectory and models using our algorithm, we attempted to fly the trajectory on the actual helicopter.

Our helicopter uses a receding-horizon differential dynamic programming (DDP) controller (Jacobson & Mayne, 1970). DDP approximately solves general continuous state-space optimal control problems by taking advantage of the fact that optimal control problems with linear dynamics and a quadratic reward function (known as linear quadratic regulator (LQR) problems) can be solved efficiently. It is well-known that the solution to the (time-varying, finite horizon) LQR problem is a sequence of linear feedback controllers. In short, DDP iteratively approximates the general control problem with LQR problems until convergence, resulting in a sequence of linear feedback controllers that are approximately optimal. In the receding-horizon algorithm, we not only run DDP initially to design the sequence of controllers, but also re-run DDP during control execution at every time step and recompute the optimal controller over a fixed-length time interval (the horizon), assuming the precomputed controller and cost-to-go are correct after this horizon.

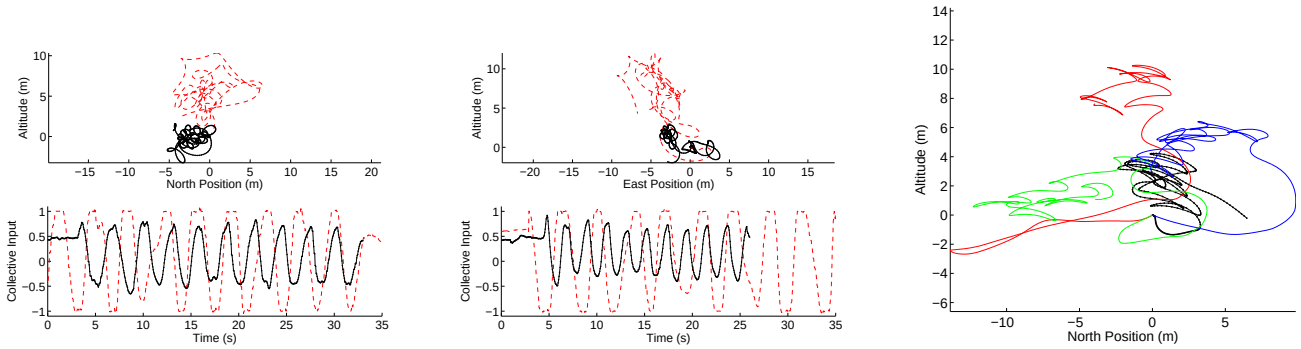
As described in Section 4, our algorithm outputs a sequence of learned local parametric models, each of the form described by Abbeel et al. (2006a). Our implementation linearizes these models on the fly with a 2 second horizon (at 20Hz). Our reward function penalizes error from the target trajectory, $s_t^\star$, as well as deviation from the desired controls, $u_t^\star$, and the desired control velocities, $u_{t+1}^\star - u_t^\star$.

First we compare our results with the previous state-of-the-art in aerobatic helicopter flight, namely the in-place rolls and flips of Abbeel et al. (2007). That work used hand-specified target trajectories and a single nonlinear model for the entire trajectory.

Figure 5(a) shows the Y-Z position[12] and the collective (thrust) control inputs for the in-place rolls for both their controller and ours. Our controller achieves (i) better position performance (standard deviation of approximately 2.3 meters in the Y-Z plane, compared to about 4.6 meters and (ii) lower overall collective control values (which roughly represents the amount of energy being used to fly the maneuver).

Similarly, Figure 5(b) shows the X-Z position and the collective control inputs for the in-place flips for both controllers. Like for the rolls, we see that our controller significantly outperforms that of Abbeel et al. (2007), both in position accuracy and in control energy expended.

[12]These are the position coordinates projected into a plane orthogonal to the axis of rotation.



(a) (b) (c)

Figure 5. Flight results. (a),(b) Solid black: our results. Dashed red: Abbeel et al. (2007). (c) Dotted black: autonomous tic-toc. Solid colored: expert demonstrations. (See text for details.)

Besides flips and rolls, we also performed autonomous "tic tocs"—widely considered to be an even more challenging aerobatic maneuver. During the (tail-down) tic-toc maneuver the helicopter pitches quickly backward and forward in-place with the tail pointed toward the ground (resembling an inverted clock pendulum). The complex relationship between pitch angle, horizontal motion, vertical motion, and thrust makes it extremely difficult to create a feasible tic-toc trajectory by hand. Our attempts to use such a hand-coded trajectory with the DDP algorithm from (Abbeel et al., 2007) failed repeatedly. By contrast, our algorithm readily yields an excellent feasible trajectory that was successfully flown on the first attempt. Figure 5(c) shows the expert trajectories (in color), and the autonomously flown tic-toc (black dotted). Our controller significantly outperforms the expert's demonstrations.

We also applied our algorithm to successfully fly a complete aerobatic airshow, which consists of the following maneuvers in rapid sequence: split-S, snap roll, stall-turn, loop, loop with pirouette, stall-turn with pirouette, "hurricane" (fast backward funnel), knife-edge, flips and rolls, tic-toc and inverted hover.

The trajectory-specific local model learning typically captures the dynamics well enough to fly all the aforementioned maneuvers reliably. Since our computer controller flies the trajectory very consistently, however, this allows us to repeatedly acquire data from the same vicinity of the target trajectory on the real helicopter. Similar to Abbeel et al. (2007), we incorporate this flight data into our model learning, allowing us to improve flight accuracy even further. For example, during the first autonomous airshow our controller achieves an RMS position error of 3.29 meters, and this procedure improved performance to 1.75 meters RMS position error.

Videos of all our flights are available at:

`http://heli.stanford.edu`

6. Related Work

Although no prior works span our entire setting of learning for control from multiple demonstrations, there are separate pieces of work that relate to various components of our approach.

Atkeson and Schaal (1997) use multiple demonstrations to learn a model for a robot arm, and then find an optimal controller in their simulator, initializing their optimal control algorithm with one of the demonstrations.

The work of Calinon et al. (2007) considered learning trajectories and constraints from demonstrations for robotic tasks. There, they do not consider the system's dynamics or provide a clear mechanism for the inclusion of prior knowledge. Our formulation presents a principled, joint optimization which takes into account the multiple demonstrations, as well as the (complex) system dynamics and prior knowledge. While Calinon et al. (2007) also use some form of dynamic time warping, they do not try to optimize a joint objective capturing both the system dynamics and time-warping.

Among others, An et al. (1988) and, more recently, Abbeel et al. (2006b) have exploited the idea of trajectory-indexed model learning for control. However, contrary to our setting, their algorithms do not time align nor coherently integrate data from multiple trajectories.

While the work by Listgarten et al. (Listgarten, 2006; Listgarten et al., 2005) does not consider robotic control and model learning, they also consider the problem of multiple continuous time series alignment with a hidden time series.

Our work also has strong similarities with recent work on inverse reinforcement learning, which extracts a reward function (rather than a trajectory) from the expert demonstrations. See, e.g., Ng and Russell (2000); Abbeel and Ng (2004); Ratliff et al. (2006); Neu and Szepesvari (2007); Ramachandran and Amir (2007); Syed and Schapire (2008).

Most prior work on autonomous helicopter flight only considers the flight-regime close to hover. There are three notable exceptions. The aerobatic work of Gavrilets et al. (2002) comprises three maneuvers: split-S, snap-roll, and stall-turn, which we also include during the first 10 seconds of our airshow for comparison. They record pilot demonstrations, and then hand-engineer a sequence of desired angular rates and velocities, as well as transition points. Ng et al. (2004) have their autonomous helicopter perform sustained inverted hover. We compared the performance of our system with the work of Abbeel et al. (2007), by far the most advanced autonomous aerobatics results to date, in Section 5.

7. Conclusion

We presented an algorithm that takes advantage of multiple suboptimal trajectory demonstrations to (i) extract (an estimate of) the ideal demonstration, (ii) learn a local model along this trajectory. Our algorithm is generally applicable for learning trajectories and dynamics models along trajectories from multiple demonstrations. We showed the effectiveness of our algorithm for control by applying it to the challenging problem of autonomous helicopter aerobatics. The ideal target trajectory and the local models output by our trajectory learning algorithm enable our controllers to significantly outperform the prior state of the art.

Spectral Clustering with Inconsistent Advice

Abstract

Clustering with advice (often known as constrained clustering) has been a recent focus of the data mining community. Success has been achieved incorporating advice into the k-means and spectral clustering frameworks. Although the theory community has explored inconsistent advice, it has not yet been incorporated into spectral clustering. Extending work of De Bie and Cristianini, we set out a framework for finding minimum normalised cuts, subject to inconsistent advice.

1. Introduction

Clustering is an exploratory data analysis problem which asks us to form groups of related objects. Although humans have a good intuition for clustering in two dimensions, if the data is in a higher dimensional space, it can be hard to visualise. In this paper, we will focus on the problem of clustering data into *two* clusters, subject to a balance criterion and *advice*.

1.1. Clustering with advice

It is sensible for clustering algorithms to be able to incorporate *must-link* and *cannot-link* advice[1], as it is known in the constrained clustering community. For example, in biology, when experimentally clustering proteins (or genes etc), it is often practical to test associations of individual pairs. However, there is no guarantee that the advice we generate in this way will be correct. Additionally, it is well known that human and biological 'experiments' are often subject to noise. If we have enough noisy advice, that advice will be inconsistent—that is, there is no way to cluster the data which agrees with all the advice.

In that case, the objective naturally becomes to respect as much advice as possible. In fact, if we ignore all the data apart from the advice, we have the the *2-correlation clustering* problem (2CC), known to be NP-hard (Bansal et al., 2004). In this context, we can think of the *advice graph*—which has an edge for each piece of advice, labelled with a + for a must-link, and a − otherwise.

1.2. Balanced clustering

A natural problem to solve when clustering in general is the *normalised cut* (Shi & Malik, 2000). Normalised cut (NCUT) asks us to find a cut which minimises inter-cluster affinity whilst maximising intra-cluster affinity in a sensible way. In the two cluster case, this is to minimise the quantity $\frac{\text{cut}(S,\bar{S})}{\text{vol}(S)\text{vol}(\bar{S})}$, where $\text{cut}(S,\bar{S})$ measures the affinity across the cut and $\text{vol}(S)$ is the total degree (out-affinity) of all the nodes within S.

Our aim for the paper is to attempt to optimise both the NCUT and 2CC criteria simultaneously. To do so we will need to relax the problems—we cannot hope to solve them combinatorially.

1.3. Relaxed versions of the clustering problems

Traditionally, spectral approaches were used for the NCUT problem, as they led to fast algorithms. Recently there has been a trend towards tighter, semidefinite programming (SDP)-based, relaxations. We will demonstrate how to alter the basic spectral clustering algorithm, and the SDP techniques, to integrate and deal sensibly with inconsistent advice.

Suppose that the advice *is* consistent (it is simple to

[1]Traditionally in the literature, what we call advice is referred to as *constraints*. We use the term advice here to avoid confusion with constraints that are introduced into the problem in later sections.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

check this fact). Once we know that this is the case, it is sensible to constrain the space of the solutions that we explore only to contain clusterings that are consistent with this advice.

1.4. Existing approaches

Spectral Clustering Spectral Clustering appeared first in the literature in the 1970s. Much of the recent popularity of the technique was instigated by the connection to NCUT as shown by Shi and Malik (2000).

Advice Advice (instance-level constraints) for clustering problems was introduced to the machine learning community in the work of Wagstaff and Cardie (2000) who developed a variant of the classic k-means algorithms to incorporate advice.

Kamvar, Klein and Manning (2003) integrated advice into the spectral formulation by directly changing entries of the Laplacian matrix. Xing et al. (2003) improve on this idea by essentially changing the Laplacian in a more consistent way. They do this by finding a metric that best agrees with the advice. These methods do not directly exploit the nature of the spectral algorithm.

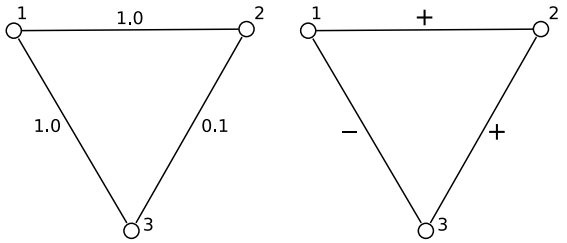
SDP relaxations for N-cut Xing and Jordan (2003) outline a SDP formulation for the NCUT problem for multiple clusters and highlight the connection to spectral clustering. De Bie and Cristianini (2006) provide an SDP which is easier to deal with, and demonstrate that the subspace trick can also be used to introduce advice to this problem.

The subspace trick De Bie, Suykens and De Moor (2004) outline a subspace trick to integrate advice into spectral clustering by constraining a solution to be within the subspace of solutions which agree with the advice. This approach was also previously mentioned in the work of Yu and Shi (2001). This technique leaves the spectral algorithm essentially unchanged; it now just searches for eigenvectors in a different subspace. However it is not necessarily apparent from their work how to extend this technique to inconsistent advice. *This is the key issue addressed in this paper.*

1.5. Addressing Inconsistency

So how can we apply the subspace trick when the advice we have is no longer consistent?

As a first approach (METHOD ONE), we could simply try to solve 2CC defined by the advice, and reject any advice that this solution fails to respect. A good solution to 2CC will ensure that we minimise the number of such edges that we will have to ignore. Then the advice that remains will be consistent, and we can then use the subspace trick. Or indeed, we could use any other constraint-based clustering algorithm in this way.



(a) N-cut problem (b) CC problem

Figure 1. A problem for which not all optimal solutions to 2CC are optimal for the accompanying NCUT problem.

However, this idea has some problems. A toy example of inconsistent advice in Figure 1 shows that deleting any one of the three edges will result in an optimal solution to 2CC. However, one specific cut (namely separating node 3 from nodes 1 and 2) has a much better NCUT cost. So, in forcing a particular optimal solution to 2CC, we are constraining our NCUT solution too much. A second approach (METHOD TWO) that solves this problem is to calculate the *cost* of an approximately optimal solution to 2CC. Rather than force our NCUT solution to be consistent with this 2CC solution, instead we simply require that our NCUT solution has the same correlation clustering cost. This approach will give the NCUT side of our algorithm some room to move, avoiding situations like Figure 1. This technique will be outlined in section 4.1.

A third approach (METHOD THREE) is to allow the algorithm to differ from the optimum correlation clustering cost, but only by some a given factor. So now the NCUT side of the problem has some breathing space in which to find a good solution, whilst we are still forcing a very good solution to 2CC. This approach is developed in section 4.2.

2. Relaxing the Problem

2.1. Normalised Cut

To define the NCUT problem, we begin with an edge-weighted affinity graph with associated affinity matrix A. Distant edges may have zero affinity—we can represent this by deleting the connecting edge, which will speed up the computation.

We represent a 2-clustering by a vector v, where each coordinate represents a datapoint, and is either $+1$ or -1 depending on cluster assignment. The NCUT value becomes:

$$\text{NCUT}(v) = \frac{v^T \mathcal{L}(A) v}{v^T \mathcal{L}(dd^T) v} \tag{1}$$

where d is the vector of vertex degrees, and $\mathcal{L}(X)$ is the *Laplacian* of matrix X. Recall that if e is the vector consisting of all ones and $\text{diag}(x)$ is the matrix with vector x on the main diagonal and zeros elsewhere, then $\mathcal{L}(X) = \text{diag}(Xe) - X$.

2.2. Spectral Clustering

In the spectral relaxation, instead of assigning ± 1 to each vertex, we assign a real number v_i. If $v = (v_1, \ldots, v_n)$ then NCUT relaxes to

P1. *Spectral clustering*

$$\min \quad \frac{v^T \mathcal{L}(A) v}{v^T D v} \qquad \text{s.t.} \qquad d^T v = 0$$

where $D = \text{diag}(d)$. This relaxation is correct because $v^T \mathcal{L}(A) v$ is invariant under translations of v so we can add the constraint $d^T v = 0$ without changing the optimum cost. With this constraint, the denominator of (1) can be simplified as in **P1**.

It turns out that $v = D^{\frac{1}{2}} u$ is an optimum solution of **P1**, where u is the eigenvector of $D^{-\frac{1}{2}} \mathcal{L}(A) D^{-\frac{1}{2}}$ corresponding to the smallest non-zero eigenvalue.

2.3. The SDP formulation

In the two cluster case, De Bie and Cristianini (2006) devised an efficient relaxation of NCUT to a semidefinite program. In this case, instead of assigning ± 1 to the vertices we assign *vectors* v_i of some common length. If X is the Gram matrix of these vectors (i.e. $X_{ij} = v_i^T v_j$) then the relaxation is

P2. *De Bie and Cristianini SDP*

$$\min_{X,q} \quad \mathcal{L}(A) \bullet X$$

$$\text{s.t.} \quad \begin{aligned} \mathcal{L}(dd^T) \bullet X &= 1 && (2) \\ \forall i \in [n] \quad X_{ii} &= q && (3) \\ X &\succeq 0 && (4) \end{aligned}$$

where $A \bullet B = \text{trace}(AB)$ for matrices of appropriate dimension. Here the free variable q is the common (squared) length of the v_i and (2) is a scaling constraint corresponding to the denominator of the NCUT objective function (1).

Importantly, given any $X \succeq 0$ we can find $v_1, \ldots, v_n$ such that $X_{ij} = v_i^T v_j$; we can thus convert a solution to **P2** to an assignment of vectors to the vertices of the graph.

Spectral clustering can be recovered from **P2** by removing the constraints of (3) (see Goemans (1997)).

2.4. The 'subspace trick'

The subspace trick of De Bie, Suykens and De Moor (2004) gives a method for incorporating consistent advice into spectral and SDP relaxations of NCUT. As an example, consider spectral clustering and suppose we have two 'blocks' of independent advice. The first that two vertices, say v_1 and v_2, should be in the same cluster and both should be in a different cluster to v_3, the second that vertices v_4 and v_5 should be in the same cluster. Then it makes sense to constrain the solution vector v so that $v_1 = v_2$ and $v_4 = v_5$ guaranteeing that these pairs of vertices end up in the same cluster after rounding. It also makes sense to constrain v so that $v_3 = -v_2 = -v_1$. This can be done by assuming v has the form

$$v = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & I_{n-5} \end{bmatrix} u = Yu$$

where $u \in \mathbb{R}^{n-3}$. The identity matrix corresponds to vertices for which we have no advice and so should not constrain.

3. Correlation Clustering

Given an advice graph, in the form of $+$ (must-link) or $-$ (cannot-link) edges between datapoints, the correlation clustering problem asks us to cluster the datapoints so that the number of pieces of advice (i.e. edge labels) that are disobeyed is minimised.

3.1. 2CC — the combinatorial problem

In general, unlike the affinity graph, the advice graph is not connected. So we can solve correlation clustering independently on each connected component. We call the vertices in a connected component an *advice block*. We assume without loss of generality that the order on the vertices ensures that the vertices within each block are consecutive. Here we will deal with the problem of solving 2CC for a single advice block $\mathcal{B}$ with m vertices. In later sections, we will consider multiple advice blocks.

If e is an edge within $\mathcal{B}$ let $w_e \in \pm 1$ correspond to the the sign of e. As for NCUT, we assign $v_i = \pm 1$ to each

vertex depending on the cluster in which we place that vertex. For convenience, let E_{ij} be the matrix with a 1 in the (i,j) entry and zeros everywhere else.

Our immediate aim is to find, in terms of v, a simple expression for the number of constraints violated by the labelling.

Consider a single edge $e = \{i,j\}$ of $\mathcal{B}$ with label w_e. Define

$$M_e = (E_{ii} + E_{jj}) - w_e(E_{ij} + E_{ji})$$

and note that $M_e \succeq 0$ because its eigenvalues are 0 and 2. Now

$$\begin{aligned} v^T M_e v &= v_i^2 - 2w_e v_i v_j + v_j^2 && (5)\\ &= |v_i - w_e v_j|^2 && (6)\\ &= \begin{cases} 0 & \text{if } v \text{ respects the advice on } e \\ 4 & \text{otherwise.} \end{cases} && (7) \end{aligned}$$

So if we define $M_{\mathcal{B}} = \sum_e M_e$ it follows that

$$v^T M_{\mathcal{B}} v = 4 \times (\#\text{ pieces of advice violated by } v).$$

Thus 2CC is essentially

$$\min_{v \in \{-1,1\}^m} v^T M_{\mathcal{B}} v. \qquad (8)$$

Note that a clustering that satisfies all the advice in a block will have cost zero. Also observe that $v^T v = m$ is a constant so we could replace the objective function with $(v^T M_{\mathcal{B}} v)/(v^T v)$ without changing the optimum vector.

3.2. Relaxations of 2CC

Recall that our overall aim is to constrain any algorithm we have for (approximately) solving NCUT to produce clusterings which are, in terms of 2CC cost, not much worse than the optimum.

Since we cannot hope to solve (8) exactly, we will instead solve a relaxed version of it. In this paper we consider two relaxations which arise in much the same way as the spectral and SDP relaxations of NCUT.

P3. *Spectral relaxation of correlation clustering*

$$\min_v \quad \frac{v^T M_{\mathcal{B}} v}{v^T v}$$

Observe that the solution of **P3** is given by any non-zero vector in the λ_{min}-eigenspace of $M_{\mathcal{B}}$.

P4. *SDP relaxation of correlation clustering*

$$\begin{aligned} \min_X \quad & M_{\mathcal{B}} \bullet X \\ \text{s.t.} \quad \forall i \in [m] \quad X_{ii} &= 1 \qquad (9)\\ X &\succeq 0 \end{aligned}$$

For either relaxation, if the advice is consistent, the relaxation produces a solution of the same cost (zero) as the optimal solution to the combinatorial problem (8). This is because any solution of the original problem is a feasible point of the relaxed problem, and the relaxed problem has non-negative cost as $M_{\mathcal{B}} \succeq 0$.

4. Clustering with inconsistent advice

In this section, we give the details of METHOD TWO and METHOD THREE, introduced in Section 1.5, for both the spectral and SDP relaxations of NCUT.

Throughout, let $\mathcal{B}_1, \ldots, \mathcal{B}_p$ be the advice blocks of the advice graph. Let $v_{\mathcal{B}}$ denote the projection of v onto the coordinates involved in advice block $\mathcal{B}$. Along similar lines, if $u_{\mathcal{B}}$ is a vector of length $|\mathcal{B}| \le n$ associated with the advice block $\mathcal{B}$, define $\widetilde{u_{\mathcal{B}}}$ to be the length n vector that agrees with $u_{\mathcal{B}}$ in the appropriate coordinates and has zeros elsewhere. For a $|\mathcal{B}| \times |\mathcal{B}|$ matrix $M_{\mathcal{B}}$ we also define $\widetilde{M_{\mathcal{B}}}$ in a similar fashion.

4.1. Combining 2CC and Ncut: Method Two

Let OPT_j denote the optimum cost of the SDP relaxation of 2CC (**P4**) for block j. For the SDP relaxation, we can add the constraint that for each advice block, the 2CC cost of point X is at most $q \cdot \text{OPT}_j$. (The scaling by q is necessary because in **P4** the variables satisfy $X_{ii} = 1$ whereas in **P2** the variables satisfy $X_{ii} = q$.) This forces the new SDP (**P5**) only to consider points of minimum SDP-relaxed 2CC cost.

P5. METHOD TWO *(SDP version)*

$$\begin{aligned} \min_{X,q} \quad & \mathcal{L}(A) \bullet X \\ & \mathcal{L}(dd^T) \bullet X = \text{vol}(\mathcal{V}) \\ \text{s.t.} \quad & \forall i \in [n] \quad X_{ii} = q \\ & \forall j \in [p] \quad \widetilde{M_{\mathcal{B}_j}} \bullet X \le q \cdot \text{OPT}_j \qquad (10)\\ & X \succeq 0 \end{aligned}$$

In the spectral case, the analogous thing to do would be to add the following constraints to the spectral relaxation of NCUT.

$$\forall j \in [p] \quad \frac{v_{\mathcal{B}_j}^T M_{B_j} v_{\mathcal{B}_j}}{v_{\mathcal{B}_j}^T v_{\mathcal{B}_j}} \le \lambda_{min}(M_{\mathcal{B}_j}) \qquad (11)$$

But doing so would mean the problem would no longer be an eigenvalue problem—in fact it would be an SDP—which would undermine the main strength of spectral clustering, its speed.

Luckily, the condition in (11) is equivalent to the condition that each $v_{\mathcal{B}_j}$ is in

the λ_{min}-eigenspace of $M_{\mathcal{B}_j}$, resulting in **P6**.

P6. METHOD TWO *(spectral version)*

$$\min_{v} \quad \frac{v^T \mathcal{L}(A) v}{v^T D v}$$

$$\text{s.t.} \qquad d^T v = 0 \tag{12}$$

$$\forall j \in [p] \quad v_{\mathcal{B}_j} \in \lambda_{min}\text{-eigenspace of } M_{\mathcal{B}_j} \tag{13}$$

The constraints (12) and (13) are forcing v to be in some linear subspace of $\mathbb{R}^n$. So the problem can then be solved using the subspace trick. Details of how to do this are in Appendix A.

4.2. Combining 2CC and Ncut: Method Three

The main drawback of METHOD TWO is that it does not give the algorithm much freedom to balance the trade-off between the 2CC and the NCUT problem. If the advice is quite inconsistent, then forcing the algorithm to follow solutions of a relaxation of 2CC too closely will result in poor performance.

Above, we forced the algorithm to produce a (relaxation of) a clustering that had cost at most the minimum cost of the appropriate relaxation of 2CC. Now we introduce a parameter $f \geq 1$ which tells us the factor by which we are willing to exceed the 2CC cost.

This is straightforward to introduce to the SDP formulation. We simply replace the constraints (11) of **P5** with

$$\forall j \in [p] \quad \widetilde{M_{\mathcal{B}_j}} \bullet X \leq f \cdot q \cdot \text{OPT}_j. \tag{14}$$

In the spectral formulation, the constraints we actually want to add are

$$\forall j \in [p] \quad \frac{v_{\mathcal{B}_j}^T M_{B_j} v_{\mathcal{B}_j}}{v_{\mathcal{B}_j}^T v_{\mathcal{B}_j}} \leq f \cdot \lambda_{min}(M_{\mathcal{B}_j}) \tag{15}$$

but, again we cannot add these and still have an eigenvalue problem. Unfortunately in this case we cannot get a constraint equivalent to (15) by the subspace trick. So, in the interests of producing a practical algorithm, we approximate (15) by

$$\forall j \in [p] \quad v_{\mathcal{B}_j} \in (\leq f \cdot \lambda_{min})\text{-eigenspace of } M_{B_j} \tag{16}$$

where the $(\leq f \cdot \lambda_{min})$-eigenspace of M_{B_j} is the span of all eigenvectors of $M_{\mathcal{B}_j}$ with eigenvalue at most $f \cdot \lambda_{min}$. If v satisfies (16) then it satisfies (15), but the converse does not necessarily hold.

Replacing the constraints in (13) of **P6** with the constraints in (16) gives our final spectral algorithm for clustering with inconsistent advice. It can again be solved with the subspace trick, using the techniques outlined in Appendix A, because all the constraints simply force v to be in some linear subspace of $\mathbb{R}^n$.

5. Experimental Investigations

5.1. Experiment Setup

In order to test the performance of the algorithms on real world datasets, we used six of the UCI repository datasets (Asuncion & Newman, 2007). All datasets are multi-dimensional binary classification problems.

Both datasets were stripped of incomplete records, and in one case (the SPAMBASE dataset), sampled down to 500 datapoints. In each case, the two clusters were of different sizes. This contributed to the mediocre performance of the pure spectral algorithm. This gives us reason to believe that adding advice will help the situation.

For reasons of speed, our experiments primarily use the spectral version of each of the algorithms. Relaxed solutions are rounded to clusterings by cutting at zero. This ensures that advice respected in the relaxed solution is respected in the final clustering.

Advice We generated two different 'types' of synthetic advice for these problems to get a sense of how the algorithms perform. The first we call DENSE—here we are generating around n pieces of advice. We are generating that advice in a dense fashion—we concentrate all advice within 5 separate groups of 20 datapoints. This simulates a few sets of experiments done on some small subset of the total dataspace. Each piece of advice agrees with the actual classification independently with some probability p.

The second type of advice is the COMPLETE case—here we are simulating pairwise comparisons that are relatively cheap, but quite noisy. So we generate a piece of advice for each pair of datapoints, and thus our advice graph is complete.

2CC Algorithms In order to test METHOD ONE, we need to solve 2CC on each advice block. In the DENSE case, we use a tight, strongly performing SDP relaxation (Agarwal et al., 2005). In the complete case, we use the simple 3-approximation algorithm of Bansal, Blum and Chalwa (2004) with a final local search step (see also our other paper (Coleman et al., 2008)).

For each advice type on each dataset, we ran spectral clustering with no advice (as a baseline), METHOD ONE (as a second baseline), and then spectral clustering with every different meaningful f value from 1 upwards. That is, every increment in f that added one additional eigenvector to a single block, until all eigenvectors were added (which is exactly the same as the no advice case).

5.2. Results

Dense advice Figure 2 displays the results of the DENSE advice problem on the HEART DISEASE dataset with $p = 0.75$. We can see that the advice here is sufficiently inconsistent that algorithms which follow it closely (i.e. METHOD ONE and METHOD TWO) perform far worse than the algorithm that ignores it completely (that is, spectral alone). But we can see that by increasing f and striking a balance between ignoring advice and respecting it too strongly, we can achieve results that outperform either extreme. We also note that two other datasets, CONGRESSIONAL VOTING RECORDS and AUSTRALIAN, perform similarly.

Figure 3 shows the results of running very similar advice (again $p = 0.75$) on the SPAMBASE dataset. Here we can see that algorithms that strictly follow the advice outperform algorithms that ignore it, quite significantly. It is perhaps unsurprising then that when we allow the algorithm more and more freedom to ignore the advice we move toward the baseline no advice score. This highlights the fact that these algorithms are not always of use—there needs to be enough inaccuracy in the advice that attempting to follow it is not a great idea.

However, if we lower p to be 0.65, the situation changes, and we get a scenario as demonstrated by Figure 4. Here as for the HEART DISEASE case, using only the 2CC solution is worse than using no advice at all, and for a large range of f values, the compromise of using some advice is better than either extreme. Here the HABERMAN dataset performs similarly. The difference in this case is that for high f values, very poor performance is exhibited. We will discuss this in the next section.

Finally, we consider the HEPATITIS dataset (Figure 5). Here we see new behaviour, as our algorithms only begin to perform well for high f values.

Complete Advice Figures 6 and 7 show the results of the experiments on the two datasets with COMPLETE advice. We first notice that in order to get meaningful experiments, we needed to set p extraordinarily low—all the way down to $p = 0.53$. If p is much higher than this, advice is *so* complete that any incorrect edges will be vastly overshadowed by correct ones, and simply solving 2CC on the instance will give 100% accuracy.

However, with $p = 0.53$ and the problem interesting, we can see that things are similar to the DENSE case. Again, when f is low, we start at the 2CC-baseline,

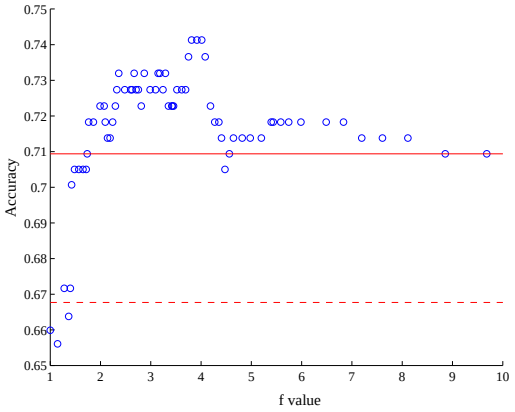


Figure 2. HEART DISEASE dataset, DENSE advice, $p = 0.75$. The unbroken line is the baseline no advice accuracy; the dashed line is the correction clustering based algorithm (METHOD ONE).

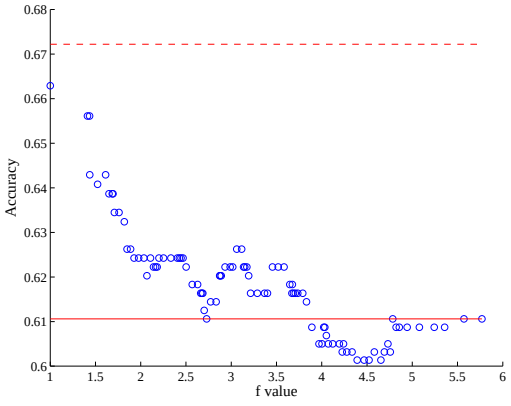

Figure 3. SPAMBASE dataset, DENSE Advice, $p = 0.75$

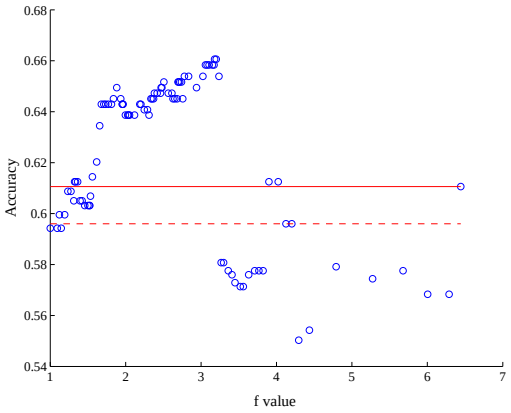

Figure 4. SPAMBASE dataset, DENSE advice, $p = 0.65$

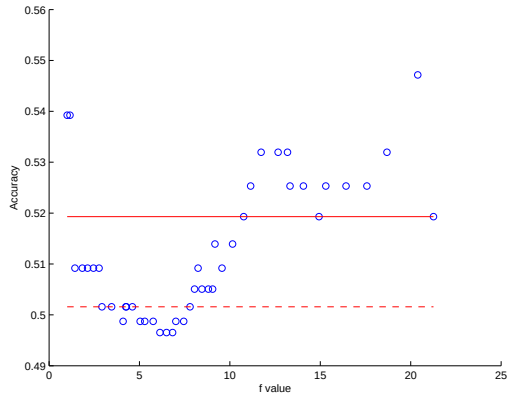

Figure 5. HEPATITIS dataset, DENSE advice, $p = 0.6$

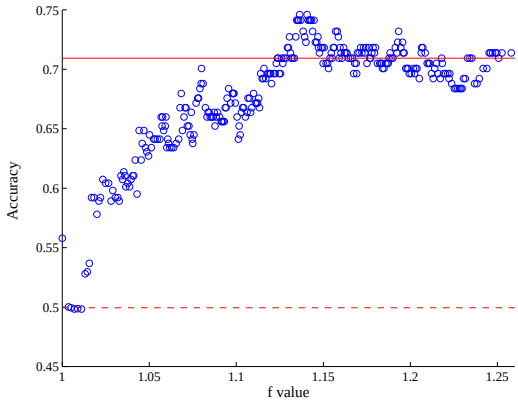

Figure 6. HEART DISEASE dataset, COMPLETE advice, $p = 0.53$

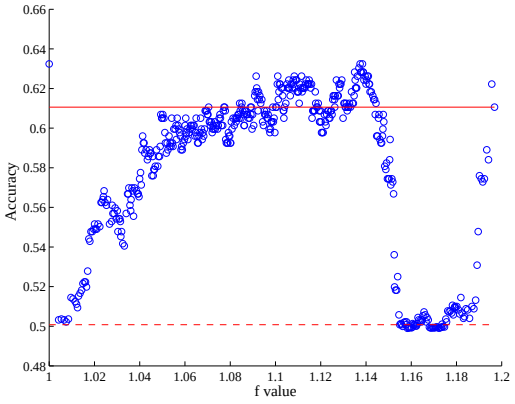

Figure 7. SPAMBASE dataset, COMPLETE advice, $p = 0.53$

and as f increases we move towards and above the no-advice baseline. An interesting point is that the 2CC baseline is around 0.5 in both cases. Note that this is an extremely low score—the advice alone is useless for solving the problem, yet it is still a useful addendum for the spectral method.

As we saw in the DENSE case, one interesting difference between the two datasets is the way the performance drops off as f increases. For HEART DISEASE, the performance seems to asymptote to the no-advice case as we increase f (as we would expect). However, in both cases for the SPAMBASE data, there is a huge dropoff in performance for high end f values. We have no explanation currently for this phenomenon.

6. Conclusions and further work

We have presented a new algorithm that uses inconsistent advice in spectral clustering. This paper is the first to do so. Initial experiments indicate that in many situations our methods are successful, however further theoretical and experimental work is needed. For example, given a clustering problem with inconsistent advice, how do we know when to use METHOD THREE rather than METHOD TWO? And if we are to use METHOD THREE, how do we decide which value of f to choose?

This paper was intended as a largely theoretical work—experiments were performed to give preliminary evidence that the techniques work. Certainly a more thorough comparison to existing work is needed—a technique similar to METHOD ONE could be used in order to compare our algorithms to other approaches that can only deal with consistent constraints. These will be tested in the full version of the paper.

Additionally, in this paper we focused on clustering into two clusters. This is for two reasons. First, there is no obvious way to express cannot-link advice when we have more than two clusters—the approach used here does not generalise nicely. Furthermore, we do not know of an SDP relaxation of the problem which fits into the framework of this paper for the case of more than two clusters. Future work will try to address these problems.

Acknowledgments

Thanks to Ian Davidson for encouraging us to pursue this problem, and to the anonymous reviewers of the draft version. This work was supported by the Australian Research Council through Discovery Project

Grant DP0663979.

A. Implementing spectral clustering with inconsistent advice

In this section we explain how to implement the spectral version of METHOD TWO and METHOD THREE using the subspace trick.

Let $W_{\mathcal{B}_j}$ be a matrix whose columns are a basis for the $(\leq f \cdot \lambda_{min})$-eigenspace of $M_{\mathcal{B}_j}$. Let $\mathcal{N}(X)$ and $\mathcal{R}(X)$ respectively denote the nullspace and range space of a matrix X. Then the problem can be written as follows:

P7. *Spectral clustering with inconsistent advice*

$$\begin{aligned} \min_{v} \quad & v^T \mathcal{L}(A) v \\ \text{s.t.} \quad & v^T D v = 1 \\ & v \in \mathcal{N}(d^T) \qquad (17) \\ \forall j \in [p] \quad & v_{\mathcal{B}_j} \in \mathcal{R}(W_{\mathcal{B}_j}) \qquad (18) \end{aligned}$$

Let

$$W = \begin{bmatrix} W_{\mathcal{B}_1} & \cdots & 0 & 0 \\ 0 & \cdots & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & W_{\mathcal{B}_p} & 0 \\ 0 & \cdots & 0 & I \end{bmatrix}$$

where the dimension of I is the number of vertices not involved in any advice. Then we can replace the constraints (17) and (18) with

$$v \in \mathcal{N}(d^T) \cap \mathcal{R}(W) = \mathcal{C}$$

Suppose Y is a matrix satisfying $\mathcal{R}(Y) = \mathcal{C}$ and $Y^T D Y = I$. Then if we let $v = Yu$ it is clear that $v \in \mathcal{R}(Y)$ which is what we want. So **P7** becomes

$$\min\ (u^T Y^T)\mathcal{L}(A)(Yu) \quad \text{s.t.} \quad u^T u = 1 \qquad (19)$$

A solution of (19) is given by taking u to be an eigenvector corresponding to the smallest eigenvalue of $Y^T \mathcal{L}(A) Y$. The solution to the original problem is then $v = Yu$.

Elementary linear algebra shows Y generated thus is satisfactory:

1. Let N be a matrix whose columns are an orthonormal basis for $\mathcal{N}(d^T W)$ with respect to the inner product $\langle x, y \rangle = y^T x$.
2. Let R be a matrix whose columns are an orthonormal basis for $\mathcal{R}(W)$ with respect to the inner product $\langle x, y \rangle_D = y^T D x$.
3. Set $Y = RN$.

A Unified Architecture for Natural Language Processing: Deep Neural Networks with Multitask Learning

Ronan Collobert COLLOBER@NEC-LABS.COM
Jason Weston JASONW@NEC-LABS.COM
NEC Labs America, 4 Independence Way, Princeton, NJ 08540 USA

Abstract

We describe a single convolutional neural network architecture that, given a sentence, outputs a host of language processing predictions: part-of-speech tags, chunks, named entity tags, semantic roles, semantically similar words and the likelihood that the sentence makes sense (grammatically and semantically) using a language model. The entire network is trained *jointly* on all these tasks using weight-sharing, an instance of *multitask learning*. All the tasks use labeled data except the language model which is learnt from unlabeled text and represents a novel form of *semi-supervised learning* for the shared tasks. We show how both *multitask learning* and *semi-supervised learning* improve the generalization of the shared tasks, resulting in state-of-the-art performance.

1. Introduction

The field of Natural Language Processing (NLP) aims to convert human language into a formal representation that is easy for computers to manipulate. Current end applications include information extraction, machine translation, summarization, search and human-computer interfaces.

While complete semantic understanding is still a far-distant goal, researchers have taken a divide and conquer approach and identified several sub-tasks useful for application development and analysis. These range from the syntactic, such as part-of-speech tagging, chunking and parsing, to the semantic, such as word-sense disambiguation, semantic-role labeling, named entity extraction and anaphora resolution.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Currently, most research analyzes those tasks *separately*. Many systems possess few characteristics that would help develop a unified architecture which would presumably be necessary for deeper semantic tasks. In particular, many systems possess three failings in this regard: (i) they are *shallow* in the sense that the classifier is often linear, (ii) for good performance with a linear classifier they must incorporate many hand-engineered features specific for the task; and (iii) they cascade features learnt separately from other tasks, thus propagating errors.

In this work we attempt to define a unified architecture for Natural Language Processing that *learns features* that are relevant to the tasks at hand given very limited prior knowledge. This is achieved by training a *deep neural network*, building upon work by (Bengio & Ducharme, 2001) and (Collobert & Weston, 2007). We define a rather general convolutional network architecture and describe its application to many well known NLP tasks including part-of-speech tagging, chunking, named-entity recognition, learning a language model and the task of semantic role-labeling.

All of these tasks are integrated into a single system which is trained *jointly*. All the tasks except the language model are supervised tasks with labeled training data. The language model is trained in an unsupervised fashion on the entire Wikipedia website. Training this task jointly with the other tasks comprises a novel form of *semi-supervised learning*.

We focus on, in our opinion, the most difficult of these tasks: the semantic role-labeling problem. We show that both (i) multitask learning and (ii) semi-supervised learning significantly improve performance on this task *in the absence of hand-engineered features*.

We also show how the combined tasks, and in particular the unsupervised task, learn powerful features with clear semantic information given no human supervision other than the (labeled) data from the tasks (see Table 1).

The article is structured as follows. In Section 2 we describe each of the NLP tasks we consider, and in Section 3 we define the general architecture that we use to solve all the tasks. Section 4 describes how this architecture is employed for *multitask* learning on all the *labeled* tasks we consider, and Section 5 describes the *unlabeled* task of building a language model in some detail. Section 6 gives experimental results of our system, and Section 7 concludes with a discussion of our results and possible directions for future research.

2. NLP Tasks

We consider six standard NLP tasks in this paper.

Part-Of-Speech Tagging (POS) aims at labeling each word with a unique tag that indicates its syntactic role, e.g. plural noun, adverb, ...

Chunking, also called shallow parsing, aims at labeling segments of a sentence with syntactic constituents such as noun or verb phrase (NP or VP). Each word is assigned only one unique tag, often encoded as a begin-chunk (e.g. B-NP) or inside-chunk tag (e.g. I-NP).

Named Entity Recognition (NER) labels atomic elements in the sentence into categories such as "PERSON", "COMPANY", or "LOCATION".

Semantic Role Labeling (SRL) aims at giving a semantic role to a syntactic constituent of a sentence. In the PropBank (Palmer et al., 2005) formalism one assigns roles ARG0-5 to words that are arguments of a predicate in the sentence, e.g. the following sentence might be tagged "[John]$_{ARG0}$ [ate]$_{REL}$ [the apple]$_{ARG1}$ ", where "ate" is the predicate. The precise arguments depend on a verb's *frame* and if there are multiple verbs in a sentence some words might have multiple tags. In addition to the ARG0-5 tags, there there are 13 modifier tags such as ARGM-LOC (locational) and ARGM-TMP (temporal) that operate in a similar way for all verbs.

Language Models A language model traditionally estimates the probability of the next word being w in a sequence. We consider a different setting: predict whether the given sequence exists in nature, or not, following the methodology of (Okanohara & Tsujii, 2007). This is achieved by labeling real texts as positive examples, and generating "fake" negative text.

Semantically Related Words ("Synonyms") This is the task of predicting whether two words are semantically related (synonyms, holonyms, hypernyms...) which is measured using the WordNet database (`http://wordnet.princeton.edu`) as ground truth.

Our main interest is SRL, as it is, in our opinion, the most complex of these tasks. We use all these tasks to: (i) show the generality of our proposed architecture; and (ii) improve SRL through multitask learning.

3. General Deep Architecture for NLP

All the NLP tasks above can be seen as tasks assigning labels to words. The traditional NLP approach is: extract from the sentence a rich set of hand-designed features which are then fed to a classical *shallow* classification algorithm, e.g. a Support Vector Machine (SVM), often with a linear kernel. The choice of features is a completely empirical process, mainly based on trial and error, and the feature selection is task dependent, implying additional research for each new NLP task. Complex tasks like SRL then require a large number of possibly complex features (e.g., extracted from a parse tree) which makes such systems slow and intractable for large-scale applications.

Instead we advocate a deep neural network (NN) architecture, trained in an end-to-end fashion. The input sentence is processed by several layers of feature extraction. The features in deep layers of the network are *automatically trained* by backpropagation to be relevant to the task. We describe in this section a general deep architecture suitable for all our NLP tasks, and easily generalizable to other NLP tasks.

Our architecture is summarized in Figure 1. The first layer extracts features for each word. The second layer extracts features from the sentence treating it as a *sequence* with local and global structure (i.e., it is not treated like a bag of words). The following layers are classical NN layers.

3.1. Transforming Indices into Vectors

As our architecture deals with raw words and not engineered features, the first layer has to map words into real-valued vectors for processing by subsequent layers of the NN. For simplicity (and efficiency) we consider words as indices in a finite dictionary of words $\mathcal{D} \subset \mathbb{N}$.

Lookup-Table Layer Each word $i \in \mathcal{D}$ is *embedded* into a d-dimensional space using a *lookup table* $LT_W(\cdot)$:

$$LT_W(i) = W_i \,,$$

where $W \in \mathbb{R}^{d \times |\mathcal{D}|}$ is a matrix of parameters to be learnt, $W_i \in \mathbb{R}^d$ is the i^{th} column of W and d is the word vector size (wsz) to be chosen by the user. In the first layer of our architecture an input sentence $\{s_1, s_2, \ldots s_n\}$ of n words in $\mathcal{D}$ is thus transformed into a series of vectors $\{W_{s_1}, W_{s_2}, \ldots W_{s_n}\}$ by apply-

ing the lookup-table to each of its words.

It is important to note that the parameters W of the layer are automatically *trained* during the learning process using backpropagation.

Variations on Word Representations In practice, one may want to introduce some basic pre-processing, such as word-stemming or dealing with upper and lower case. In our experiments, we limited ourselves to converting all words to lower case, and represent the capitalization as a separate feature (yes or no).

When a word is decomposed into K elements (features), it can be represented as a tuple $\boldsymbol{i} = \{i^1, i^2, \dots i^K\} \in \mathcal{D}^1 \times \cdots \times \mathcal{D}^K$, where $\mathcal{D}^k$ is the dictionary for the k^{th}-element. We associate to each element a lookup-table $LT_{W^k}(\cdot)$, with parameters $W^k \in \mathbb{R}^{d^k \times |\mathcal{D}^k|}$ where $d_k \in \mathbb{N}$ is a user-specified vector size. A word $\boldsymbol{i}$ is then embedded in a $d = \sum_k d^k$ dimensional space by concatenating all lookup-table outputs:

$$LT_{W^1,\dots,W^K}(\boldsymbol{i})^{\mathrm{T}} = (LT_{W^1}(i^1)^{\mathrm{T}}, \dots, LT_{W^K}(i^K)^{\mathrm{T}})$$

Classifying with Respect to a Predicate In a complex task like SRL, the class label of each word in a sentence depends on a given *predicate*. It is thus necessary to encode in the NN architecture which predicate we are considering in the sentence.

We propose to add a feature for each word that encodes its relative distance to the chosen predicate. For the i^{th} word in the sentence, if the predicate is at position pos_p we use an additional lookup table $LT^{dist_p}(i - pos_p)$.

3.2. Variable Sentence Length

The lookup table layer maps the original sentence into a sequence $\boldsymbol{x}(\cdot)$ of n identically sized vectors:

$$(\boldsymbol{x}_1, \boldsymbol{x}_2, \dots, \boldsymbol{x}_n), \quad \forall t \ \boldsymbol{x}_t \in \mathbb{R}^d \,. \tag{1}$$

Obviously the size n of the sequence varies depending on the sentence. Unfortunately normal NNs are not able to handle sequences of variable length.

The simplest solution is to use a *window approach*: consider a window of fixed size ksz around each word we want to label. While this approach works with great success on simple tasks like POS, it fails on more complex tasks like SRL. In the latter case it is common for the role of a word to depend on words far away in the sentence, and hence outside of the considered window.

When modeling long-distance dependencies is important, Time-Delay Neural Networks (TDNNs) (Waibel et al., 1989) are a better choice. Here, *time* refers

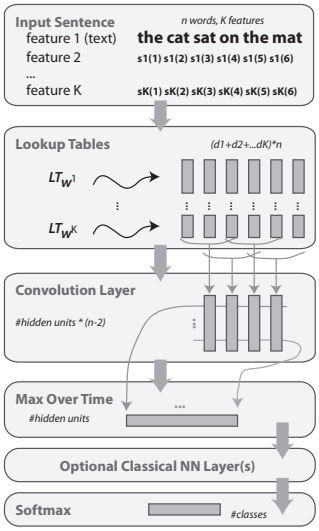

Figure 1. A general deep NN architecture for NLP. Given an input sentence, the NN outputs class probabilities for *one* chosen word. A classical window approach is a special case where the input has a fixed size ksz, and the TDNN kernel size is ksz; in that case the TDNN layer outputs only one vector and the Max layer performs an identity.

to the idea that a sequence has a notion of order. A TDNN "reads" the sequence in an online fashion: at *time* $t \geq 1$, one sees $\boldsymbol{x}_t$, the t^{th} word in the sentence.

A classical TDNN layer performs a *convolution* on a given sequence $\boldsymbol{x}(\cdot)$, outputting another sequence $\boldsymbol{o}(\cdot)$ whose value at time t is:

$$\boldsymbol{o}(t) = \sum_{j=1-t}^{n-t} \boldsymbol{L}_j \cdot \boldsymbol{x}_{t+j} \,, \tag{2}$$

where $\boldsymbol{L}_j \in \mathbb{R}^{n_{hu} \times d}$ $(-n \leq j \leq n)$ are the parameters of the layer (with n_{hu} hidden units) trained by backpropagation. One usually constrains this convolution by defining a *kernel width*, ksz, which enforces

$$\forall \ |j| > (ksz - 1)/2, \quad \boldsymbol{L}_j = \boldsymbol{0} \,. \tag{3}$$

A classical window approach only considers words in a window of size ksz around the word to be labeled. Instead, if we use (2) and (3), a TDNN considers at the same time *all* windows of ksz words in the sentence.

TDNN layers can also be *stacked* so that one can extract local features in lower layers, and more global features in subsequent ones. This is an approach typically used in convolutional networks for vision tasks, such as the LeNet architecture (LeCun et al., 1998).

We then add to our architecture a layer which captures the *most relevant features over the sentence* by feeding

the TDNN layer(s) into a "Max" Layer, which takes the maximum over time (over the sentence) in (2) for each of the n_{hu} output features.

As the layer's output is of fixed dimension (independent of sentence size) subsequent layers can be classical NN layers. Provided we have a way to indicate to our architecture the word *to be labeled*, it is then able to use features extracted from *all* windows of ksz words in the sentence to compute the label of *one* word of interest.

We indicate the word to be labeled to the NN with an additional lookup-table, as suggested in Section 3.1. Considering the word at position pos_w we encode the relative distance between the i^{th} word in the sentence and this word using a lookup-table $LT^{dist_w}(i - pos_w)$.

3.3. Deep Architecture

A TDNN (or window) layer performs a linear operation over the input words. While linear approaches work fairly well for POS or NER, more complex tasks like SRL require nonlinear models. One can add to the NN one or more classical NN layers. The output of the l^{th} layer containing n_{hu_l} hidden units is computed with $\boldsymbol{o^l} = \tanh(\boldsymbol{L^l} \cdot \boldsymbol{o^{l-1}})$, where the matrix of parameters $\boldsymbol{L^l} \in \mathbb{R}^{n_{hu_l} \times n_{hu_{l-1}}}$ is trained by backpropagation.

The size of the last (parametric) layer's output $\boldsymbol{o^{last}}$ is the number of classes considered in the NLP task. This layer is followed by a *softmax* layer (Bridle, 1990) which makes sure the outputs are positive and sum to 1, allowing us to interpret the outputs of the NN as probabilities for each class. The i^{th} output is given by $e^{o_i^{last}} / \sum_j e^{o_j^{last}}$. The whole network is trained with the cross-entropy criterion (Bridle, 1990).

3.4. Related Architectures

In (Collobert & Weston, 2007) we described a NN suited for SRL. This work also used a lookup-table to generate word features (see also (Bengio & Ducharme, 2001)). The issue of labeling with respect to a predicate was handled with a special hidden layer: its output, given input sequence (1), predicate position pos_p, and the word of interest pos_w was defined as:

$$\boldsymbol{o}(t) = \mathcal{C}(t - pos_w,\, t - pos_p) \cdot \boldsymbol{x}_t.$$

The function $\mathcal{C}(\cdot)$ is shared through time t: one could say that this is a variant of a TDNN layer with a kernel width $ksz = 1$ but where the parameters are *conditioned* with other variables (distances with respect to the verb and word of interest).

The fact that $\mathcal{C}(\cdot)$ does not combine several words in the same neighborhood as in our TDNN approach limits the dependencies between words it can model. Also $\mathcal{C}(\cdot)$ is itself a NN inside a NN. Not only does one have to carefully design this additional architecture, but it also makes the approach more complicated to train and implement. Integrating all the desired features in $\boldsymbol{x}()$ (including the predicate position) via lookup-tables makes our approach simpler, more general and easier to tune.

4. Multitasking with Deep NN

Multitask learning (MTL) is the procedure of learning several tasks at the same time with the aim of mutual benefit. This an old idea in machine learning; a good overview, especially focusing on NNs, can be found in (Caruana, 1997).

4.1. Deep Joint Training

If one considers *related* tasks, it makes sense that features useful for one task might be useful for other ones. In NLP for example, POS predictions are often used as features for SRL and NER. Improving generalization on the POS task might therefore improve both SRL and NER.

A NN automatically learns features for the desired tasks in the deep layers of its architecture. In the case of our general architecture for NLP presented in Section 3, the deepest layer (consisting of lookup-tables) *implicitly learns* relevant features for each word in the dictionary. It is thus reasonable to expect that when training NNs on *related* tasks, sharing deep layers in these NNs would improve features produced by these deep layers, and thus improve generalization performance. The last layers of the network can then be task specific.

In this paper we show this procedure performs very well for NLP tasks when sharing the lookup-tables of each considered task, as depicted in Figure 2. Training is achieved in a stochastic manner by looping over the tasks:

1. Select the next task.
2. Select a random training example for this task.
3. Update the NN for this task by taking a gradient step with respect to this example.
4. Go to 1.

It is worth noticing that labeled data for training each task can come from completely different datasets.

4.2. Previous Work in MTL for NLP

The NLP field contains many related tasks. This makes it a natural field for applying MTL, and sev-

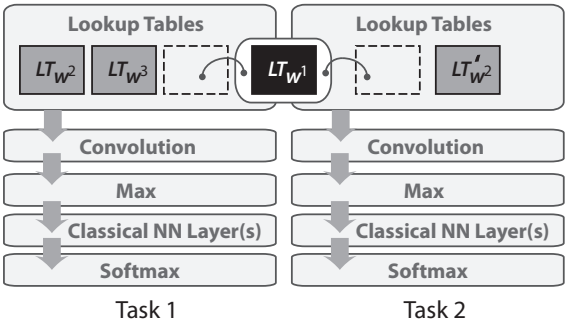

Figure 2. Example of deep multitasking with NN. Task 1 and Task 2 are two tasks trained with the architecture presented in Figure 1. One lookup-table (in black) is shared (the other lookup-tables and layers are task specific). The principle is the same with more than two tasks.

eral techniques have already been explored.

Cascading Features The most obvious way to achieve MTL is to train one task, and then use this task as a feature for another task. This is a very common approach in NLP. For example, in the case of SRL, several methods (e.g., (Pradhan et al., 2004)) train a POS classifier and use the output as features for training a parser, which is then used for building features for SRL itself. Unfortunately, tasks (features) are learnt separately in such a cascade, thus propagating errors from one classifier to the next.

Shallow Joint Training If one possesses a dataset labeled for several tasks, it is then possible to train these tasks jointly in a *shallow* manner: one unique model can predict all task labels at the same time. Using this scheme, the authors of (Sutton et al., 2007) proposed a conditional random field approach where they showed improvements from joint training on POS tagging and noun-phrase chunking tasks. However the requirement of jointly annotated data is a limitation, as this is often not the case. Similarly, in (Miller et al., 2000) NER, parsing and relation extraction were jointly trained in a statistical parsing model achieving improved performance on all tasks. This work has the same joint labeling requirement problem, which the authors avoided by using a predictor to fill in the missing annotations.

In (Sutton & McCallum, 2005a) the authors showed that one could learn the tasks independently, hence using different training sets, by only leveraging predictions jointly in a *test time* decoding step, and still obtain improved results. The problem is, however, that this will not make use of the shared tasks at *training time*. The NN approach used here seems more flexible in these regards.

Finally, the authors of (Musillo & Merlo, 2006) made an attempt at improving the semantic role labeling task by joint inference with syntactic parsing, but their results are not state-of-the-art. The authors of (Sutton & McCallum, 2005b) also describe a negative result at the same joint task.

5. Leveraging Unlabeled Data

Labeling a dataset can be an expensive task, especially in NLP where labeling often requires skilled linguists. On the other hand, unlabeled data is abundant and freely available on the web. Leveraging unlabeled data in NLP tasks seems to be a very attractive, and challenging, goal.

In our MTL framework presented in Figure 2, there is nothing stopping us from jointly training supervised tasks on labeled data *and* unsupervised tasks on unlabeled data. We now present an unsupervised task suitable for NLP.

Language Model We consider a *language model* based on a simple fixed window of text of size ksz using our NN architecture, given in Figure 2. We trained our language model to discriminate a two-class classification task: if the word in the middle of the input window is related to its context or not. We construct a dataset for this task by considering all possible ksz windows of text from the entire of English Wikipedia (`http://en.wikipedia.org`). Positive examples are windows from Wikipedia, negative examples are the same windows but where the middle word has been replaced by a random word.

We train this problem with a ranking-type cost:

$$\sum_{s \in \mathcal{S}} \sum_{w \in \mathcal{D}} \max\left(0,\, 1 - f(s) + f(s^w)\right) , \qquad (4)$$

where $\mathcal{S}$ is the set of sentence windows of text, $\mathcal{D}$ is the dictionary of words, and $f(\cdot)$ represents our NN architecture without the softmax layer and s^w is a sentence window where the middle word has been replaced by the word w. We sample this cost *online* w.r.t. (s, w).

We will see in our experiments that the features (embedding) learnt by the lookup-table layer of this NN clusters semantically similar words. These discovered features will prove very useful for our shared tasks.

Previous Work on Language Models (Bengio & Ducharme, 2001) and (Schwenk & Gauvain, 2002) already presented very similar language models. However, their goal was to give a *probability* of a word given *previous* ones in a sentence. Here, we only want to have a good representation of words: we take advantage of the complete context of a word (before and af-

ter) to predict its relevance. Perhaps this is the reason the authors were never able to obtain a good embedding of their words. Also, using probabilities imposes using a cross-entropy type criterion and can require many tricks to speed-up the training, due to normalization issues. Our criterion (4) is much simpler in that respect.

The authors of (Okanohara & Tsujii, 2007), like us, also take a two-class approach (true/fake sentences). They use a *shallow* (kernel) classifier.

Previous Work in Semi-Supervised Learning For an overview of semi-supervised learning, see (Chapelle et al., 2006). There have been several uses of semi-supervised learning in NLP before, for example in NER (Rosenfeld & Feldman, 2007), machine translation (Ueffing et al., 2007), parsing (McClosky et al., 2006) and text classification (Joachims, 1999). The first work is a highly problem-specific approach whereas the last three all use a self-training type approach (Transductive SVMs in the case of text classification, which is a kind of self-training method). These methods augment the training set with labeled examples from the unlabeled set which are predicted by the model itself. This can give large improvements in a model, but care must be taken as the predictions are of course prone to noise.

The authors of (Ando & Zhang, 2005) propose a setup more similar to ours: they learn from unlabeled data as an auxiliary task in a MTL framework. The main difference is that they use *shallow* classifiers; however they report positive results on POS and NER tasks.

Semantically Related Words Task We found it interesting to compare the embedding obtained with a language model on unlabeled data with an embedding obtained with labeled data. WordNet is a database which contains semantic relations (synonyms, holonyms, hypernyms, ...) between around 150,000 words. We used it to train a NN similar to the language model one. We considered the problem as a two-class classification task: positive examples are pairs with a relation in Wordnet, and negative examples are random pairs.

6. Experiments

We used Sections 02-21 of the PropBank dataset version 1 (about 1 million words) for training and Section 23 for testing as standard in all SRL experiments. POS and chunking tasks use the same data split via the Penn TreeBank. NER labeled data was obtained by running the Stanford Named Entity Recognizer (a CRF based classifier) over the same data.

Table 1. Language model performance for learning an embedding in $wsz = 50$ dimensions (dictionary size: 30,000). For each column the queried word is followed by its index in the dictionary (higher means more rare) and its 10 nearest neighbors (arbitrary using the Euclidean metric).

Language models were trained on Wikipedia. In all cases, any numeric number was converted as "NUMBER". Accentuated characters were transformed to their non-accentuated versions. All paragraphs containing other non-ASCII characters were discarded. For Wikipedia, we obtain a database of *631M* words. We used WordNet to train the "synonyms" (semantically related words) task.

All tasks use the same dictionary of the 30,000 most common words from Wikipedia, converted to lower case. Other words were considered as *unknown* and mapped to a special word.

Architectures All tasks were trained using the NN shown in Figure 1. POS, NER, and chunking tasks were trained with the window version with $ksz = 5$. We chose linear models for POS and NER. For chunking we chose a hidden layer of 200 units. The language model task had a window size $ksz = 11$, and a hidden layer of 100 units. All these tasks used two lookup-tables: one of dimension wsz for the word in lower case, and one of dimension 2 specifying if the first letter of the word is a capital letter or not.

For SRL, the network had a convolution layer with $ksz = 3$ and 100 hidden units, followed by another hidden layer of 100 hidden units. It had three lookup-tables in the first layer: one for the word (in lower case), and two that encode relative distances (to the word of interest and the verb). The last two lookup-tables embed in 5 dimensional spaces. Verb positions are obtained with our POS classifier.

The language model network had only one lookup-table (the word in lower case) and 100 hidden units. It used a window of size $ksz = 11$.

We show results for different encoding sizes of the word in lower case: $wsz = 15$, 50 and 100.

Table 2. A Deep Architecture for SRL improves by learning auxiliary tasks that share the first layer that represents words as wsz-dimensional vectors. We give word error rates for wsz=15, 50 and 100 and various shared tasks.

SRL + POS + Chunking + NER + Language model	14.63	14.44	14.50

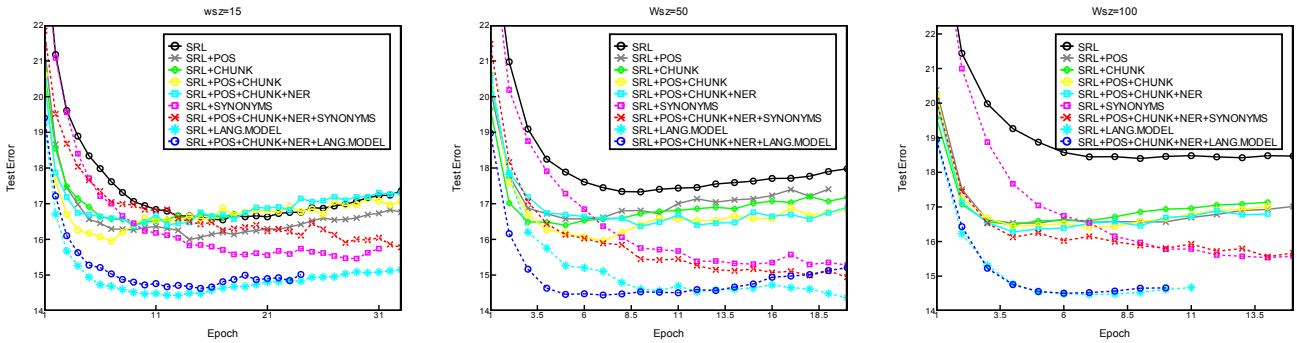

Figure 3. Test error versus number of training epochs over PropBank, for the SRL task alone and SRL jointly trained with various other NLP tasks, using deep NNs.

Results: Language Model Because the language model was trained on a huge database we first trained it *alone*. It takes about a week to train on one computer. The embedding obtained in the word lookup-table was extremely good, even for uncommon words, as shown in Table 1. The embedding obtained by training on labeled data from WordNet "synonyms" is also good (results not shown) however the coverage is not as good as using unlabeled data, e.g. "Dreamcast" is not in the database.

The resulting word lookup-table from the language model was used as an initializer of the lookup-table used in MTL experiments with a language model.

Results: SRL Our main interest was improving SRL performance, the most complex of our tasks. In Table 2, we show results comparing the SRL task alone with the SRL task jointly trained with different combinations of the other tasks. For all our experiments, training was achieved in a few epochs (about a day) over the PropBank dataset as shown in Figure 3. Testing takes 0.015s to label a complete sentence (given one verb).

All MTL experiments performed better than SRL alone. With larger wsz (and thus large capacity) the relative improvement becomes larger from using MTL compared to the task alone, which shows MTL is a good way of regularizing: in fact with MTL results are fairly stable with capacity changes.

The *semi-supervised* training of SRL using the language model performs better than other combinations. Our best model performed as low as 14.30% in per-word error rate, which is to be compared to previously published results of 16.36% with an NN architecture (Collobert & Weston, 2007) and 16.54% for a state-of-the-art method based on parse trees (Pradhan et al., 2004)[1]. Further, our system is the only one not to use POS tags or parse tree features.

Results: POS and Chunking Training takes about 30 min for these tasks alone. Testing time for labeling a complete sentence is about 0.003s. We obtained modest improvements to POS and chunking results us-

[1]Our loss function optimized per-word error rate. We note that many SRL results e.g. the CONLL 2005 evaluation use F1 as a standard measure.

ing MTL. Without MTL (for $wsz = 50$) we obtain 2.95% test error for POS and 4.5% (91.1 F-measure) for chunking. With MTL we obtain 2.91% for POS and 3.8% (92.71 F-measure) for chunking. POS error rates in the 3% range are state-of-the-art. For chunking, although we use a different train/test setup to the CoNLL-2000 shared task (`http://www.cnts.ua.ac.be/conll2000/chunking`) our system seems competitive with existing systems (better than 9 of the 11 submitted systems). However, our system is the only one that does *not use* POS tags as input features.

Note, we did not evaluate NER error rates because we used non-gold standard annotations in our setup. Future work will more thoroughly evaluate these tasks.

7. Conclusion

We proposed a general deep NN architecture for NLP. Our architecture is extremely fast enabling us to take advantage of huge databases (e.g. 631 million words from Wikipedia). We showed our deep NN could be applied to various tasks such as SRL, NER, POS, chunking and language modeling. We demonstrated that learning tasks simultaneously can improve generalization performance. In particular, when training the SRL task jointly with our language model our architecture achieved state-of-the-art performance in SRL without any explicit syntactic features. This is an important result, given that the NLP community considers syntax as a mandatory feature for semantic extraction (Gildea & Palmer, 2001).

Autonomous Geometric Precision Error Estimation in Low-Level Computer Vision Tasks

Andrés Corrada-Emmanuel CORRADA@CS.UMASS.EDU
Howard Schultz HSCHULTZ@CS.UMASS.EDU
Computer Science Department, University of Massachusetts at Amherst, 140 Governors Drive,Amherst, MA 01003-9264

Abstract

Errors in map-making tasks using computer vision are sparse. We demonstrate this by considering the construction of digital elevation models that employ stereo matching algorithms to triangulate real-world points. This sparsity, coupled with a geometric theory of errors recently developed by the authors, allows for autonomous agents to calculate their own precision independently of ground truth. We connect these developments with recent advances in the mathematics of sparse signal reconstruction or compressed sensing. The theory presented here extends the autonomy of 3-D model reconstructions discovered in the 1990s to their errors.

1. Introduction

Autonomy of robots or intelligent sensors depends on developing algorithms that can assess their own performance independent of ground truth. Consider an Aerial Mapping Appliance (AMA) that must construct a map or 3-D model of the world based on photographs. Researchers in computer vision discovered in the 1990s that a faithful 3-D model of an imaged scene was possible without any knowledge of the positions, or orientations of the camera that took the photographs (Beardsley et al., 1996). This reconstruction is even possible without knowing the internal parameters of the camera (Pollefeys et al., 1999). The geometry of multiple images contains all the necessary information to do this reconstruction. This independence of 3-D model reconstruction from ground truth (in this case, camera positions, etc.) raises the possibility that the errors in the reconstruction can also be recovered autonomously by an intelligent agent such as the AMA.

Autonomous error estimation for 3-D model reconstruction was recently demonstrated to be possible by the authors (Corrada-Emmanuel et al., 2007; Corrada-Emmanuel & Schultz, 2008). The theory depends on making a distinction between accuracy and precision. Knowledge of accuracy is not possible without ground truth. Precision can be estimated autonomously. This paper will demonstrate that autonomous precision estimation is also related to the mathematics of sparse signal reconstruction or compressed sensing (Donoho, 2006a). The precision errors of measurements, not just the measurements, are sparse themselves. This sparsity is the key to their reconstruction.

2. The Distinction between Geometric Accuracy and Precision

The concepts of accuracy and precision are well known to all scientists. The Machine Learning community knows these concepts as bias and variance (Bishop, 2007). Bias refers to how far an estimate is from the true value. Variance captures how noisy that estimate is given the measurements used to compute it. Our meaning of accuracy and precision in 3-D models is analogous to bias and variance but not equivalent. Our definitions are geometrical in nature.

Imagine that one had a set of 3-D models of a scene. Furthermore, along with the models one also has the ground truth or exact locations of points in the scene. The total error of the models can be defined as

$$\sum_{\text{models}} \sum_{\text{points}} [\vec{x}_{\text{model}}(\text{point}) - \vec{x}_{\text{true}}(\text{point})]^2 \quad (1)$$

We can decrease the total error in the models by applying a global transformation to all the models. For

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

example, the models may be systematically off by 1 meter in some direction. The *geometric precision* of the models is defined as the minimum possible total error after application of a global transformation to all the models:

$$\min_{T} \sum_{\text{models}} \sum_{\text{points}} \left[T(\vec{x}_{\text{model}}(\text{point})) - \vec{x}_{\text{true}}(\text{point})\right]^2 . \tag{2}$$

The *geometric accuracy* is defined as difference between the total error and the geometric precision.

We describe some simple examples to clarify these definitions. Imagine a 3-D model reconstruction that is merely a translated example of the real world, i.e. all locations are off by 1 meter to the North. The reconstruction has an accuracy error of 1 meter and zero precision error. A model with zero accuracy error but some precision error can be created by taking a perfect reconstruction and individually randomizing the elevation of the reconstruction with zero mean.

The concept of geometric accuracy can thus be captured by a successive set of transformations that the reader may want to view as encompassing the usual hierarchy of projective, affine and euclidean transformations (Hartley & Zisserman, 2000; Faugeras et al., 2001) or some subset of them. The rest of this paper will use the words accuracy and precision as shorthand for these geometric definitions.

2.1. Autonomous Elevation Difference Equations and Geometric Precision

Our central claim is that precision can be estimated autonomously even as the accuracy of the models is completely unknown. Autonomous geometric precision error estimation is possible by creating quantities that are invariant under global accuracy transformations. In this paper we will consider one such quantity that is useful for characterizing the precision errors in DEMs and has been discussed in our previous papers (Corrada-Emmanuel et al., 2007):

$$\Delta_{P,Q}(x,y) = \frac{1}{P}\sum_{i=1}^{P} Z_i - \frac{1}{Q}\sum_{j=1}^{Q} Z_j \tag{3}$$

$$= \frac{1}{P}\sum_{i=1}^{P} \delta_i - \frac{1}{Q}\sum_{j=1}^{Q} \delta_j, \tag{4}$$

where the integers P and Q are between 1 and the number of models being compared, $1 \leq P \leq M$ and $1 \leq Q \leq M$. A DEM i is a collection of elevation postings at different (x,y) locations, $\{Z_i(x,y)\}$. The precision error in each posting is denoted by $\delta_i(x,y)$, so in general one can write

$$Z_i(x,y) = Z_{\text{true}}(x,y) + \delta_i(x,y). \tag{5}$$

By picking the integers P and Q less than or equal to the number of DEM models, we guarantee that the true value of the elevation cancels out at each posting since

$$\frac{1}{P} * (P * Z_{\text{true}}) - \frac{1}{Q} * (Q * Z_{\text{true}}) = 0 \tag{6}$$

so that equation 4 follows from equation 3.

By considering all possible values P and Q one can find a set of linearly independent equations for the elevation precision errors. We call this independent set the *autonomous difference equations*. Note that these equations are not being used to construct a better estimate of the true elevation by performing some simple averaging over them. Their sole purpose is to probe the errors in the reconstructed elevations. More general expressions that take into account x and y position errors can be constructed but we defer discussion of these to future papers.

Equation 3 can be calculated from the observable elevations. The task of the autonomous agent is to estimate the precision errors $\{\delta_i\}$ in equation 4 and how they are correlated with each other. Once the agent knows these correlations, the precision error of a fused estimated can be decreased while possibly increasing its accuracy error. This may be a suitable action to take since in many computer vision tasks accuracy is cheaper to fix than precision, a point we clarify in our concluding remarks.

3. The Covariance Matrix for Precision Errors

An AMA or robot on a mapping mission will not know beforehand what errors it will make during its activities. Sensors could systematically malfunction. Lighting conditions may be unfavorable at certain viewing angles. These and other factors will inevitably mean that repeated measurements of the same scene will be partly correlated, or their precision may vary widely. How should the 3-D models obtained from different vantage points be fused? How fast is the precision error in the reconstructions decreasing as a function of the collected images? Has the AMA attained a desired precision level and therefore completed its mission? Autonomous mission planning by robots requires answers to these questions.

We argue that a principled approach to answering these questions must rely on an autonomous estima-

tion of the covariance matrix of the 3-D models. Having multiple measurements whose errors are strongly correlated is not much better than a single measurement, for example. Knowing the covariance matrix would allow the agent to discard bad data, understand its rate of error decrease as a function of data collection, and provide a fused estimate that monotonically improves with time.

The covariance matrix for DEM errors is composed of entries of the form $\langle \delta_i \delta_j \rangle - \langle \delta_i \rangle \langle \delta_j \rangle$. For ease of discussion, we will assume that the precision error has been de-meaned so $\langle \delta_i \rangle = 0$ for all i, so the covariance matrix is equivalent to $\langle \delta_i \delta_j \rangle$ in this paper.

It is impossible, generally, to calculate this covariance matrix given a set of measurements. We explain this fully by constructing a linear algebra system for the covariance matrix based on the autonomous difference equations (eqs. 3 and 4) to demonstrate that it defines an under-determined system – one where we have less equations that unknowns.

3.1. An Under-Determined Linear Algebra System for the Covariance Matrix Entries

Squaring the autonomous difference equations and averaging over all the posting locations (x, y) gives a set of linear equations for all the entries in the covariance matrix. We denote this system by

$$S = \Phi \Delta. \tag{7}$$

The vector S is the "signal" of the DEM precision errors. Its components are calculated using equation 3. The matrix Φ consists of the rational fractions that come from expanding the square of equation 4. The vector Δ are the entries $< \delta_i \delta_j >$ of the covariance matrix that we want to estimate.

Equation 7 defines an under-determined linear system because the number of independent entries in the covariance matrix is $M(M+1)/2$ given M models (the matrix is symmetric). The number of independent equations that can be constructed from the autonomous difference equations is equal to $M(M+1)/2 - M$. Therefore, the system is always under-determined by M equations.

3.2. The Correlated-Pair Error Model

This limitation was circumvented in our earlier papers (Corrada-Emmanuel et al., 2007) by *assuming* that the covariance matrix had the simple form

$$\begin{pmatrix} * & * & 0 & 0 & \dots \\ * & * & 0 & 0 & \dots \\ 0 & 0 & * & * & \dots \\ 0 & 0 & * & * & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{pmatrix} \tag{8}$$

The block-diagonal shape came from our production of two DEMs from every photographic pair, a practice that differs from the usual photogrammetric convention of producing a single DEM from a photographic pair. We assumed that only the two DEMs from the same photographic pair were correlated with each other. These correlated-pair DEMs gave rise to the block-diagonal form of the covariance matrix. In effect, we assumed that the covariance matrix was sparse since this correlated-pair model only requires $n + n/2$ non-zero terms to be estimated for the covariance matrix.

3.2.1. Asymmetry in Computer Vision Stereo Matching

The reason one can produce two different DEMs from two photographs is that stereo matching algorithms may not be perfectly symmetric in their output (Brown et al., 2003). This means that a DEM produced by matching image A to image B, which we denote by $A \rightarrow B$, will not lead to the same DEM as doing $B \rightarrow A$. Of course, the resulting DEM pair ($A \rightarrow B$, $B \rightarrow A$) is highly correlated. The correlated-pair error model in equation 8 is meant to capture this unknown, but possibly large, cross-correlation between the errors in the pair. One can readily calculate that this block-diagonal error model allows one to calculate the precision error exactly whenever three or more photographs overlap on the same scene.

4. Sparsity of Geometric Precision Error

As useful as the correlated-pair error model may be in certain circumstances it is a *model* and therefore cannot form the foundation of a robust process for error estimation. It is conceivable that DEMs from unrelated photographs could become correlated in their errors due to environmental factors or even instrument malfunction. A robust estimation of the covariance matrix should not depend on any assumptions of how DEMs are correlated.

Recent developments in the mathematics of sparse signal reconstruction or compressed sensing (Donoho, 2006a) offer us a mathematical procedure to deal with

this situation. During a mapping mission photographs taken from different viewing positions and orientations will lead to mapping errors that are uncorrelated but occasionally may have strong correlations between them. We just do not know a priori which DEMs will be correlated with each other, only that these cross-correlations will be sparse.

As we noted in section 3.1, the linear system is at the margin of being completely determined being shy by just M equations. If the covariance matrix was sparse enough in the sense that on the order of M independent entries were zero, the estimation would be robust. We can express this condition by dividing the number of equations we have $(M(M+1)/2 - M)$ by the number we need $(M(M+1)/2)$

$$1 - \frac{2}{M+1}. \tag{9}$$

As the number of models increases, this fraction becomes increasingly near to one – the condition for being well-determined.

We hypothesize that given enough models ($M \to \infty$), any experimental situation can be driven into a sparse regime for the precision error covariance matrix. Note that we are not talking about sparsity of the models themselves, but of the correlations between their precision errors.

The under-determined linear system 7 can be solved by using the ℓ_1-minimization technique advocated in the compressed sensing literature (Donoho, 2006b)

$$\min ||\Delta||_1 \text{ subject to } S = \Phi\Delta. \tag{10}$$

This problem can be solved as a convex optimization problem (Donoho, 2006b) by recasting it as the equivalent linear program:

$$\min \sum_i u_i \text{ subject to} \tag{11}$$

$$u_i + \Delta_i \geq 0 \tag{12}$$

$$u_i - \Delta_i \geq 0 \tag{13}$$

$$\Phi\Delta = S \tag{14}$$

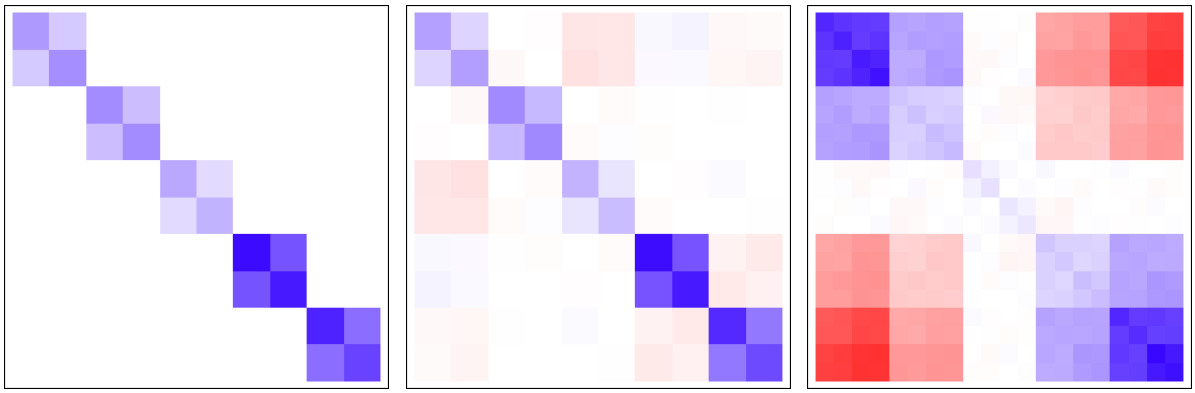
In the experimental section of the paper we will show that this approach reconstructs a covariance matrix for the precision errors that is very close to the correlated-pair model (eq. 8). Some off-diagonal terms hypothesized to be zero are about 5 times smaller than the in-pair cross correlation. We emphasize that this sparsity of errors hypothesis is an experimental assertion. No mathematical proof can be given that this sparsity condition can be met. The applicability of the assertion is based on the experimental realization of the AMA and the features of the terrain. A device built with stable imaging sensors of high quality that is mapping a reasonably static terrain would be a good candidate for a suitable condition that meets our sparsity assumption.

5. More Data Means Higher Resolution Error Maps

The name *compressed sensing* comes from the realization that sparsity implies a low-dimensional or compressible signal. If pictures of a natural scene taken with a $n \times n$ CCD can always be compressed, why take n^2 measurements? The imaging of the scene can be compressed by using less pixels and then reconstructed with an under-determined linear system. This has been dramatically demonstrated by the Rice University one-pixel camera (Wakin et al., 2006). About 1,000 measurements with a single pixel reproduced images captured by a 4,000 pixel CCD. Compressed sensing implies that we are wasting effort by taking too many measurements.

The error theory presented here gives a different perspective on this issue. Yes, reconstructing a 3-D model of the world can be done with less measurements. However, errors are an important aspect of all measurements. How confident can we be of any particular reconstruction? The only way to understand this is to produce not just maps of the territory that is being mapped, i.e. DEMs, but to also produce error maps of the same territory. The procedure for precision error estimation depends on averaging over all postings that a collection of DEMs have in common. Sparsity is only present after this averaging. The error map therefore has a much lower resolution than the DEM itself. Multiple measurements are needed to increase the resolution of this error map. In this view, no measurement is ever wasted – it leads to higher resolution in the error map of the measurements.

This suggests that the resolution of the error map should be studied by decreasing the map area that is used to create the average covariance matrix of the precision errors. As the averaging area is diminished, various cross-correlations between different DEMs will start to turn on. At some point, the number of these off-diagonal terms will be large enough to violate the condition of sparsity and the resolution limit of the error map would be reached. This resolution limit may vary across the mapped area and would naturally depend on the particular dataset. This phenomenon will be demonstrated in the experimental section.



(a) Twenty-Nine Palms correlated-pair model covariance

(b) Twenty-Nine Palms ℓ_1 minimization covariance

(c) Duke Forest covariance

Figure 1. Comparison of the covariance matrix obtained with ℓ_1-minimization versus that obtained by using the correlated-pair error model. All values are in units of m^2. Blue represents positive values, red negative values. The hue scale for figures (a) and (b) is normalized so that a value of 0.12 m^2 results in a completely saturated color pixel. Figure (c) is normalized with 2.5 m^2.

6. Experimental Results

We demonstrate the formalism for sparse precision error estimation by using a set of four aerial images taken of a desert terrain in the Twenty-Nine Palms region in California, USA. The images have been arbitrarily labeled as $\{A, B, C, D\}$. Four photographs allow us to produce 4*3=12 DEMs from all possible *matching chains* of the form $i \rightarrow j$. A blunder removal process, however, automatically identified that two of the DEMs ($B \rightarrow D$, and $D \rightarrow B$) differed in their elevation estimates by more than one meter for all postings. This pair was excluded from our calculations so the results presented here involve the remaining 10 DEMs.

6.1. Random Reconstructions via ℓ_1-Minimization

For 10 DEMs there are on the order of fifty thousand ways to write equation 4. The number of independent equations in this set is 45. An independent set selected from all possible permutations of the difference equations leads to a different reconstruction matrix Φ. To carry out the ℓ_1-minimization estimate of the 10x10 covariance matrix for the DEMs, we randomly selected ten different linearly independent sets and their corresponding Φ matrices. This was done to study the numerical stability of the reconstruction procedure. The statistical average was done over an overlap region of the DEMS that spanned the postings 500 to 1500 where 2000 by 2000 was the original size of the individual DEMs. This was done to exclude edge effects and increase the density of postings on which all DEMs gave an elevation estimate. Only postings for which we had a full 10 measurements were used. The number of postings was equal to 940,010 out of a possible million. Each posting represents an area of $(0.38\ m)^2$.

The reconstruction of the covariance matrix is shown in figure 1(b). The covariance matrix is presented as a 10x10 pixel image. For comparison, the covariance matrix reconstructed with the correlated-pair error model is shown in figure 1(a). No numerically significant variation in the reconstructed covariance matrix was observed with 10 randomly selected Φ matrices so a single figure is sufficient to summarize the results. Note that about 12 entries in the covariance matrix are practically zero – two more than the 10 entries required to define a well-determined linear system.

The ℓ_1-minimization procedure also ascribes most of the cross-correlations to the DEMs that come from asymmetrically matching the same pair of photographs. In addition, the sparse reconstruction has discovered that some of the DEMs are negatively correlated.

Is this error reconstruction correct? At this time we can point to its *self-consistent* character as strong evidence for its correctness. Neither the autonomous elevation difference equations or the ℓ_1-minimization procedure assume that certain DEMs are strongly correlated. Yet the empirically reconstructed matrix clearly shows that the 10 DEMs have a strong 5-pair structure exemplified by the block-diagonal structure. The reconstruction has 'discovered' that we used DEMs from asymmetric matching pairs.

Another self-consistent feature of the reconstruction is

that the more precise a DEM is, the smaller its cross-correlation with its asymmetric pair becomes. This is a behavior that we would expect from a system that is producing increasingly precise estimates.

6.1.1. Duke Forest DEMs

The Twenty-Nine Palms data, just discussed, is extremely high quality. The images were taken with a high-quality photogrammetric instrument. To confirm that precision errors can be recovered in more noisy data, we studied a series of aerial photographs of a forest canopy in the Duke Forest, NC taken with an off-the-shelf digital camera.

We randomly selected a track of images and picked four consecutive images. The images where multi-band and we chose the near-ir and green bands. The combination of bands and asymmetric pair matches resulted in twenty DEMs. The recovered precision error covariance matrix is shown in Figure 1(c). The recovery is similar to that for the Twenty-Nine Palms data, in that the highly-correlated pairs were discovered once again. As befits the noisier data set, the precision error estimated is $\approx 2.0\ m^2$ versus the $0.1\ m^2$ value for the Twenty-Nine Palms images.

6.2. Horizontal Resolution of the Precision Error Covariance Matrix

The self-consistent character of the reconstruction can be exploited further. The linear program that recovers the error has as side constraints that the diagonal terms of the covariance matrix have to be positive, a required property for the $\langle \delta_i^2 \rangle$ terms. To keep the reconstruction as a linear program, we did not require that the cross-correlations terms satisfy the inequality

$$\left| \frac{< \delta_i \delta_j >}{\sqrt{< \delta_i^2 >< \delta_j^2 >}} \right| \leq 1. \qquad (15)$$

The output of the linear program just turns out to satisfy these constraints for this particular dataset. Indeed, we now use the breakdown in these cross-correlation constraints to probe how much resolution can be obtained in the error map of the DEMs.

To study the resolution limit of ℓ_1-minimization procedure, we shrank the size of the area in the Twenty-Nine maps over which the difference equations were averaged. We have no independent way of verifying the validity of the reconstruction except the self-consistency check that the reconstructed vector does indeed represent a covariance matrix – its dimensionless cross-correlations should have an absolute value less than or equal to one.

Surprisingly the resolution of the covariance matrix for this data is on the order of 5x5 postings. We show an example of the covariance matrix for a patch encompassing the postings 500 to 505 in both directions in figure 2(a). The covariance matrix for the patch encompassing the postings 500 to 510 is shown in figure 2(b). The breakdown in reconstruction for the 5x5 patch is most evident in the cross-correlations related to the DEM in position 9. For this particular patch the variance of DEM 9 is calculated as $1.1\ 10^{-5}\ m^2$ and the variance of DEM 1 is calculated as $1.0\ 10^{-1}\ m^2$. The dimensionless cross-correlation between them has a value of 30.0 – the ℓ_1-minimization has not produced a proper covariance matrix for this small patch.

No breakdown is found in the 10x10 patch. Similar results were obtained over a handful of other patches over the mapped scene. Interestingly, an earlier paper by the authors had found that for this dataset the horizontal decorrelation length was in the order of 5 postings, a result that was obtained by a "cheating" experiment that used ray-tracing to establish a pseudo ground truth against which the error at the individual posting level could be calculated.

7. Conclusions and Future Work

We conclude by discussing the utility of estimating precision error even while neglecting or increasing the accuracy error. Geometric accuracy is defined by a global set of transformations. The parameters needed to define it are finite and readily extracted by knowing at most the location for three points in the world. In that sense, accuracy is cheap to obtain. Precision, on the other hand, captures the local variability of the 3-D model reconstructions. The parameters needed to model it, if one wished to do so, are correspondingly large. Therefore, 3-D model precision is expensive for the user to correct since it involves multiple measurements spread over the whole scene. Therefore, the autonomous error estimation algorithm presented here should have application in computer vision tasks where accuracy is not needed. An example of such a task is species identification by shape where the resolution is more important than the absolute size or orientation of the objects. Many more examples can be thought of, where accuracy is not relevant but precision is. One obvious class of problems for which this algorithm would not be helpful is those that require accurate geolocation of an object in the scene. A reasonable guarantee of accuracy can be obtained by using proper external references (GPS, attitude-heading sensors, etc.) but this algorithm is invariant to their accuracy error.

Table 1. Covariance matrix entries along the block diagonal for the ten DEMs in the 29 Palms dataset. Variance is in units of m^2.

The present paper has demonstrated that the covariance matrix of the geometric precision errors can be measured autonomously. The present formalism applies to other areas of Machine Learning, indeed, to any scientific setting where multiple scalar predictions are available for a set of entities. For example, the precision error equations (3) can used for comparing the relevance judgment of various information retrieval algorithms. Instead of elevations, one would use the binary judgment of relevancy to compare the retrieval models.

Future work will continue to explore the utility of the precision error covariance matrix for data fusion (what is the optimal way to combine the DEMs to minimize the total precision error?), and extend the formalism of the precision error equations (3) to multi-dimensional or other non-scalar models such as 3-D locations or parse trees in computational linguistics.

Abstract

This paper uses the notion of algorithmic stability to derive novel generalization bounds for several families of transductive regression algorithms, both by using convexity and closed-form solutions. Our analysis helps compare the stability of these algorithms. It suggests that several existing algorithms might not be stable but prescribes a technique to make them stable. It also reports the results of experiments with local transductive regression demonstrating the benefit of our stability bounds for model selection, in particular for determining the radius of the local neighborhood used by the algorithm.

1. Introduction

Many learning problems in information extraction, computational biology, natural language processing and other domains can be formulated as *transductive inference* problems (Vapnik, 1982). In the transductive setting, the learning algorithm receives both a labeled training set, as in the standard induction setting, and a set of unlabeled test points. The objective is to predict the labels of the test points. No other test points will ever be considered. This setting arises in a variety of applications. Often, the points to label are known but they have not been assigned a label due to the prohibitive cost of labeling. This motivates the use of transductive algorithms which leverage the unlabeled data during training to improve learning performance.

This paper deals with transductive regression, which arises in problems such as predicting the real-valued labels of the nodes of a known graph in computational biology, or the scores associated with known documents in information extraction or search engine tasks.

Several algorithms have been devised for the specific setting of transductive regression (Belkin et al., 2004b; Chapelle et al., 1999; Schuurmans & Southey, 2002; Cortes & Mohri, 2007). Several other algorithms introduced for transductive classification can be viewed in fact as transductive regression ones as their objective function is based on the squared loss, e.g., (Belkin et al.2004a; 2004b). Cortes and Mohri (2007) also gave explicit VC-dimension generalization bounds for transductive regression that hold for all bounded loss functions and coincide with the tight classification bounds of Vapnik (1998) when applied to classification.

This paper presents novel algorithm-dependent generalization bounds for transductive regression. Since they are algorithm-specific, these bounds can often be tighter than bounds based on general complexity measures such as the VC-dimension. Our analysis is based on the notion of algorithmic stability.

In Sec. 2 we give a formal definition of the transductive regression setting and the notion of stability for transduction. Our bounds generalize the stability bounds given by Bousquet and Elisseeff (2002) for the inductive setting and extend to regression the stability-based transductive classification bounds of (El-Yaniv & Pechyony, 2006). Standard concentration bounds

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

such as McDiarmid's bound (McDiarmid, 1989) cannot be readily applied to the transductive regression setting since the points are not drawn independently but uniformly without replacement from a finite set. Instead, a generalization of McDiarmid's bound that holds for random variables sampled without replacement is used, as in (El-Yaniv & Pechyony, 2006). Sec. 3.1 gives a simpler proof of this bound.

This concentration bound is used to derive a general transductive regression stability bound in Sec. 3.2. In Sec. 4, we present the stability coefficients for a family of local transductive regression algorithms. The analysis in this section is based on convexity. In Sec. 5, we study the stability of other transductive regression algorithms (Belkin et al., 2004a; Wu & Schölkopf, 2007; Zhou et al., 2004; Zhu et al., 2003) based on their closed form solution and propose a modification to the seemingly unstable algorithm that makes them stable and guarantees a non-trivial generalization bound. Finally, Sec. 6 shows the results of experiments with local transductive regression demonstrating the benefit of our stability bounds for model selection, in particular for determining the radius of the local neighborhood used by the algorithm. This provides a partial validation of our bounds and analysis.

2. Definitions

Let us first describe the transductive learning setting. Assume that a full sample X of $m+u$ examples is given. The learning algorithm further receives the labels of a random subset S of X of size m which serves as a training sample. The remaining u unlabeled examples, $x_{m+1}, \ldots, x_{m+u} \in X$, serve as test data. We denote by $X \vdash (S,T)$ a partitioning of X into the training set S and the test set T. The *transductive learning* problem consists of predicting accurately the labels $y_{m+1}, \ldots, y_{m+u}$ of the test examples, no other test examples will ever be considered (Vapnik, 1998).[1] The specific problems where the labels are real-valued numbers, as in the case studied in this paper, is that of *transduction regression*. It differs from the standard (*induction*) regression since the learning algorithm is given the unlabeled test examples beforehand and can thus exploit this information to improve performance.

We denote by $c(h,x)$ the cost of an error of a hypothesis h on a point x labeled with $y(x)$. The cost function commonly used in regression is the squared loss $c(h,x) = (h(x) - y(x))^2$. In the remaining of this paper, we will assume a squared loss but many of our results generalize to other convex cost functions. The training and test errors of h are respectively $\widehat{R}(h) = \frac{1}{m}\sum_{k=1}^{m} c(h,x_k)$ and $R(h) = \frac{1}{u}\sum_{k=1}^{u} c(h,x_{m+k})$. The generalization bounds we derive are based on the notion of transductive algorithmic stability.

Definition 1 (Transduction β-stability)**.** *Let L be a transductive learning algorithm and let h denote the hypothesis returned by L for $X \vdash (S,T)$ and h' the hypothesis returned for $X \vdash (S',T')$. L is said to be* uniformly β-stable *with respect to the cost function c if there exists $\beta \geq 0$ such that for any two partitionings $X \vdash (S,T)$ and $X \vdash (S',T')$ that differ in exactly one training (and thus test) point and for all $x \in X$,*

$$\left|c(h,x) - c(h',x)\right| \leq \beta. \tag{1}$$

3. Transduction Stability Bounds

3.1. Concentration Bound for Sampling without Replacement

Stability-based generalization bounds in the inductive setting are based on McDiarmid's inequality (1989). In the transductive setting, the points are drawn uniformly without replacement and thus are not independent. Therefore, McDiarmid's concentration bound cannot be readily used. Instead, a generalization of McDiarmid's bound for sampling without replacement is needed as in El-Yaniv and Pechyony (2006).

We will denote by $\mathbf{S}_1^m$ a sequence of random variables $S_1, \ldots, S_m$ and write $\mathbf{S}_1^m = \mathbf{x}_1^m$ as a shorthand for the m equalities $S_i = x_i$, $i = 1, \ldots, m$ and $\Pr[\mathbf{x}_{i+1}^m | \mathbf{x}_1^{i-1}, x_i] = \Pr[\mathbf{S}_{i+1}^m = \mathbf{x}_{i+1}^m | \mathbf{S}_1^{i-1} = \mathbf{x}_1^{i-1}, S_i = x_i]$.

Theorem 1 ((McDiarmid, 1989), 6.10)**.** *Let $\mathbf{S}_1^m$ be a sequence of random variables, each S_i taking values in the set X, and assume that a measurable function $\phi : X^m \mapsto \mathbb{R}$ satisfies: $\forall i \in [1,m], \forall x_i, x_i' \in X$,*

$$\left|\mathbb{E}_{\mathbf{S}_{i+1}^m}\left[\phi | \mathbf{S}_1^{i-1}, S_i = x_i\right] - \mathbb{E}_{\mathbf{S}_{i+1}^m}\left[\phi | \mathbf{S}_1^{i-1}, S_i = x_i'\right]\right| \leq c_i.$$

$$\textit{Then, } \forall \epsilon > 0, \quad \Pr\left[|\phi - \mathbb{E}\left[\phi\right]| \geq \epsilon\right] \leq 2\exp\left(\frac{-2\epsilon^2}{\sum_{i=1}^m c_i^2}\right).$$

The following is a concentration bound for sampling without replacement needed to analyze the generalization of transductive algorithms.

Theorem 2. *Let $\mathbf{x}_1^m$ be a sequence of random variables, sampled from an underlying set X of $m+u$ elements without replacement, and let that $\phi : X^m \mapsto \mathbb{R}$*

[1] Another natural setting for transduction is one where the training and test samples are both drawn according to the same distribution and where the test points, but not their labels, are made available to the learning algorithm. However, as pointed out by Vapnik (1998), any generalization bound in the setting we analyze directly yields a bound for this other setting, essentially by taking the expectation.

be a symmetric function such that for all $i \in [1,m]$ and for all $x_1,\ldots,x_m \in X$ and $x'_1,\ldots,x'_m \in X$,

$$\left|\phi(x_1,\ldots,x_m) - \phi(x_1,\ldots,x_{i-1},x'_i,x_{i+1},\ldots,x_m)\right| \leq c.$$

Then, $\forall \epsilon > 0, \quad \Pr\left[\left|\phi - \mathbb{E}\left[\phi\right]\right| \geq \epsilon\right] \leq 2\exp\left(\frac{-2\epsilon^2}{\alpha(m,u)c^2}\right),$

where $\alpha(m,u) = \frac{mu}{m+u-1/2} \cdot \frac{1}{1-1/(2\max\{m,u\})}$.

Proof. For a fixed $i \in [1,m]$, let $g(\mathbf{S}_1^{i-1}) = \mathbb{E}_{\mathbf{S}_{i+1}^m}\left[\phi|\mathbf{S}_1^{i-1}, S_i{=}x_i\right] - \mathbb{E}_{\mathbf{S}_{i+1}^m}\left[\phi|\mathbf{S}_1^{i-1}, S_i{=}x'_i\right]$. Then, $g(\mathbf{x}_1^{i-1}) = \sum_{\mathbf{x}_{i+1}^m} \phi(\mathbf{x}_1^{i-1}, x_i, \mathbf{x}_{i+1}^m) \Pr[\mathbf{x}_{i+1}^m|\mathbf{x}_1^{i-1}, x_i] - \sum_{\mathbf{x'}_{i+1}^m} \phi(\mathbf{x}_1^{i-1}, x'_i, \mathbf{x'}_{i+1}^m) \Pr[\mathbf{x'}_{i+1}^m|\mathbf{x}_1^{i-1}, x'_i]$.

For uniform sampling without replacement, the probability terms can be written as: $\Pr\left[\mathbf{x}_{i+1}^m|\mathbf{x}_1^{i-1}, x_i\right] = \prod_{k=i}^{m-1} \frac{1}{m+u-k} = \frac{u!}{(m+u-i)!}$. Thus, $g(\mathbf{x}_1^{i-1}) = \frac{u!}{(m+u-i)!}[\sum_{\mathbf{x}_{i+1}^m} \phi(\mathbf{x}_1^{i-1}, x_i, \mathbf{x}_{i+1}^m) - \sum_{\mathbf{x'}_{i+1}^m} \phi(\mathbf{x}_1^{i-1}, x'_i, \mathbf{x'}_{i+1}^m)]$. To compute the expression between brackets, we divide the set of permutations $\{\mathbf{x'}_{i+1}^m\}$ into two sets, those that contain x_i and those that do not. If a permutation $\mathbf{x'}_{i+1}^m$ contains x_i we can write it as $\mathbf{x'}_{i+1}^{k-1} x_i \mathbf{x'}_{k+1}^m$, where k is such that $x'_k = x_i$. We then match it up with the permutation $x_i \mathbf{x'}_{i+1}^{k-1} \mathbf{x'}_{k+1}^m$ from the set $\{x_i \mathbf{x}_{i+1}^m\}$. These two permutations contain exactly the same elements, and since the function ϕ is symmetric in its arguments, the difference in the value of the function on the permutations is zero.

In the other case, if a permutation $\mathbf{x'}_{i+1}^m$ does not contain the element x_i, then we simply match it up with the same permutation in $\{\mathbf{x}_{i+1}^m\}$. The matching permutations appearing in the summation are then $x_i \mathbf{x'}_{i+1}^m$ and $x'_i \mathbf{x'}_{i+1}^m$ which clearly only differ with respect to x_i. The difference in the value of the function ϕ in this case can be bounded by c. The number of such permutations is $(m-i)!\binom{m+u-(i+1)}{m-i} = \frac{(m+u-i-1)!}{(u-1)!}$, which leads to the following upper bound: $\sum_{\mathbf{x}_{i+1}^m} \phi(\mathbf{x}_1^{i-1}, x_i, \mathbf{x}_{i+1}^m) - \sum_{\mathbf{x'}_{i+1}^m} \phi(\mathbf{x}_1^{i-1}, x'_i, \mathbf{x'}_{i+1}^m) \leq \frac{(m+u-i-1)!}{(u-1)!} c$, which implies that $|g(\mathbf{x}_1^{i-1})| \leq \frac{u!}{(m+u-i)!} \cdot \frac{(m+u-i-1)!}{(u-1)!} c \leq \frac{u}{m+u-i} c$. Then, combining Theorem 1 with the identity $\sum_{i=1}^m \frac{1}{(m+u-i)^2} \leq \frac{m}{m+u-1/2} \frac{1}{u-1/2}$, yields that $\Pr\left[\left|\phi - \mathbb{E}\left[\phi\right]\right| \geq \epsilon\right] \leq 2\exp\left(\frac{-2\epsilon^2}{\alpha_u(m,u)c^2}\right)$, where $\alpha_u(m,u) = \frac{mu}{m+u-1/2} \cdot \frac{1}{1-1/(2u)}$. The function ϕ is symmetric in m and u in the sense that selecting one of the sets uniquely determines the other set. The statement of the theorem then follows from a similar bound with $\alpha_m(m,u) = \frac{mu}{m+u-1/2} \cdot \frac{1}{1-1/(2m)}$, taking the tighter of the two. □

3.2. Transductive Stability Bound

To obtain a general transductive regression stability bound, we apply the concentration bound of Theorem 2 to the random variable $\phi(S) = R(h) - \widehat{R}(h)$. To do so, we need to bound $\mathbb{E}_S\left[\phi(S)\right]$, where S is a random subset of X of size m, and $|\phi(S) - \phi(S')|$ where S and S' are samples differing by exactly one point.

Lemma 1. *Let H be a bounded hypothesis set ($\forall x \in X, |h(x) - y(x)| \leq B$) and L a β-stable algorithm returning the hypotheses h and h' for two training sets S and S of size m each, respectively, differing in exactly one point. Then,*

$$|\phi(S) - \phi(S')| \leq 2\beta + B^2(m+u)/(mu). \tag{2}$$

Proof. By definition, S and S' differ exactly in one point. Let $x_i \in S$, $x_{m+j} \in S'$ be the points in which the two sets differ. The lemma follows from the observation that for each one of the $m-1$ common labeled points in S and S', and for each one of the $u-1$ common test points in T and T' (recall $T = X \setminus S$, $T' = X \setminus S'$), the difference in cost is bounded by β, while for x_i and x_{m+j}, the difference in cost is bounded by B^2. Then, it follows that $|\phi(S) - \phi(S')| \leq \frac{(u-1)\beta}{u} + \frac{(m-1)\beta}{m} + \frac{B^2}{u} + \frac{B^2}{m} \leq 2\beta + B^2\left(\frac{1}{u} + \frac{1}{m}\right)$. □

Lemma 2. *Let h be the hypothesis returned by a β-stable algorithm L. Then, $|\mathbb{E}_S\left[\phi(S)\right]| \leq \beta$.*

Proof. By definition of $\phi(S)$, its expectation is $\frac{1}{u}\sum_{k=1}^u \mathbb{E}_S\left[c(h, x_{m+k})\right] - \frac{1}{m}\sum_{k=1}^m \mathbb{E}_S\left[c(h, x_k)\right]$. Since $\mathbb{E}_S\left[c(h, x_{m+j})\right]$ is the same for all $j \in [1,u]$, and $\mathbb{E}_S\left[c(h, x_i)\right]$ the same for all $i \in [1,m]$, for any i and j, $\mathbb{E}_S\left[\phi(S)\right] = \mathbb{E}_S\left[c(h, x_{m+j})\right] - \mathbb{E}_S\left[c(h, x_i)\right] = \mathbb{E}_{S'}\left[c(h', x_i)\right] - \mathbb{E}_S\left[c(h, x_i)\right]$. Thus, $\mathbb{E}_S\left[\phi(S)\right] = \mathbb{E}_{S,S' \sim X}\left[c(h', x_i) - c(h, x_i)\right] \leq \beta$. □

Theorem 3. *Let H be a bounded hypothesis set ($\forall x \in X, |h(x) - y(x)| \leq B$) and L a β-stable algorithm. Let h be the hypothesis returned by L when trained on $X \vdash (S,T)$. Then, for any $\delta > 0$, with prob. at least $1-\delta$,*

$$R(h) \leq \widehat{R}(h) + \beta + \left(2\beta + \frac{B^2(m+u)}{mu}\right)\sqrt{\frac{\alpha(m,u)\ln\frac{1}{\delta}}{2}}.$$

Proof. The result follows directly from Theorem 2 and Lemmas 1 and 2. □

This is a general bound that applies to *any* transductive algorithm. To apply it, the stability coefficient β, which depends on m and u, needs to be determined. In the subsequent sections, we derive bounds on β for a number of transductive regression algorithms (Cortes

& Mohri, 2007; Belkin et al., 2004a; Wu & Schölkopf, 2007; Zhou et al., 2004; Zhu et al., 2003).

4. Stability of Local Transductive Regression Algorithms

This section describes and analyzes a general family of local transductive regression algorithms (LTR) generalizing the algorithm of Cortes and Mohri (2007).

LTR algorithms can be viewed as a generalization of the so-called kernel regularization-based learning algorithms to the transductive setting. The objective function that they minimize is of the form:

$$F(h,S) = \|h\|_K^2 + \frac{C}{m}\sum_{k=1}^{m} c(h,x_k) + \frac{C'}{u}\sum_{k=1}^{u} \widetilde{c}(h,x_{m+k}), \quad (3)$$

where $\|\cdot\|_K$ is the norm in the reproducing kernel Hilbert space (RKHS) with associated kernel K, $C \geq 0$ and $C' \geq 0$ are trade-off parameters, and $\widetilde{c}(h,x) = (h(x) - \widetilde{y}(x))^2$ is the error of the hypothesis h on the unlabeled point x with respect to a pseudo-target $\widetilde{y}$.

Pseudo-targets are obtained from neighborhood labels $y(x)$ by a local weighted average. Neighborhoods can be defined as a ball of radius r around each point in the feature space. We will denote by β_{loc} the score-stability coefficient of the local algorithm used, that is the maximal amount by which the two hypotheses differ on an given point, when trained on samples disagreeing on one point. This notion is stronger than that of cost-based stability.

In this section, we use the bounded-labels assumption, that is $\forall x \in S$, $|y(x)| \leq M$. We also assume that for any $x \in X$, $K(x,x) \leq \kappa^2$. We will use the following bound based on the reproducing property and the Cauchy-Schwarz inequality valid for any hypothesis $h \in H : \forall x \in X$,

$$|h(x)| = |\langle h, K(x,\cdot)\rangle| \leq \|h\|_K \sqrt{K(x,x)} \leq \kappa \|h\|_K. \quad (4)$$

Lemma 3. *Let h be the hypothesis minimizing (3). Assume that for any $x \in X$, $K(x,x) \leq \kappa^2$. Then, for any $x \in X$, $|h(x)| \leq \kappa M\sqrt{C+C'}$.*

Proof. The proof is a straightforward adaptation of the technique of (Bousquet & Elisseeff, 2002) to LTR algorithms. By Eqn. 4, $|h(x)| \leq \kappa \|h\|_K$. Let $\mathbf{0} \in \mathbb{R}^{m+u}$ be the hypothesis assigning label zero to all examples. By definition of h,

$$F(h,S) \leq F(\mathbf{0},S) \leq (C+C')M^2.$$

Using $\|h\|_K \leq \sqrt{F(h,S)}$ yields the statement. □

Since $|h(x)| \leq \kappa M\sqrt{C+C'}$, this immediately gives us a bound on $|h(x) - y(x)| \leq M(1 + \kappa\sqrt{C+C'})$. Thus, we are in a position to apply Theorem 3 with $B = AM$, $A = 1 + \kappa\sqrt{C+C'}$.

We now derive a bound on the stability coefficient β. To do so, the key property we will use is the convexity of $h \mapsto c(h,x)$. Note, however, that in the case of $\widetilde{c}$, the pseudo-targets may depend on the training set S. This dependency matters when we wish to apply convexity with two hypotheses h and h' obtained by training on different samples S and S'. For convenience, for any two such fixed hypotheses h and h', we extend the definition of $\widetilde{c}$ as follows. For all $t \in [0,1]$,

$$\widetilde{c}(th+(1-t)h',x) = \big((th+(1-t)h')(x) - (t\widetilde{y}+(1-t)\widetilde{y}')\big)^2.$$

This allows us to use the same convexity property for $\widetilde{c}$ as for c for any two fixed hypotheses h and h', as verified by the following lemma, and does not affect the proofs otherwise.

Lemma 4. *Let h be a hypothesis obtained by training on S and h' by training on S'. Then, for all $t \in [0,1]$,*

$$t\widetilde{c}(h,x) + (1-t)\widetilde{c}(h',x) \geq \widetilde{c}(th+(1-t)h',x). \quad (5)$$

Proof. Let $\widetilde{y} = \widetilde{y}(x)$ be the pseudo-target value at x when the training set is S and $\widetilde{y}' = \widetilde{y}'(x)$ when the training set is S'. For all $t \in [0,1]$,

$$\begin{aligned} &tc(h,x) + (1-t)c(h',x) - c(th+(1-t)h',x) \\ &= t(h(x)-\widetilde{y})^2 + (1-t)(h'(x)-\widetilde{y}')^2 \\ &- \left[t(h(x)-\widetilde{y}) + (1-t)(h'(x)-\widetilde{y}')\right]^2. \end{aligned}$$

The statement of the lemma follows directly by the convexity of $x \mapsto x^2$ over real numbers. □

Let h be a hypothesis obtained by training on S and h' by training on S'. Let $\Delta = h - h'$. Then, for all $x \in X$, $|c(h,x) - c(h',x)| = |\Delta(x)\left((h(x)-y(x)) + (h'(x)-y(x))\right)| \leq 2M(1 + \kappa\sqrt{C+C'})|\Delta(x)|$. As in 4, for all $x \in X$, $|\Delta(x)| \leq \kappa\|\Delta\|_K$, thus for all $x \in X$,

$$|c(h,x) - c(h',x)| \leq 2M(1+\kappa\sqrt{C+C'})\kappa\|\Delta\|_K. \quad (6)$$

Lemma 5. *Assume that for all $x \in X$, $|y(x)| \leq M$. Let S and S' be two samples differing by exactly one point. Let h be the hypothesis returned by the algorithm minimizing the objective function $F(h,S)$, h' be the hypothesis obtained by minimization of $F(h,S')$ and let $\widetilde{y}$ and $\widetilde{y}'$ be the corresponding pseudo-targets. Then,*

$$\begin{aligned} &C\left[c(h',x_i) - c(h,x_i)\right]/m - C'\left[\widetilde{c}(h',x_i) - \widetilde{c}(h,x_i)\right]/u \\ &\leq 2AM\left(\kappa\|\Delta\|_K\left(C/m + C'/u\right) + \beta_{loc}C'/u\right). \end{aligned}$$

where $\Delta = h' - h$ and $A = 1 + \kappa\sqrt{C+C'}$.

Proof. Let $\tilde{c}(h_i, \tilde{y}_i) = \tilde{c}(h, x_i)$ and $\tilde{c}(h'_i, \tilde{y}'_i) = \tilde{c}(h', x_i)$. By Lemma 3 and the bounded-labels assumption,

$$\begin{aligned}
&|\widetilde{c}(h'_i, \widetilde{y}'_i) - \widetilde{c}(h_i, \widetilde{y}_i)| \\
&= |\widetilde{c}(h'_i, \widetilde{y}'_i) - \widetilde{c}(h'_i, \widetilde{y}_i) + \widetilde{c}(h'_i, \widetilde{y}_i) - \widetilde{c}(h_i, \widetilde{y}_i)| \\
&\leq |(\widetilde{y}'_i - \widetilde{y}_i)(\widetilde{y}'_i + \widetilde{y}_i - 2h'_i)| + |(h'_i - h_i)(h'_i + h_i - 2\widetilde{y}_i)|\,.
\end{aligned}$$

By the score-stability of local estimates, $\widetilde{y}'(x_i) - \widetilde{y}(x_i) \leq \beta_{loc}$. Thus,

$$|\widetilde{c}(h'_i, \widetilde{y}'_i) - \widetilde{c}(h_i, \widetilde{y}_i)| \leq 2AM(\beta_{loc} + \kappa\|\Delta\|_K). \quad (7)$$

Using 6 leads after simplification to the statement of the lemma. □

The proof of the following theorem is based on Lemma 4 and Lemma 5 and is reserved to a longer version of this paper.

Theorem 4. *Assume that for all $x \in X$, $|y(x)| \leq M$ and there exists κ such that $\forall x \in X$, $K(x,x) \leq \kappa^2$. Further, assume that the local estimator has uniform stability coefficient β_{loc}. Let $A = 1+\kappa\sqrt{C+C'}$. Then,* LTR *is uniformly β-stable with*

$$\beta \leq 2(AM)^2\kappa^2\left[\frac{C}{m}+\frac{C'}{u}+\sqrt{\left(\frac{C}{m}+\frac{C'}{u}\right)^2+\frac{2C'\beta_{loc}}{AM\kappa^2 u}}\right].$$

Our experiments with LTR will demonstrate the benefit of this bound for model selection (Sec. 6).

5. Stability Based on Closed-Form Solutions

5.1. Unconstrained Regularization Algorithms

In this section, we consider a family of transductive regression algorithms that can be formulated as the following optimization problem:

$$\min_{\mathbf{h}} \mathbf{h}^T\mathbf{Q}\mathbf{h} + (\mathbf{h}-\mathbf{y})^T\mathbf{C}(\mathbf{h}-\mathbf{y}). \quad (8)$$

$\mathbf{Q} \in \mathbb{R}^{(m+u)\times(m+u)}$ is a symmetric regularization matrix, $\mathbf{C} \in \mathbb{R}^{(m+u)\times(m+u)}$ is a symmetric matrix of empirical weights (in practice it is often a diagonal matrix), $\mathbf{y} \in \mathbb{R}^{(m+u)\times 1}$ are the target values of the m labeled points together with the pseudo-target values of the u unlabeled points (in some formulations, the pseudo-target value is 0), and $\mathbf{h} \in \mathbb{R}^{(m+u)\times 1}$ is a column vector whose ith row is the predicted target value for the x_i. The closed-form solution of (8) is given by

$$\mathbf{h} = (\mathbf{C}^{-1}\mathbf{Q} + \mathbf{I})^{-1}\mathbf{y}. \quad (9)$$

The formulation (8) is quite general and includes as special cases the algorithms of (Belkin et al., 2004a; Wu & Schölkopf, 2007; Zhou et al., 2004; Zhu et al., 2003). We present a general framework for bounding the stability coefficient of these algorithms and then examine the stability coefficient of each of these algorithms in turn.

For a symmetric matrix $\mathbf{A} \in \mathbb{R}^{n\times n}$ we will denote by $\lambda_M(\mathbf{A})$ its largest eigenvalue and $\lambda_m(\mathbf{A})$ its smallest. Then, for any $\mathbf{v} \in \mathbb{R}^{n\times 1}$, $\lambda_m(\mathbf{A})\|\mathbf{v}\|_2 \leq \|\mathbf{A}\mathbf{v}\|_2 \leq \lambda_M(\mathbf{A})\|\mathbf{v}\|_2$. We will also use in the proof of the following proposition the fact that for symmetric matrices $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{n\times n}$, $\lambda_M(\mathbf{AB}) \leq \lambda_M(\mathbf{A})\lambda_M(\mathbf{B})$.

Proposition 1. *Let $\mathbf{h}$ and $\mathbf{h}'$ solve (8), under test and training sets that differ exactly in one point and let $\mathbf{C}, \mathbf{C}', \mathbf{y}, \mathbf{y}'$ be the analogous empirical weight and the target value matrices. Then,*

$$\|\mathbf{h}'-\mathbf{h}\|_2 \leq \frac{\|\mathbf{y}'-\mathbf{y}\|_2}{\frac{\lambda_m(\mathbf{Q})}{\lambda_M(\mathbf{C})}+1} + \frac{\lambda_M(\mathbf{Q})\|\mathbf{C}'^{-1}-\mathbf{C}^{-1}\|_2\,\|\mathbf{y}\|_2}{\left(\frac{\lambda_m(\mathbf{Q})}{\lambda_M(\mathbf{C}')}+1\right)\left(\frac{\lambda_m(\mathbf{Q})}{\lambda_M(\mathbf{C})}+1\right)}.$$

Proof. Let $\Delta = \mathbf{h}' - \mathbf{h}$ and $\Delta\mathbf{y} = \mathbf{y}' - \mathbf{y}$. Let $\mathfrak{C} = (\mathbf{C}^{-1}\mathbf{Q} + \mathbf{I})$ and $\mathfrak{C}' = (\mathbf{C}'^{-1}\mathbf{Q} + \mathbf{I})$. By definition,

$$\begin{aligned}
\Delta &= \mathfrak{C}'^{-1}\mathbf{y}' - \mathfrak{C}^{-1}\mathbf{y} \\
&= \mathfrak{C}'^{-1}\Delta\mathbf{y} + (\mathfrak{C}'^{-1} - \mathfrak{C}^{-1})\mathbf{y} \\
&= \mathfrak{C}'^{-1}\Delta\mathbf{y} + (\mathfrak{C}^{-1}\left[(\mathbf{C}^{-1} - \mathbf{C}'^{-1})\mathbf{Q}\right]\mathfrak{C}'^{-1})\mathbf{y}.
\end{aligned}$$

$$\text{Thus, } \|\Delta\|_2 \leq \frac{\|\Delta\mathbf{y}\|_2}{\lambda_m(\mathfrak{C})} + \frac{\lambda_M(\mathbf{Q})\|\mathbf{C}'^{-1}-\mathbf{C}^{-1}\|_2 \cdot \|\mathbf{y}\|_2}{\lambda_m(\mathfrak{C}')\lambda_m(\mathfrak{C})}. \quad (10)$$

Furthermore, $\lambda_m(\mathfrak{C}) \geq \frac{\lambda_m(\mathbf{Q})}{\lambda_M(\mathbf{C})}+1$. Plugging this bound back into Eqn. 10 yields:

$$\|\Delta\|_2 \leq \frac{\|\Delta\mathbf{y}\|_2}{\frac{\lambda_m(\mathbf{Q})}{\lambda_M(\mathbf{C})}+1} + \frac{\lambda_M(\mathbf{Q})\|\mathbf{C}'^{-1}-\mathbf{C}^{-1}\|_2\|\mathbf{y}\|_2}{\left(\frac{\lambda_m(\mathbf{Q})}{\lambda_M(\mathbf{C}')}+1\right)\left(\frac{\lambda_m(\mathbf{Q})}{\lambda_M(\mathbf{C})}+1\right)}. \quad \square$$

Since $\|\mathbf{h}'-\mathbf{h}\|_\infty$ is bounded by $\|\mathbf{h}'-\mathbf{h}\|_2$, the proposition provides a bound on the score-stability of $\mathbf{h}$ for the transductive regression algorithms of Zhou et al. (2004); Wu and Schölkopf (2007); Zhu et al. (2003). For each of these algorithms, the pseudo-targets used are zero. If we make the bounded labels assumption ($\forall x \in X, |y(x)| \leq M$, for some $M > 0$), it is not difficult to show that $\|\mathbf{y}-\mathbf{y}'\|_2 \leq \sqrt{2}M$ and $\|\mathbf{y}\|_2 \leq \sqrt{m}M$. We now examine each algorithm in turn.

Consistency method (CM) In the CM algorithm (Zhou et al., 2004), the matrix $\mathbf{Q}$ is a normalized Laplacian of a weight matrix $\mathbf{W} \in \mathbb{R}^{(m+u)\times(m+u)}$ that captures affinity between pairs of points in the full sample X. Thus, $\mathbf{Q} = \mathbf{I} - \mathbf{D}^{-1/2}\mathbf{W}\mathbf{D}^{-1/2}$, where $\mathbf{D} \in \mathbb{R}^{(m+u)\times(m+u)}$ is a diagonal matrix, with $[\mathbf{D}]_{i,i} =$

$\sum_j [\mathbf{W}]_{i,j}$. Note that $\lambda_m(\mathbf{Q}) = 0$. Furthermore, matrices $\mathbf{C}$ and $\mathbf{C}'$ are identical in CM, both diagonal matrices with (i,i)th entry equal to a positive constant $\mu > 0$. Thus $\mathbf{C}^{-1} = \mathbf{C}'^{-1}$ and using Prop. 1, we obtain the following bound on the score-stability of the CM algorithm: $\beta_{\texttt{CM}} \leq \sqrt{2}M$.

Local learning regularization ($\texttt{LL}-\texttt{Reg}$) In the $\texttt{LL}-\texttt{Reg}$ algorithm (Wu & Schölkopf, 2007), the regularization matrix $\mathbf{Q}$ is $(\mathbf{I}-\mathbf{A})^T(\mathbf{I}-\mathbf{A})$, where $\mathbf{I} \in \mathbb{R}^{(m+u)\times(m+u)}$ is an identity matrix and $\mathbf{A} \in \mathbb{R}^{(m+u)\times(m+u)}$ is a non-negative weight matrix that captures the local similarity between all pairs of points in X. $\mathbf{A}$ is normalized, i.e. each of its rows sum to 1. Let $C_l, C_u > 0$ be two positive constants. The matrix $\mathbf{C}$ is a diagonal matrix with $[\mathbf{C}]_{i,i} = C_l$ if $x_i \in S$ and C_u otherwise. Let $C_{\max} = \max\{C_l, C_u\}$ and $C_{\min} = \min\{C_l, C_u\}$. Thus, $\|\mathbf{C}'^{-1} - \mathbf{C}^{-1}\|_2 = \sqrt{2}\left(\frac{1}{C_{\min}} - \frac{1}{C_{\max}}\right)$. By the Perron-Frobenius theorem, its eigenvalues lie in the interval $(-1, 1]$ and $\lambda_M(\mathbf{A}) \leq 1$. Thus, $\lambda_m(\mathbf{Q}) \geq 0$ and $\lambda_M(\mathbf{Q}) \leq 4$ and we have the following bound on the score-stability of the $\texttt{LL}-\texttt{Reg}$ algorithm: $\beta_{\texttt{LL}-\texttt{Reg}} \leq \sqrt{2}M + 4\sqrt{m}M\left(\frac{1}{C_{\min}} - \frac{1}{C_{\max}}\right) \leq \sqrt{2}M + \frac{4\sqrt{m}M}{C_{\min}}$.

Gaussian Mean Fields algorithm GMF (Zhu et al., 2003) is very similar to the $\texttt{LL}-\texttt{Reg}$, and admits exactly the same stability coefficient.

Thus, the stability coefficients of the algorithms of $\texttt{CM}, \texttt{LL}-\texttt{Reg}$, and GMF can be large. Without additional constraints on the matrix $\mathbf{Q}$, these algorithms do not seem to be stable enough for the generalization bound of Theorem 3 to converge. A particular example of constraint is the condition $\sum_{i=1}^{m+u} h(x_i) = 0$ used by Belkin et al.'s algorithm (2004a). In the next section, we give a generalization bound for this algorithm and then describe a general method for making the algorithms just examined stable.

5.2. Stability of Constrained Regularization Algorithms

This subsection analyzes constrained regularization algorithms such as the Laplacian-based graph regularization algorithm of Belkin et al. (2004a). Given a weighted graph $G = (X, E)$ in which edge weights represent the extent of similarity between vertices, the task consists of predicting the vertex labels. The hypothesis h returned by the algorithm is solution of the following optimization problem:

$$\begin{aligned} &\min_{h\in H} \ \mathbf{h}^T\mathbf{L}\mathbf{h} + \frac{C}{m}\sum_{i=1}^{m}(h(x_i) - y_i)^2 \\ &\text{subject to: } \sum_{i=1}^{m+u} h(x_i) = 0, \end{aligned} \tag{11}$$

where $\mathbf{L} \in \mathbb{R}^{(m+u)\times(m+u)}$ is a smoothness matrix, e.g., the graph Laplacian, $\{y_i \mid i \in [1, m]\}$ are the target values of the m labeled nodes.

The hypothesis set H in this case can be thought of as a hyperplane in $\mathbb{R}^{m+u}$ that is orthogonal to the vector $\mathbf{1} \in \mathbb{R}^{m+u}$. Maintaining the notation used in (Belkin et al., 2004a), we let P_H denote the operator corresponding to the orthogonal projection on H. For a sample S drawn without replacement from X, define $\mathbf{I}_S \in \mathbb{R}^{(m+u)\times(m+u)}$ to be the diagonal matrix with $[\mathbf{I}_S]_{i,i} = 1$ if $x_i \in S$ and 0 otherwise. Similarly, let $\mathbf{y}_S \in \mathbb{R}^{(m+u)\times 1}$ be the column vector with $[\mathbf{y}_S]_{i,1} = y_i$ if $x_i \in S$ and 0 otherwise. The closed-form solution on a training sample S is given by (Belkin et al., 2004a):

$$\mathbf{h}_S = \left(P_H\left(\frac{m}{C}\mathbf{L} + \mathbf{I}_S\right)\right)^{-1}\mathbf{y}_S. \tag{12}$$

Theorem 5. *Assume that the vertex labels of the graph $G = (X, E)$ and the hypothesis h obtained by optimizing Eqn. 11 are both bounded ($\forall x, |h(x)| \leq M$ and $|y(x)| \leq M$ for some $M > 0$). Let $A = 1 + \kappa\sqrt{C}$. Then, for any $\delta > 0$, with probability at least $1 - \delta$,*

$$R(h) \leq \widehat{R}(h) + \beta + \left(2\beta + \frac{(AM)^2(m+u)}{mu}\right)\sqrt{\frac{\alpha(m,u)\ln\frac{1}{\delta}}{2}},$$

with $\alpha(m,u) = \frac{mu}{m+u-1/2} \cdot \frac{1}{1-1/(2\max\{m,u\})}$ and $\beta \leq (4\sqrt{2}M^2)/(m\lambda_2/C - 1) + (4\sqrt{2m}M^2)/(m\lambda_2/C - 1)^2$, λ_2 is the second smallest eigenvalue of the Laplacian.

Proof. The proof is similar to that of (Belkin et al., 2004a) but uses our general transductive regression bound instead. □

The generalization bound we just presented differs in several respects from that of Belkin et al. (2004a). Our bound explicitly depends on both m and u while theirs shows only a dependency on m. Also, our bound does not depend on the number of times a point is sampled in the training set (parameter t), thanks to our analysis based on sampling without replacement.

Contrasting the stability coefficient of Belkin's algorithm with the stability coefficient of LTR (Theorem 4), we note that it does not depend on C' and β_{loc}. This is because unlabeled points do not enter the objective function, and thus $C' = 0$ and $\widetilde{y}(x) = 0$ for all

$x \in X$. However, the stability does depend on the second smallest eigenvalue λ_2 and the bound diverges as λ_2 approaches $\frac{C}{m}$. In all our regression experiments, we observed that this algorithm does not perform as well in comparison with LTR.

5.3. Making Seemingly Unstable Algorithms Stable

In Sec. 5.2, we saw that imposing additional constraints on the hypothesis, e.g., $\mathbf{h} \cdot \mathbf{1} = 0$, allowed one to derive non-trivial stability bounds. This idea can be generalized and similar non-trivial stability bounds can be derived for "stable" versions of the algorithms presented in Sec. 5.1 $\mathtt{CM}, \mathtt{LL-Reg}$, and GMF. Recall that the stability bound in Prop. 1 is inversely proportional to the smallest eigenvalue $\lambda_m(\mathbf{Q})$. The main difficulty with using the proposition for these algorithms is that $\lambda_m(\mathbf{Q}) = 0$ in each case. Let $\mathbf{v}_m$ denote the eigenvector corresponding to $\lambda_m(\mathbf{Q})$ and let λ_2 be the second smallest eigenvalue of $\mathbf{Q}$. One can modify (8) and constrain the solution to be orthogonal to $\mathbf{v}_m$ by imposing $\mathbf{h} \cdot \mathbf{v}_m = 0$. In the case of (Belkin et al., 2004a), $\mathbf{v}_m = \mathbf{1}$. This modification, motivated by the algorithm of (Belkin et al., 2004a), is equivalent to increasing the smallest eigenvalue to be λ_2.

As an example, by imposing the additional constraint, we can show that the stability coefficient of CM becomes bounded by $O(C/\lambda_2)$, instead of $\Theta(1)$. Thus, if $C = O(1/m)$ and $\lambda_2 = \Omega(1)$, it is bounded by $O(1/m)$ and the generalization bound converges as $O(1/m)$.

6. Experiments

6.1. Model Selection Based on Bound

This section reports the results of experiments using our stability-based generalization bound for model selection for the LTR algorithm. A crucial parameter of this algorithm is the stability coefficient $\beta_{loc}(r)$ of the local algorithm, which computes pseudo-targets $\widetilde{y}_x$ based on a ball of radius r around each point. We derive an expression for $\beta_{loc}(r)$ and show, using extensive experiments with multiple data sets, that the value r^* minimizing the bound is a remarkably good estimate of the best r for the test error. This demonstrates the benefit of our generalization bound for model selection, avoiding the need for a held-out validation set.

The experiments were carried out on several publicly available regression data sets: *Boston Housing*, *Elevators* and *Ailerons*[2]. For each of these data sets, we used $m = u$, inspired by the observation that, all other parameters being fixed, the bound of Theorem 3 is tightest when $m = u$. The value of the input variables were normalized to have mean zero and variance one. For the Boston Housing data set, the total number of examples was 506. For the Elevators and the Ailerons data set, a random subset of 2000 examples was used. For both of these data sets, other random subsets of 2000 samples led to similar results. The Boston Housing experiments were repeated for 50 random partitions, while for the Elevators and the Ailerons data set, the experiments were repeated for 20 random partitions each. Since the target values for the Elevators and the Ailerons data set were extremely small, they were scaled by a factor 1000 and 100 respectively in a pre-processing step.

In our experiments, we estimated the pseudo-target of a point $x' \in T$ as a weighted average of the labeled points $x \in N(x')$ in a neighborhood of x'. Thus, $\widetilde{y}_{x'} = \sum_{x \in N(x')} \alpha_x y_x / \sum_{x \in N(x')} \alpha_x$. Weights are defined in terms of a similarity measure $K(x, x')$ captured by a kernel K: $\alpha_x = K(x, x')$. Let $m(r)$ be the number of labeled points in $N(x')$. Then, it is easy to show that $\beta_{loc} \leq 4\alpha_{\max} M/(\alpha_{\min} m(r))$, where $\alpha_{\max} = \max_{x \in N(x')} \alpha_x$ and $\alpha_{\min} = \min_{x \in N(x')} \alpha_x$. Thus, for a Gaussian kernel with parameter σ, $\beta_{loc} \leq 4M/(m(r)e^{-2r^2/\sigma^2})$. To estimate β_{loc}, one needs an estimate of $m(r)$, the number of samples in a ball of radius r from an unlabeled point x'. In our experiments, we estimated $m(r)$ as the number of samples in a ball of radius r from the origin. Since all features are normalized to mean zero and variance one, the origin is also the centroid of the set X.

We implemented a dual solution of LTR and used Gaussian kernels, for which, the parameter σ was selected using cross-validation on the training set. Experiments were repeated across 36 different pairs of values of (C, C'). For each pair, we varied the radius r of the neighborhood used to determine estimates from zero to the radius of the ball containing all points.

Figure 1(a) shows the mean values of the test MSE of our experiments on the Boston Housing data set for typical values of C and C'. Figures 1(b)-(c) show similar results for the Ailerons and Elevators data sets. For the sake of comparison, we also report results for induction. The relative standard deviations on the MSE are not indicated, but were typically of the order of 10%. LTR generally achieves a significant improvement over induction.

The generalization bound we derived in Eqn. 3 consists of the training error and a complexity term that depends on the parameters of the LTR algorithm $(C, C', M, m, u, \kappa, \beta_{loc}, \delta)$. Only two terms depend

upon the choice of the radius r: $\widehat{R}(h)$ and β_{loc}. Thus, keeping all other parameters fixed, the theoretically optimal radius r^* is the one that minimizes the training error plus the slack term. The figures also include plots of the training error combined with the complexity term, appropriately scaled. The empirical minimization of the radius r coincides with or is close to r^*. The optimal r based on test MSE is indicated with error bars.

6.2. Stable Versions of Unstable Algorithms

We refer to the stable version of the CM algorithm presented in Sec. 5.1 as CM − STABLE. We compared CM and CM − STABLE empirically on the same datasets, again using $m = u$. For the normalized Laplacian we used k-nearest neighbors graphs based on Euclidean distance. The parameters k and C were chosen by five-fold cross-validation over the training set. The experiment was repeated 20 times with random partitions. The averaged mean-squared errors with standard deviations, are reported in Table 6.2.

Dataset	CM	CM − STABLE
Elevators	0.3228 ± 0.0264	0.3293 ± 0.0286
Ailerons	0.1149 ± 0.0081	0.1184 ± 0.0087
Housing	57.93 ± 6.5	57.92 ± 6.5

We conclude from this experiment that CM and CM − STABLE have the same performance. However, as we showed previously, CM − STABLE has a non-trivial risk bound and thus comes with some guarantee.

7. Conclusion

We presented a comprehensive analysis of the stability of transductive regression algorithms with novel generalization bounds for a number of algorithms. Since they are algorithm-dependent, our bounds are often tighter than those based on complexity measures such as the VC-dimension. Our experiments also show the effectiveness of our bounds for model selection and the good performance of LTR algorithms.

A Rate-Distortion One-Class Model and its Applications to Clustering

Abstract

In one-class classification we seek a rule to find a coherent subset of instances similar to a few positive examples in a large pool of instances. The problem can be formulated and analyzed naturally in a rate-distortion framework, leading to an efficient algorithm that compares well with two previous one-class methods. The model can be also be extended to remove background clutter in clustering to improve cluster purity.

1. Introduction

Often we are given a large set of data items among which we would like to find a coherent subset. For instance, in document retrieval we might want to retrieve a small set of relevant documents similar to a few seed documents. In genomics, it is useful to find the set of genes that are strongly co-expressed with a few genes of interest. In both cases, we prefer high-precision answers over high-recall ones.

A popular intuition for this *one-class classification* problem is that of finding a small ball (under some appropriate norm) that contains as many of the seed elements as possible (Tax & Duin, 1999). Most previous approaches to the problem take the point of view of outlier and novelty detection, in which most of the examples are identified as relevant. However, Crammer and Chechik (2004) seek a small subset of relevant examples, rather than keep all but few outliers.

Most approaches to one-class classification use convex cost functions that focus on the large-scale distribution of the data. Those functions grow linearly outside class and and are constant inside it (Schölkopf et al., 1995; Tax & Duin, 1999; Ben-Hur et al., 2001). In a related study, Schölkopf et al. (2001) seek to separate most of the examples from the origin using a single hyperplane. More recently, Crammer and Singer (2003) generalized that approach to the general case of Bregman divergences. In all of those methods, the convexity of the cost function forces the the solution to shrink to the center of mass as the radius of the ball goes to zero, thus ignoring any local substructure.

In contrast to the previous work, Crammer and Chechik (2004) assumed that the distribution of points outside the one class is not relevant, so they chose a cost function that grows linearly inside the class but is constant outside it. This cost function is thus indifferent to the values of the irrelevant instances. A flat cost outside the class is expected to be better than a growing cost when the relevant instances are mostly in a small region, or when there are relatively few relevant instances. Unfortunately, their cost function leads to a non-convex optimization problem that requires an approximate solution.

Using ideas from rate-distortion theory (Cover & Thomas, 1991), we express the one-class problem as a lossy coding of each instance into a few possible instance-dependent codewords. Unlike previous methods that use just two (Crammer & Chechik, 2004) or a small number (Bekkerman & McCallum, 2005) of possible codewords for all instances, the total number of codewords in our method is greater than the number of instances. To preclude trivial codings, we force each instance to associate only with a few possible codewords. Finding the best coding function is an optimization problem for which we provide an efficient algorithm. The optimization has an "inverse temperature" parameter that represents the tradeoff between compression and distortion. As temperature

[1]Work done mainly at the University of Pennsylvania.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

decreases, the solution passes through a series of phase transitions associated with different sizes for the one class. This model outperforms two previous algorithms proposed for the problem, which are effective only in more restricted situations.

Our one-class model is also effective on the task of clustering a set of instances into multiple classes when some of the instances are clutter that should not be included in any cluster. This task can be reduced to an alternation between applications of the one-class algorithm and hard clustering. Initial experiments with synthetic and real world data show that by leaving some instances out of the clusters, the quality of the clustering improves.

2. One-Class as Rate-Distortion Optimization

We are given a set of instances indexed by the integer random variable $1 \leq X \leq m$. Each instance is described by a *point* $\mathbf{v}_x \in \mathbb{R}^d$ (possibly restricted to the simplex), and $p(x) = p(X = x)$ is a prior distribution over instances. Our goal is to find a *small coherent* subset of instances from a large set of possible instances. In particular, the learning task is to find a *centroid* $\mathbf{w}$ in the space such that there are many seed instances $\mathbf{v}_x$ close to it.

We formalize the task as a source coding problem. An instance x is either coded with the one class, with distortion $\mathcal{D}(\mathbf{v}_x \| \mathbf{w})$, and assigned the code 0, or it is coded as itself with zero distortion. The distortion $\mathcal{D}$ can be any Bregman divergence (Censor & Zenios, 1997), which includes as special cases the Euclidean distance and the KL divergence between distributions.

The random variable T represents the code for an instance: if $T = 0$, the instance was coded with the one class, while if $T = x > 0$, the instance is coded as itself. Although T has $m + 1$ distinct values, only one code x is associated with the event $T = x > 0$. The coding process is summarized by the conditional probability $q(t|x)$ of encoding x as t. These constraints mean that $q(t|x) = 0$ if $t \notin \{x, 0\}$, that is, the only nonzero probability outcomes for x are $T = 0$ or $T = x$.

The marginal

$$q(0) = \sum_x p(x)q(0|x) \ , \tag{1}$$

is the probability of assigning any instance to the one class. The other marginals are a product of two terms $q(x) = p(x)q(x|x)$, because of the constraints that $q(t|x) = 0$ for $t \neq 0$ and $t \neq x$. We explicitly allow soft assignments, $0 \leq q(0|x) \leq 1$. As we will see below, instances in the one class have a hard assignment to the class, but instances outside have a soft assignment.

We use the information bottleneck (IB) framework (Tishby et al., 1999) to formalize the assignment process. IB is an information-theoretic approach to regularized unsupervised learning that aims to extract a meaningful representation of some data X based on its association with side information. For generality, we choose here the rate-distortion formulation of the IB, which solves for the assignment by optimizing the tradeoff between two quantities: the amount of compression applied to the source data X, measured by the mutual information $I(T; X)$, and the average distortion between the data and its representation:

$$\min_{\mathbf{w}, \{q(0|x)\}} I(T; X) + \beta D(\mathbf{w}, \{q(0|x)\}) \ . \tag{2}$$

For one-class learning, the distortion term measures how well on average the centroid $\mathbf{w}$ serves as a proxy to each of the instances $\mathbf{v}_x$:

$$D(\mathbf{w}, \{q(0|x)\}) = \sum_x p(x)q(0|x)\mathcal{D}(\mathbf{v}_x \| \mathbf{w}) \ .$$

In contrast with standard rate distortion and IB formulations, the average distortion is computed only for $T = 0$, because the distortion is zero for $T > 0$.

We first rewrite the mutual information term using the constraints $q(t|x) = 0$ if $t \neq x$ and $t \neq 0$:

$$\begin{aligned} I(T; X) &= \textstyle\sum_{x,t} p(x)q(t|x) \log\left(\frac{q(t|x)}{q(t)}\right) \\ &= \textstyle\sum_x p(x) \left[q(0|x) \log\left(\frac{q(0|x)}{q(0)}\right) + q(x|x) \log\left(\frac{q(x|x)}{q(x)}\right)\right] \\ &= \textstyle\sum_x p(x) \left[\begin{array}{l} q(0|x) \log\left(\frac{q(0|x)}{q(0)}\right) + \\ (1 - q(0|x)) \log\left(\frac{q(x|x)}{q(x|x)p(x)}\right) \end{array}\right] . \end{aligned}$$

Then, the minimization (2) can be written as:

$$\begin{aligned} \min_{\{q(t|x), \mathbf{w}\}} \quad & \sum_{x=1}^{m} p(x) \left[q(0|x) \log\left(\frac{q(0|x)}{q(0)}\right)\right. \\ & \left. + (1 - q(0|x)) \log\left(\frac{1}{p(x)}\right)\right] \\ & + \beta \sum_x p(x)q(0|x)\mathcal{D}(\mathbf{v}_x \| \mathbf{w}) \qquad (3) \\ \text{s.t.} \quad & 0 \leq q(0|x) \leq 1, 1 \leq x \leq m \qquad (4) \end{aligned}$$

The corresponding Lagrangian is:

$$\textstyle\sum_{x=1}^{m} p(x) \left[q(0|x) \log\left(\frac{q(0|x)}{q(0)}\right) + (1 - q(0|x)) \log\left(\frac{1}{p(x)}\right)\right] + \beta \sum_x p(x)q(0|x)\mathcal{D}(\mathbf{v}_x \| \mathbf{w}) + \sum_x p(x)\nu_x q(0|x) \ .$$

Setting to zero its derivative with respect to $q(0|x)$, we get:

$$p(x)\left[\log\left(\frac{q(0|x)}{q(0)}\right)+\beta p(x)\mathcal{D}\left(\mathbf{v}_x\|\mathbf{w}\right)+\log p(x)+\nu_x\right]=0\ ,$$

Using the KKT conditions, we solve for $q(0|x)$:

$$q(0|x)=\min\left\{q(0)\frac{e^{-\beta\mathcal{D}(\mathbf{v}_x\|\mathbf{w})}}{p(x)},1\right\}\ . \qquad (5)$$

Setting the derivative of the Lagrangian with respect to $\mathbf{w}$ to zero we get:

$$\mathbf{w}=\frac{\sum_x p(x)q(0|x)\mathbf{v}_x}{\sum_x p(x)q(0|x)}=\sum_x q(x|0)\mathbf{v}_x\ . \qquad (6)$$

That is, the centroid is the average of all the points $\mathbf{v}_x$ weighted by their probability of membership in the single class.Like in the IB, the solution has a set of self-consistent equations: (1), (5), and (6).

Note that this rate-distortion formulation can be expressed as a tradeoff between two information quantities, as in the original IB. When $\mathcal{D}$ is the KL divergence, the optimization in (2) (or (3)) is equivalent to minimizing the tradeoff $I(X;T)-\beta I(T;Y)$ under the above constraints, where the random variable Y gives side information through the vectors $\mathbf{v}_x$.

3. Algorithm

The sequential algorithm of Slonim (2003) finds efficiently a local maximum of the IB objective. The algorithm alternates between selecting an instance and deciding whether moving it to another cluster would improve the objective. The item is reassigned to the cluster which yields the best improvement. A similar algorithm has been proposed for one-class problems (Crammer & Chechik, 2004). At each round, an instance is either removed from the class or added to the class, depending on what would most improve the objective.

We present a different algorithm for our model, inspired by Blahut-Arimoto algorithm and the original IB algorithm. The new algorithm iterates between the self-consistent equations (1), (5), and (6). Analogously to those algorithms, ours alternates between fixing $q(0|x)$ and $q(0)$ and fixing $\mathbf{w}$, and solving for the other parameters. We solve easily for $\mathbf{w}$ by computing the weighted average in (6). To solve for $q(0|x)$ and $q(0)$, let $\mathbf{w}$ be fixed and define $d_x=\mathcal{D}\left(\mathbf{v}_x\|\mathbf{w}\right)$. We now show how to compute $q(0|x)$ and $q(0)$ efficiently.

Eq. (5) cannot be solved directly for $q(0|x)$ because it involves $q(0)$, which in turn depends on $q(0|x)$. However, we can break this cycle by analyzing more carefully the properties of the solution. Let $\mathcal{C}=\{x:q(0|x)=1\}$. From (1) we get:

$$q(0)=\sum_x p(x)q(0|x)=\sum_{x\in\mathcal{C}}p(x)+q(0)\sum_{x\notin\mathcal{C}}e^{-\beta d_x} \qquad (7)$$

Assume that $\mathcal{C}\neq\emptyset$. Solving for $q(0)$, we obtain: $q(0)=\left(\sum_{x\in\mathcal{C}}p(x)\right)/\left(1-\sum_{x\notin\mathcal{C}}e^{-\beta d_x}\right)$. This equation is well defined if $0\leq q(0)\leq 1$, or equivalently:

$$\sum_{x\notin\mathcal{C}}e^{-\beta d_x}\leq 1-\sum_{x\in\mathcal{C}}p(x)\ . \qquad (8)$$

If $\mathcal{C}$ contains all the points, this is trivially satisfied. If $\mathcal{C}=\emptyset$, (7) becomes $q(0)\left(1-\sum_x e^{-\beta d_x}\right)=0$. Therefore, there is a unique β_0 such that for all $\beta\geq\beta_0$ we have $q(0)=0$. If $p(x)>0$ for all x we then have $q(0|x)=0$.

In summary, the solution of the optimization problem is given by the set $\mathcal{C}=\{x:q(0|x)=1\}$. We cannot search for that set naïvely, but fortunately the following lemma gives an efficient way to find the set by sorting its possible members.

Lemma 1 *Let $x_1,\ldots,x_m$ be a permutation of $[1,m]$ such that $0<\beta d_{x_1}+\log p(x_1)\leq\cdots\leq\beta d_{x_m}+\log p(x_m)$. Then $\mathcal{C}=\{x_i:1\leq i\leq k\}$ for some $k\in[0,m]$.*

Proof: Assume that $\mathcal{C}\neq\emptyset$. From (5) we know that $q(0|x)=\min\left\{q(0)e^{-\beta d_x-\log(p(x))},1\right\}$. We now show that if $x_k\in\mathcal{C}$ for some k, then $x_j\in\mathcal{C}$ for all $1\leq j<k$. If $x_k\in\mathcal{C}$, by definition $q(0)e^{-\beta d_{x_k}-\log p(x_k)}\geq 1$. For $j<k$, by hypothesis we have $-\beta d_{x_k}-\log p(x_k)\geq-\beta d_{x_j}-\log p(x_j)$. Thus, $q(0)e^{-\beta d_{x_j}-\log p(x_j)}\geq 1$, and thus $x_j\in\mathcal{C}$. ■

The lemma allows us to solve (3) easily for a fixed $\mathbf{w}$. The inputs for the algorithm are the prior over items $p(x)$, the distortions d_x, and the tradeoff parameter β. First, we order the items x in ascending order of the combined distortion and log-prior $\beta d_x+\log(p(x))$. As in the lemma, we obtain an ordering $x_1,\ldots,x_m$. Among the possible $\mathcal{C}=\{x_i:1\leq i\leq k\}$ that satisfy (8), we choose the one that minimizes the objective. A naïve implementation would require $\mathcal{O}(m\log m)$ time to sort the items, and then additional $\mathcal{O}(m)$ steps for each of the m candidate subsets $\mathcal{C}$, yielding an overall complexity of $\mathcal{O}(m^2)$. However, we can use dynamic programming to compute the objective for $\mathcal{C}\cup\{x_k\}$ from quantities saved from computing the objective for $\mathcal{C}$. Equation (3) can be rearranged as:

Input

- Distortion values d_x for $x \in \{1 \dots m\}$
- Prior $p(x)$ for $x \in \{1 \dots m\}$
- Tradeoff parameter $\beta \geq 0$

Sort the words in accordance to their score

$$\beta d_{x_1} + \log(p(x_1)) \leq \cdots \leq \beta d_{x_m} + \log(p(x_m))$$

Initialize $k = m$, $a_k = 1$, $p_k = 1$, $\mathcal{J}_k = \beta \sum_x p(x) d_x$, $c_{\text{best}} = k$, $\mathcal{J}_{\text{best}} = \mathcal{J}_k$.

Loop: While $k > 0$

1. Compute $a_{k-1} = a_k - e^{-\beta d_{x_{k-1}}}$
2. Compute $p_{k-1} = p_k - p(x_{k-1})$
3. if $p_{k-1} \leq a_{k-1}$
   - Compute $\mathcal{J}_{k-1}$ using (10).
   - If $\mathcal{J}_{k-1} < \mathcal{J}_{\text{best}}$ then set $k_{\text{best}} = k-1$ and $\mathcal{J}_{\text{best}} = \mathcal{J}_{k-1}$.
4. Set $k \leftarrow k - 1$.

Compute: $q(0|x)$ using (5) and (7)

Output: $q(0|x)$

Figure 1. Finding the one class for fixed distortion.

$$H\left[p(x)\right] + \sum_x p(x) \left[q(0|x) \log \left(\frac{p(x) q(0|x)}{q(0)} \right) \right] + \beta \sum_x p(x) q(0|x) d_x$$

The sum can be split according to whether $x \in \mathcal{C}$ and rearranged again:

$$\begin{array}{l} H\left[p(x)\right] + \sum_{x \in \mathcal{C}} p(x) \left[\log\left(p(x)\right) + \beta d_x\right] \\ - \left(\sum_{x \in \mathcal{C}} p(x)\right) \log \left(\sum_{x \in \mathcal{C}} p(x)\right) \\ + \left(\sum_{x \in \mathcal{C}} p(x)\right) \log \left(1 - \sum_{x \notin \mathcal{C}} e^{-\beta d_x}\right) \ . \end{array} \quad (9)$$

Let $\mathcal{C}_k = \{x_i : 1 \leq i \leq k\}$, $\mathcal{J}_k$ the value of the objective on $\mathcal{C}_k$, $p_k = \sum_{j=1}^{k} p(x_j) = \sum_{x \in \mathcal{C}} p(x)$, and by $a_c = 1 - \sum_{j=k+1}^{m} e^{-\beta d_{x_j}} = 1 - \sum_{x \notin \mathcal{C}} e^{-\beta d_x}$. These quantities can be computed recursively as follows. Let $\mathcal{J}_m = \beta \sum_x p(x) d_x$, $p_m = 1$ and $a_m = 1$. Given $\mathcal{J}_k$, p_k and a_k, we can compute the following in unit time: $a_{k-1} = a_k - e^{-\beta d_{x_k}}$ and $p_{k-1} = p_k - p(x_k)$. Finally, by examining (9) we get,

$$\begin{array}{rcl} \mathcal{J}_{k-1} & = & \mathcal{J}_k - p(x_{k-1})[\beta d_{x_{k-1}} + \log p(x_{k-1})] \\ & & + [p_k \log(p_k) - p_k \log(a_k)] \\ & & - [p_{k-1} \log(p_{k-1}) - p_{k-1} \log(a_{k-1})] \end{array} \quad (10)$$

Fig. 1 gives an outline of the algorithm.

The following properties of the solution are worth noting. When the temperature $t = 1/\beta$ is high, all the instances belong to the single cluster with probability 1. As the temperature drops, instances are pulled out of the class, one after the other, as $q(0|x)$ becomes strictly less than 1. Finally, at a critical temperature t_0, all the instances are pulled out of the class, that is, $q(0|x) = 0$ for all x. We show this process in Fig. 2. There are five points, indexed 1 through 5. The distortion of each point is proportional to its index. The y axis is temperature $t = 1/\beta$. For high values of t, all the instances belong to the class with probability 1. At $t \approx 3.1$ the model goes through its first phase transition, as the instance with the highest distortion is pulled out of the class, and its probability of belonging there drops exponentially. There are three more similar phase transition for instances 4, 3 and 2 respectively. Then, at $t \approx 1.5$ the model goes through a discontinuous phase transition and $q(0|x)$ falls to zero for all instances.

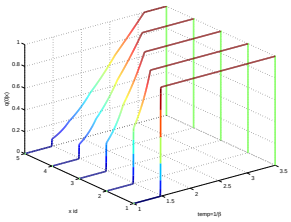

Figure 2. Illustration of the serious of phase transitions of $q(0|x)$ as the temperature $1/\beta$ is modified.

In summary, the algorithm iterates between two steps: compute $\mathbf{w}$ given $q(0|x)$ and $q(0)$ using (6) (expectation), and use the algorithm in Fig. 1 to find $q(0|x)$ and $q(0)$ from $d_x = \mathcal{D}\left(\mathbf{v}_x \| \mathbf{w}\right)$ (maximization). In this aspect the algorithm is similar to EM, and thus we might suspect that it has a maximum-likelihood analog (Slonim & Weiss, 2002).

4. Multiclass Clustering

It seems natural to generalize from one class to multiple classes by replacing the one class centroid with $k > 1$ centroids. There are $k + 1$ outcomes for each instance: either code it using one of the k centroids, or code it with itself. We now formalize this extension.

We might at first think that we could just generalize $q(t|x)$ from the previous model to range over a set of $k+m$ values — m points and k centroids — where for given x the value of $q(t|x)$ is non-zero for at most $k+1$ values of t, the k clusters and self-coding. However, this direct approach leads to a derivation that can not be decomposed nicely as in the one class case, because

$1-q(x|x)$ is not informative about individual clusters, just about their sum.

Instead, we break the coding scheme into two stages. First, given an instance x, we determine whether to code it using one of the centroids or by itself $t = x$. Then, for non-self-coded instances, we decide their cluster. Formally, given x we decide if we want to code it by itself (with probability $q(x|x)$) or by some centroid (with probability $q(0|x)$). Next, if we decide to code the instance with one of the centroids, we denote the centroid's identity by S, and denote the probability of encoding using centroid S given the point identity x and the decision to code it 0 by $r(s|0,x) = \Pr[S = s|0,x]$ We also define the marginals, $q(s,0) = \sum_x p(x)q(0|x)r(s|0,x)$.

As in (2), we write a rate-distortion objective. The rate equals to the mutual information between possible codings and input variables. The distortion-rate optimization is

$$\min_{\{q(\cdot|x)\},r(s|0,x),\{\mathbf{w}_s\}} \beta \sum_{x,s} p(x)q(0|x)r(s|0,x)\mathcal{D}\left(\mathbf{v}_x\|\mathbf{w}_s\right) + \sum_x p(x) \sum_s q(0|x)r(s|0,x) \log\left(\frac{q(0|x)r(s|0,x)}{q(s,0)}\right) + \sum_x p(x)q(x|x) \log\left(\frac{q(x|x)}{q(x)}\right) , \quad (11)$$

subject to normalization $q(0|x) + q(x|x) = 1$ and $\sum_s r(s|0,x) = 1$. The marginals are defined naturally, $q(x) = p(x)q(x|x)$ and $q(0) = \sum_x p(x)q(0|x)$. Before solving the optimization problem we further assume that every point x is associated with exactly one centroid (if any), that is $r(s|0,x) = 1$ or $r(s|0,x) = 0$. From normalization there is only a single cluster s for which $r(s|0,x) = 1$, denoted by $s(x)$. We also denote by $E(s) = \{x : s(x) = s\}$. We do so for two reasons, first, without doing so we could not separate $q(0|x)$ and $q(s,0)$ from each other (for different values of s) and could not get a solution similar to (5). Second, we show below that we can solve this problem by alternating between two algorithms, one of them is the sequential-IB (sIB) (Slonim, 2003) designed for hard clustering. We call this algorithm MCRD (multiclass rate-distortion-based algorithm).

We now solve the optimization analogously to the derivation starting at (3). After writing the Lagrangian we use its derivations to compute self consistent equations. (details omitted for lack of space). First, we have

$$q(0|x) = \min\left\{\frac{q(s(x),0)}{p(x)} e^{-d_{s(x),x}}, 1\right\} , \quad (12)$$

which is the equivalent of (5). Note that the values of $q(0|x)$ are tied for $x \in E(s)$. Thus, there are k sets of equations, each set tying all points in $E(s)$ and the exact value of $q(0|x)$ for $x \in E(s)$ and $q(s,0)$ can be solved separately using the algorithm of Fig. 1.

Next, we can compute the derivative of the Lagrangian with respect to the other variables and obtain self consistent equations

$$\mathbf{w}_s = \frac{\sum_x p(x)q(0|x)r(s|0,x)\mathbf{v}_x}{\sum_x p(x)q(0|x)r(s|0,x)} = \frac{\sum_{x\in E(s)} p(x)q(0|x)\mathbf{v}_x}{\sum_{x\in E(s)} p(x)q(0|x)} ,$$

and $r(s|0,x) \propto q(s,0)e^{-\beta\mathcal{D}(\mathbf{v}_x\|\mathbf{w}_s)}$. The last equation can not be used to solve the problem since we assume that $r(s|0,x)$ is an integer. In practice, we use the following lemma which relates the optimization problem of (11) and the optimization problem of the IB method (Tishby et al., 1999).

Lemma 2 *The following two optimization problems are equivalent up to a linear transformation:*

1. *The optimization problem of* (11) *over* $\mathbf{w}_s$ *and* $r(s|0,x)$*, where we fix* $q(0|x)$ *and* $q(s,0)$*, and* $r(s|0,x) \in \{0,1\}$.
2. *The rate-distortion formulation of the IB method (Slonim, 2003), where the assignment probabilities are either* 0 *or* 1*, and a reweighted prior proportional to* $p(x)q(0|x)$.

(Proof omitted due to lack of space.) Using the lemma and the discussion preceding it, we have an algorithm for MCRD that alternates between two steps: (1) Use the sIB algorithm to set the values of $\mathbf{w}_s$ and $r(s|0,x)$, given $q(0|x)$ and $q(s,0)$, with prior proportional to $p(x)q(0|x)$. (2) Use k calls to the algorithm on Fig. 1 to find $q(0|x)$ and $q(s,0)$ from $d_{s(x),x} = \mathcal{D}\left(\mathbf{v}_x\|\mathbf{w}_s\right)$.

5. Experiments

We compare our algorithm (OCRD-BA) with two previously proposed methods: the IB-related one-class algorithm of Crammer and Chechik (2004) (OC-IB), and a well-known convex optimization method (Tax & Duin, 1999; Schölkopf et al., 2001; Crammer & Singer, 2003) (OC-Convex). We obtained Crammer and Chechik's data and followed their evaluation protocol to achieve comparable results. For lack of space, we just discuss document retrieval experiments, although we obtained qualitatively comparable results on gene expression data as well.

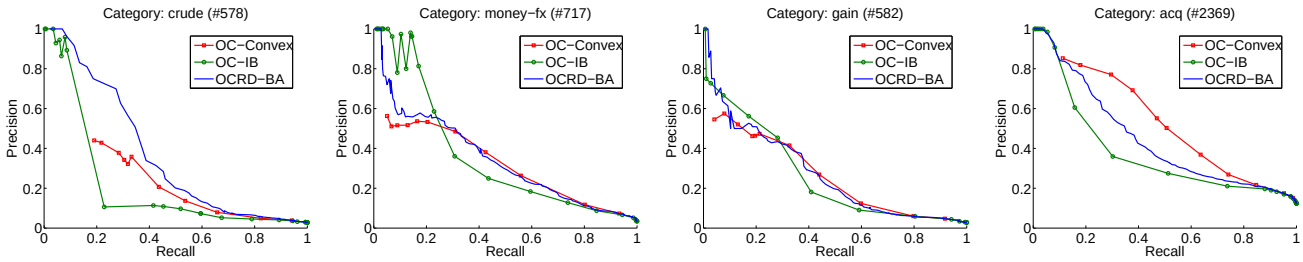

Figure 3. Precision-Recall plots for four (out of five) categories of Reuters-21678 dataset using OC-IB, OC-Convex, and OCRD-BA (this paper).

5.1. Document Retrieval

This is a document retrieval task that was previously described in detail (Crammer & Chechik, 2004, Sec. 6.2). The task uses a subset of the five most frequent categories of Reuters-21578. For each category, half of its documents were used for training, and the remaining half, together with the remaining documents from other categories, were used for evaluation. During training, each of the algorithms searched for a meaningful subset of the training data and generated a centroid. The centroid was used then to label the test data, and to compute recall and precision.

All algorithms used the KL divergence to compare empirical word distributions for different documents. For OC-IB and OC-Convex, we used the parameter values in the previous study (Crammer & Chechik, 2004). For our algorithm, OCRD-BA, we set the prior $p(x)$ to be uniform over the training set, and used a range of values of β that yielded a range of class sizes. We used a single random document to initialize the centroid maintained by OCRD-BA, as was done for OC-IB. We trained five models for each value of β, each using a different random example for initialization, and picked the one which attained the best value of the objective.

After picking a model, we fixed the induced centroid $\mathbf{w}$ and computed the distortion $\mathcal{D}(\mathbf{v}_x \| \mathbf{w})$ for all the test examples $\mathbf{v}_x$. We then ran the first half of our algorithm (Fig. 1) to compute the cluster assignments $q(0|x)$. Finally, a test point $\mathbf{v}_x$ was assigned to the class if $q(0|x) = 1$. We used the actual Reuters labels to plot precision and recall values for different β values.

The results are summarized in Fig. 3, where there is one plot per category (except the *earn* category where all algorithms perform the same). As in the previous study (Crammer & Chechik, 2004), we observe that OC-IB achieves better precision than OC-Convex on low recall values. The previous study argues that OC-Convex converges to the center-of-mass of the data for low values of recall while OC-IB exploits local structure and thus performs better. As recall increases, OC-Convex improves and OC-IB degrades, until OC-Convex performs better than OC-IB for high values of recall.

Our method, OCRD-BA, strikes a balance between the two previous methods: at low values of recall, OCRD-BA is comparable in performance to OC-IB and at higher values of recall OCRD-BA is comparable to OC-Convex. Furthermore, in the *crude* category, our method outperformed both algorithms. This suggests that OCRD-BA is similar to OC-IB for small classes and to OC-Convex for large classes. We discuss this issue later.

5.2. Clustering

We evaluated the MCRD algorithm using a synthetic dataset and a real dataset. The synthetic dataset (Synth4G) has 900 points in the plane. Of those, 400 were generated from 4 Gaussian distributions with $\sigma = 0.1$, 100 points from each Gaussian. The remaining 500 point were generated from a uniform distribution. We ran the algorithm allowing up to five clusters with various values of β. The output of the algorithm for four values of β is plotted in Fig. 4. The title of each plots summarize the value of β used, number of points associated with a cluster, and (in parenthesis) the size of each cluster. For low values of β the algorithm prefers to reduce the rate (over distortion) and effectively group all points into a single cluster. As β increases the algorithm uses more clusters until all 5 possible clusters are used (left panel). As β is increased the algorithm prefers to remove points from the clusters, but still use 5 centroids (second panel), until at some point the algorithm only four clusters are used (third panel). Then, for higher values of β five clusters are used again (right panel). This may be due to the fact, that for large β, the actual length scale is small, and thus, practically, there are more than five

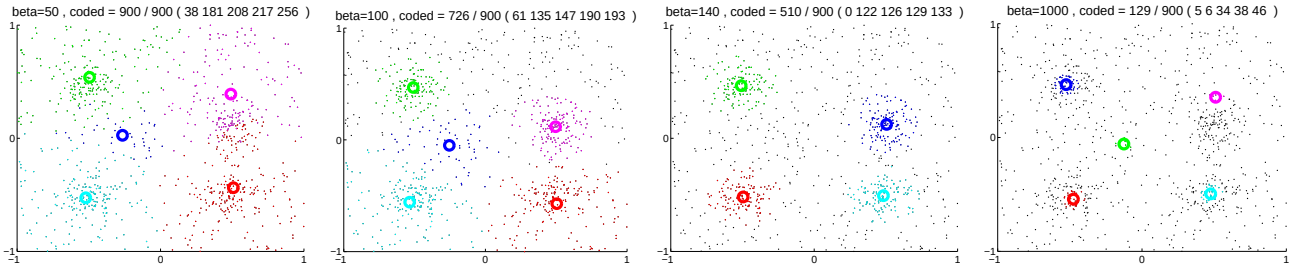

Figure 4. Clusterings produced by MCRD with ($k = 5$) on the synthetic data set for four values of β. Self-coded points are marked by black dots, coded points by colored dots and cluster centroids by bold circles.

clusters (more than five small, dense regions).

We also evaluated on Multi5_1, a real-world high dimensional multiclass dataset which has been used by Slonim et al. (2002) to evaluate the sIB clustering algorithm. The dataset has 500 documents from 5 categories, each represented as a distribution over 2,000 words. We compare the MCRD algorithm ($\beta = 1.6$) with sIB, which by default, uses all the points in clustering thereby achieving 100% recall. We follow Slonim et al., (2002, Sec. 7.4) to get precision at various recall values for sIB, and for other experimental details. The precision at various recall values is summarized in Fig. 5. We observe that MCRD consistently outperforms sIB at all recall levels. Specifically, MCRD achieves very high precision at low recall values, which is one of the objectives of current work. These experimental results further support our hypothesis that better clustering of the data can be obtained if the algorithm is allowed to selectively leave out data points which are unlikely to help the clustering task.

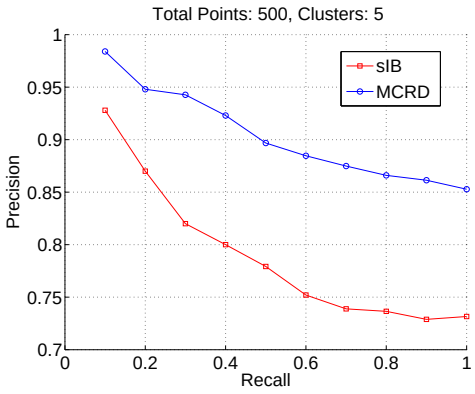

Figure 5. Precision vs. Recall for sIB and MCRD algorithms ($\beta = 1.6$) on the Multi5_1 dataset. Results are obtained by averaging over 5 random permutations of the data. For each permutation, 5 restarts were used and the model with the best objective was selected.

6. Related Work

Crammer and Chechik (2004) proposed to use the information bottleneck for one-class problems. They compressed the points using two possible events: a point can be either belong to the single class or not. In the former case, the distortion is proportional to the distance between the point and the centroid. In the later case, the distortion equals fixed predefined value R, which intuitively sets the diameter of the class. This formulation suffers from some drawbacks. First, it uses two interacting parameters, the R parameter just discussed, and an inverse temperature β to set the hardness of the solution. In practice, they set β to yield only hard solutions. Second, their distortion does not make sense in term of compression, as the compressor effectively can either approximate a point (using the single class) or ignore it.

Instead, we use $m+1$ values for the compression variable T, but regularization forces the compressor to generate sparse solutions. In contrast to a fixed nonzero distortion used for out-of-class points, we use a zero distortion because the out-of-class points are not encoded. As a result, our method uses a single inverse temperature parameter to set the size of the class. A point can either be in the class alone (hard assignment) or both in the class and outside (soft assignment).

The centroid is defined as a weighted average of all of the data. Points which belong to the cluster have the same weight, while other points are weighted proportionally to the exponent of their distance from the centroid. This behavior combines properties of two previous approaches. As in Crammer and Chechik's work, the points belonging to the class give an equal contribution in the location of the centroid. But like in discriminative one-class methods (Crammer & Singer, 2003) points outside the class still affect its centroid. Thus our method uses information from all

the data, unlike discriminative methods that only see outliers (Tax & Duin, 1999).

The fact that the centroid in our model is contributed to by both typical points and outliers may explain the results of the experiments. The OC-IB method (Crammer & Chechik, 2004) works in a low-recall condition, that is, with a small class. In this condition, points outside the cluster will have a negligible effect on the centroid, yielding the OC-IB solution. For large values of β, points outside the class have a stronger effect on the centroid's location, similarly to discriminative methods (Crammer & Singer, 2003). Furthermore, when using the KL divergence, points that are not contributing to the centroids at all (removed from data), would typically have a divergence of infinity to the centroids. Our methods allows to reduce the effect of outliers (by giving them exponential small weight), but still allow them to contribute to the centroids (positive weight).

Gupta and Ghosh (2006) present an extension of the Crammer and Chechik algorith that clusters points while allowing some of them to be ignored. Recently, Lashkari and Golland (2008) proposed an exemplar-based algorithm , in which any point can serve as a centroid (similarly to k-medians). They show that under some choices, some points can be coded by themselves. Our method is different in that it allows centroids that do not coincide with any data point (similar to k-means).

7. Conclusions

Building on the rate-distortion formulation of the information bottleneck method, we cast the problem of identifying a small coherent subset of data as an optimization problem that trades off class size (compression) for accuracy (distortion). We analyzed a rate-distortion view of the model and demonstrated that it goes through a sequence of phase transitions that correspond to different class sizes. We demonstrated that our method combines the best of two previous methods, each of which is good in a narrower range of class sizes. We also showed that our method allows us to move from one-class to standard clustering, but with background noise left out. The proposed approach for one-class learning can be extended to the idea of regularizing by using constraints over a large set of decisions which can be used for other more complex associations among random variables, and in particular for bi-clustering.

Abstract

Point processes are difficult to analyze because they provide only a sparse and noisy observation of the intensity function driving the process. Gaussian Processes offer an attractive framework within which to infer underlying intensity functions. The result of this inference is a continuous function defined across time that is typically more amenable to analytical efforts. However, a naive implementation will become computationally infeasible in any problem of reasonable size, both in memory and run time requirements. We demonstrate problem specific methods for a class of renewal processes that eliminate the memory burden and reduce the solve time by orders of magnitude.

1. Introduction

Point processes with temporally or spatially varying intensity functions arise naturally in many fields of study. When the intensity function is itself a random process (often a Gaussian Process), the process is called a doubly-stochastic or Cox point process. Application domains including economics and finance (*e.g.* Basu & Dassios, 2002), neuroscience (*e.g.* Cunningham et al., 2008), ecology (*e.g.* Moller et al., 1998), and others.

Given observed point process data, one can use a Gaussian Process (GP) framework to infer an optimal estimate of the underlying intensity. In this paper we consider GP prior intensity functions coupled with point process observation models. The problem of intensity estimation then becomes a modification of GP regression and inherits the computational complexity inherent in GP methods (*e.g.* Rasmussen & Williams, 2006). The data size n will grow with the length (*e.g.* total time) of the point process. Naive methods will be $\mathcal{O}(n^2)$ in memory requirements (storing Hessian matrices) and $\mathcal{O}(n^3)$ in run time (matrix inversions and determinants). At one thousand data points (such as one second of millisecond-resolution data), a naive solution to this problem is already quite burdensome on a common workstation. At ten thousand or more, this problem is for all practical purposes intractable.

While applications of doubly-stochastic point processes are numerous, there is little work proposing solutions to the serious computational issues inherent in these methods. Thus, the development of efficient methods for intensity estimation would be of broad appeal. In this paper, we do not address the appropriateness of doubly-stochastic point process models for particular applications, but rather we focus on the significant steps required to make such modelling computationally tractable. We build on previous work from both GP regression and large-scale optimization to create a considerably faster and less memory intensive algorithm for doubly-stochastic point-process intensity estimation.

As part of the GP intensity estimation problem we optimize model hyperparameters using a Laplace approximation to the marginal likelihood or evidence. This requires an iterative approach which divides into two major parts. First, at each iteration we must find a modal (MAP) estimate of the intensity function. Second, we must calculate the approximate model evidence and its gradients with respect to GP hyperparameters. Both aspects of this problem present computational and memory problems. We develop methods to reduce the costs of both drastically.

We show that for certain classes of renewal process observation models, MAP estimation may be framed as a tractable convex program. To ensure nonnegativity in the intensity function we use a log barrier Newton method

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

(Boyd & Vandenberghe, 2004), which we solve efficiently by deriving decompositions of matrices with known structure. By exploiting a recursion embedded in the algorithm, we avoid many costly matrix inversions. We combine these advances with large scale optimization techniques, such as conjugate gradients (CG, as used by Gibbs & MacKay, 1997) and fast fourier transform (FFT) matrix multiplication methods.

To evaluate the model evidence, as well as its gradients with respect to hyperparameters, we again exploit the structure imposed by the renewal process framework to find an exact but considerably less burdensome representation. We then show that a further approximation loses little in accuracy, but makes the cost of this computation insignificant.

Combining these advances, we are able to reduce a problem that is effectively computationally infeasible to a problem with minimal memory load and very fast solution time. $\mathcal{O}(n^2)$ memory requirements are eliminated, and $\mathcal{O}(n^3)$ computation is reduced to modestly superlinear.

2. Problem Overview

Define $\mathbf{x} \in \mathbb{R}^n$ to be the intensity function (the high dimensional signal of interest); $\mathbf{x}$ is indexed by input[1] time points $\mathbf{t} \in \mathbb{R}^n$. Let the observed data $\mathbf{y} = \{y_0, \ldots, y_N\} \in \mathbb{R}^{N+1}$ be a set of $N+1$ time indices into the vector $\mathbf{x}$; that is, the ith point event occurs at time y_i, and the intensity at that time is x_{y_i}. Denote all hyperparameters by θ. In general, the prior and observation models are both functions of θ. The GP framework implies a normal prior on the intensity $p(\mathbf{x} \mid \theta) = \mathcal{N}(\mu\mathbf{1}, \Sigma)$, where the nonzero mean is a sensible choice because the intensity function is constrained to be nonnegative. Thus we treat μ as a hyperparameter ($\mu \in \theta$). The positive definite covariance matrix Σ (also a function of θ) is defined by an appropriate kernel such as a squared exponential or Ornstein-Uhlenbeck kernel (see Rasmussen & Williams, 2006, for a discussion of GP kernels). The point-process observation model gives the likelihood $p(\mathbf{y} \mid \mathbf{x}, \theta)$. In this work, we consider renewal processes (*i.e.* one-dimensional point processes with independent event interarrival times), a family of point processes that has both been well-studied theoretically and applied in many domains (Daley & Vere-Jones, 2002).

The GP prior is log concave in $\mathbf{x}$, and the nonnegativity constraint on intensity ($\mathbf{x} \succeq 0$) is convex (constraining $\mathbf{x}$ to be nonnegative is equivalent to solving an unconstrained problem where the prior on the vector $\mathbf{x}$ is a truncated multivariate normal distribution, but this is not the same as truncating the GP prior in the continuous, infinite dimensional function space; see Horrace, 2005). Thus, if the observation model is also log concave in $\mathbf{x}$, the MAP estimate $\mathbf{x}^*$ is unique and can be readily found using a log barrier Newton method (Boyd & Vandenberghe, 2004; Paninski, 2004). Renewal processes are simply defined by their interarrival distribution $f_z(z)$. A common construction for a renewal process with an inhomogeneous underlying intensity is to use the intensity rescaling $m(t_i \mid t_{i-1}) = \int_{t_{i-1}}^{t_i} x(u)du$ (in practice, a discretized sum of $\mathbf{x}$) (Barbieri et al., 2001; Daley & Vere-Jones, 2002). Accordingly, the density for an observation of event times $\mathbf{y}$ can be defined

$$\begin{aligned} p(\mathbf{y}) &= \prod_{i=1}^{N} p(y_i \mid y_{i-1}) \\ &= \prod_{i=1}^{N} |m'(y_i \mid y_{i-1})|\, f_z(m(y_i \mid y_{i-1})) \end{aligned} \quad (1)$$

by a change of variables for the interarrival distribution (Papoulis & Pillai, 2002). Since $m(t)$ is a linear transformation of the intensity function (our variables of interest), the observation model obeys log concavity as long as the distribution primitive $f_z(z)$ is log concave. Examples of suitable renewal processes include the inhomogeneous Poisson, gamma interval, Weibull interval, inverse Gaussian (Wald) interval, Rayleigh interval, and other processes (Papoulis & Pillai, 2002). For this paper, we choose one of these distributions and focus on its details. However, for processes of the form above, the implementation details are identical up to the forms of the actual distributions.

To solve the GP intensity estimation, we first find a MAP estimate $\mathbf{x}^*$ given fixed hyperparameters θ, and then we approximate the model evidence $p(\mathbf{y} \mid \theta)$ (for which we need $\mathbf{x}^*$) and its gradients in θ. Iterating these two steps, we can find the optimal model $\hat{\theta}$ (we do not integrate over hyperparameters). Finally, MAP estimation under these optimal hyperparameters $\hat{\theta}$ gives an optimal estimate of the underlying intensity. This iterative solution for $\hat{\theta}$ can be written:

$$\begin{aligned} \hat{\theta} &= \operatorname*{argmax}_{\theta} p(\theta) p(\mathbf{y} \mid \theta) \\ &\approx \operatorname*{argmax}_{\theta} p(\theta) p(\mathbf{y} \mid \mathbf{x}^*, \theta) p(\mathbf{x}^* \mid \theta) \frac{(2\pi)^{\frac{n}{2}}}{|\Lambda^* + \Sigma^{-1}|^{\frac{1}{2}}}, \end{aligned} \quad (2)$$

where the last term is a Laplace approximation to the intractable form of $p(\mathbf{y} \mid \theta)$, $\mathbf{x}^*$ is the mode of $p(\mathbf{y} \mid \mathbf{x}) p(\mathbf{x})$ (MAP estimate), and $\Lambda^* = -\nabla^2_{\mathbf{x}} \log p(\mathbf{y} \mid \mathbf{x}, \theta) \mid_{\mathbf{x}=\mathbf{x}^*}$. The log concavity of our problem in $\mathbf{x}$ supports the choice of a Laplace approximation. Each of the two major steps in this algorithm (MAP estimation and model selection) involves computational and memory challenges. We address these challenges in Sections 4 and 5.

[1] In this work we restrict ourselves to a single input dimension (which we call time), as it aligns with the family of renewal processes in one-dimension. Some ideas here can be extended to multiple dimensions (*e.g.* if using a spatial Poisson process).

The computational problems inherent in GP methods have been well studied, and much progress has been made in sparsification (*e.g.* Quinonero-Candela & Rasmussen, 2005). Unfortunately, these methods do not apply directly to point process estimation, as there are no distinct training and test sets. The reader might wonder if a coarser grid would be adequate, thereby obviating the detailed methods developed here. We have found in experiments (not shown) that the sacrifice in accuracy required to allow reasonable computational tractability is large, and thus we do not consider the coarse grid a viable option. One could also consider re-expressing the problem in terms of the integrals $m(y_i \mid y_{i-1})$ appearing in Eq. 1. While this is possible in certain cases, it requires additional approximation. Finally, we note that the Laplace approximation is often inferior to Expectation Propagation (EP) (Kuss & Rasmussen, 2005) for GP methods. While many of the same techniques used here could also be used with EP, EP requires additional approximations and computational overhead. We find in experiments (not shown) that EP yields similar accuracy to the Laplace approximation in this domain, but EP incurs increased complexity and computational load.

3. Model Construction

To demonstrate our fast method, we choose the specific observation model of an inhomogeneous gamma interval process (Barbieri et al., 2001) (with hyperparameter $\gamma \in \theta$, $\gamma \geq 1$). If time has been discretized with precision Δ, this can be written

$$p(\mathbf{y} \mid \mathbf{x}, \theta) = \prod_{i=1}^{N} \left[\frac{\gamma x_{y_i}}{\Gamma(\gamma)} \left(\gamma \sum_{k=y_{i-1}}^{y_i - 1} x_k \Delta \right)^{\gamma - 1} \cdot \exp\left\{ -\gamma \sum_{k=y_{i-1}}^{y_i - 1} x_k \Delta \right\} \right], \quad (3)$$

(where we have ignored terms that scale with Δ). Let $f(\mathbf{x}) = -\log p(\mathbf{y} \mid \mathbf{x}, \theta) p(\mathbf{x} \mid \theta)$. Our MAP estimation problem is to minimize $f(\mathbf{x})$ subject to the constraint $\mathbf{x} \succeq 0$ (nonnegativity). In the log barrier method, we consider the above problem as a sequence of convex problems where we seek to minimize, at increasing values of τ, the (unconstrained) objective function

$$f_\tau(\mathbf{x}) = f(\mathbf{x}) - \sum_{k=1}^{n} \left(\frac{1}{\tau} \right) \log(x_k) \quad (4)$$

which has Hessian (positive definite by our log concave construction):

$$H = \nabla^2_{\mathbf{x}} f_\tau(\mathbf{x}) = \Sigma^{-1} + \Lambda, \quad \text{where} \quad \Lambda = B + D, \quad (5)$$

with $D = \mathbf{diag}(x_{y_0}^{-2}, \ldots, 0, \ldots, x_{y_i}^{-2}, \ldots, 0 \ldots, x_{y_N}^{-2}) + (\frac{1}{\tau})\mathbf{diag}(x_1^{-2}, \ldots, x_n^{-2})$ being positive definite and diagonal. B is block diagonal with N blocks $\hat{B}_i$:

$$\hat{B}_i = b_i b_i^T \quad \text{where} \quad b_i = \sqrt{(\gamma - 1)} \left(\sum_{k=y_{i-1}}^{y_i - 1} x_k \right)^{-1} \mathbf{1}. \quad (6)$$

B is thus block rank 1 (with the positive eigenvalue in each block corresponding to the eigenvector b_i). This matrix is key, as we exploit its structure to achieve improvements in computational performance.

4. MAP Estimation Problem

As outlined in Section 2, we first find the MAP estimate $\mathbf{x}^*$ for any model defined by hyperparameters θ. The log barrier method has the intensive requirements of calculating the objective Eq. 4, its gradient $\mathbf{g}$ (in $\mathbf{x}$), and the Newton step $\mathbf{x}_{nt} = -H^{-1}\mathbf{g}$. Each of these calculations is $\mathcal{O}(n^3)$ in run time and $\mathcal{O}(n^2)$ in memory. We show an approach that alleviates these burdens.

4.1. Finding the Newton Step $\mathbf{x}_{nt}$

First we consider the Hessian, $H = \Sigma^{-1} + \Lambda$, which itself contains the costly inverse Σ^{-1}. We would like to avoid this inversion of Σ entirely with the matrix inversion lemma (Sherman-Woodbury-Morrison formula):

$$\begin{aligned} -H^{-1} &= -(\Sigma^{-1} + \Lambda)^{-1} \\ &= -\Sigma + \Sigma R (I + R^T \Sigma R)^{-1} R^T \Sigma \end{aligned} \quad (7)$$

where R is any valid factorization such that $RR^T = \Lambda$. This decomposition preserves symmetry in the remaining matrix inverse (required for CG) and has advantageous numerical properties. With this form, instead of calculating $\mathbf{x}_{nt} = -H^{-1}\mathbf{g}$ directly, we need only multiply the rightmost expression in Eq. 7 with the gradient $\mathbf{g}$. Doing so requires the inversion $(I + R^T \Sigma R)^{-1}\mathbf{v}$ where $\mathbf{v} = R^T \Sigma \mathbf{g}$. CG allows us to avoid directly calculating matrix inverses and instead achieve the desired inversion by iteratively multiplying $(I + R^T \Sigma R)\mathbf{z}$ for different vectors $\mathbf{z}$ (Gibbs & MacKay, 1997).

It is common to precondition the CG method to reduce the number of iterations required for convergence. However, our experience with preconditioning (using both classic preconditioners and some of our own design) was that it actually degraded run-time performance. Preconditioners typically aim to improve the condition number of the Hessian, which indeed they do in this problem. However, the rapidity of CG convergence here is facilitated more by spectral concentration – many eigenvalues being equal or close to 1 – than by overall conditioning. Thus, we found it more effective to use CG inversion directly on $(I + R^T \Sigma R)$.

In general, however, finding the decomposition $\Lambda = RR^T$ is an $\mathcal{O}(n^3)$ operation, which would remove any computational benefit from this approach. For log concave renewal processes, we can derive a valid decomposition in closed form and linear computation time. Since Λ is block diagonal, we consider only one block without loss of generality. Calling this block $\hat{\Lambda}$, we know $\hat{\Lambda} = bb^T + \hat{D}$, where $\hat{D}$ is a diagonal block of the larger diagonal matrix D, and b is defined in Eq. 6. $\hat{D}$ is positive definite, so $T = \hat{D}^{-\frac{1}{2}}$ satisfies $T\hat{D}T = I$ (a similarity transform). Then, calling $\tilde{b} = Tb$, we have $T\hat{\Lambda}T = \tilde{b}\tilde{b}^T + I$. With this form, we see that the general structure of $T\hat{\Lambda}T$ is preserved under the desired matrix decomposition, up to scaling of the components:

$$(\alpha\tilde{b}\tilde{b}^T + I)(\alpha\tilde{b}\tilde{b}^T + I)^T = (\alpha^2\|\tilde{b}\|^2 + 2\alpha)\tilde{b}\tilde{b}^T + I \quad (8)$$

and we want to choose α such that (Eq. 8) equals $\tilde{b}\tilde{b}^T + I$. Using the quadratic formula to find this α, we see then that

$$\tilde{R} = \left(\frac{\sqrt{1 + \|\tilde{b}\|^2} - 1}{\|\tilde{b}\|^2}\right)\tilde{b}\tilde{b}^T + I \quad (9)$$

satisfies $T\hat{\Lambda}T = \tilde{R}\tilde{R}^T$. Since T is diagonal, it easily inverts to $T^{-1} = \hat{D}^{\frac{1}{2}}$. Then:

$$\hat{\Lambda} = T^{-1}\tilde{R}\tilde{R}^T T^{-1} = (T^{-1}\tilde{R})(T^{-1}\tilde{R})^T = \hat{R}\hat{R}^T. \quad (10)$$

To be explicit, we have found that

$$\hat{R} = \left(\frac{\sqrt{1 + \|\hat{D}^{-\frac{1}{2}}b\|^2} - 1}{\|\hat{D}^{-\frac{1}{2}}b\|^2}\right)bb^T\hat{D}^{-\frac{1}{2}} + \hat{D}^{\frac{1}{2}} \quad (11)$$

is a valid decomposition $\hat{R}\hat{R}^T = \hat{\Lambda}$. This decomposition can be seen as a partial rank-one (blockwise) update to a Cholesky factorization (Gill et al., 1974), in that $\hat{D}$ can trivially be factorized to $\hat{D}^{\frac{1}{2}}$. The final form is not, however, a Cholesky factorization, since $\hat{R}$ is not triangular (making a triangular factor would require additional computation and the explicit representation of the Cholesky matrix).

Since all of the products needed to construct $\hat{R}$ can be formed in $\mathcal{O}(m)$ time (where m is the size of the block), and since the larger matrix R can be formed by tiling the blocks $\hat{R}$, we have a total complexity for this decomposition of $\mathcal{O}(n)$. We can then use CG to find the solution to $(I + R^T\Sigma R)^{-1}(R^T\Sigma\mathbf{g})$. With this inversion calculated, we can perform the remaining forward multiplications in Eq. 7; this completes calculation of a Newton step.

In fact, we need not form the matrix R in memory. Instead, we retain each of its component elements (in Eq. 11), and reduce multiplication of a vector by R to a sequence of inner products and multiplications by diagonal matrices, all of which can be stored and calculated in $\mathcal{O}(n)$ time. Thus, we eliminate the need for $\mathcal{O}(n^2)$ storage, and we perform the relevant matrix multiplications in $\mathcal{O}(n)$ time. Since R can be multiplied in linear time, the complexity of multiplying vectors by $(I + R^T\Sigma R)$ depends on multiplying vectors by the covariance matrix Σ.

Since we have evenly spaced resolution of our data $\mathbf{x}$ in time indices t_i, Σ is Toeplitz. This matrix can be embedded in a larger circulant matrix, multiplication by which is simply a convolution operation of the argument vector with a row of this circulant matrix. Thus, the operation can be quickly done in $\mathcal{O}(n\log n)$ using frequency domain multiplications(Silverman, 1982). Further, we need never represent the matrix Σ; we only store the first row of the circulant matrix. Again we have eliminated $\mathcal{O}(n^2)$ memory needs. Other methods for fast kernel matrix multiplications include Fast Gauss Transforms (FGT) (Raykar et al., 2005) and kd-Trees (Shen et al., 2006; Gray & Moore, 2003). We note that the single input dimension (time) enables this Toeplitz structure, and thus an extension to multiple dimensions should use FGT or similar. The regular structure of the data points in any dimension make Σ multiplications very fast with such a method. Further, these methods avoid explicit representation of Σ. Here, the simple FFT approach for this one-dimensional problem significantly outperforms other (more general) methods in both speed and accuracy.

Finally, we note that the matrix $(I + R^T\Sigma R)$ is particularly well suited to CG. Although $R^T\Sigma R$ is full rank by definition, in practice its spectrum has very few large eigenvalues (typically fewer than N, the number of events). Loosely, the matrix looks like identity plus low rank. In practice, the CG method converges with high accuracy almost always in fewer than 50 steps (very often under 30). This is drastically fewer than the worst case of n steps (n of 10^3 to 10^4).

Instead of decomposing $\Lambda = RR^T$, one might have considered using the matrix inversion lemma to write $(\Sigma^{-1} + \Lambda)^{-1} = \Sigma - \Sigma\Lambda(\Lambda + \Lambda\Sigma\Lambda)^{-1}\Lambda\Sigma$. Indeed this valid form enables all of the CG and fast multiplication methods previously discussed. While it may seem that this form's ease of derivation (compared to the matrix decomposition in Eq. 11) warrants its use in general, the matrix to be inverted is poorly conditioned compared to $(I + R^T\Sigma R)$, and thus the inversion requires more CG steps. We have found in testing that the number of CG steps can roughly double. Thus, the decomposition of Eq. 11 is computationally worthwhile.

In this section, we have constructed a fast method for calculating the Newton step that costs $\mathcal{O}(n\log n)$ per CG step and incurs a very small number of CG steps. Also, we have avoided explicit representation of any matrix, so that memory requirements are only linear in the data size n, al-

lowing problem sizes of potentially millions of time steps. These two factors stand in contrast to the cubic run time and quadratic storage needs of a naive method.

4.2. Evaluating the Gradient and Objective

Calculating the objective $f_\tau(\mathbf{x})$ (Eq. 4) and its gradient (both required for the log barrier method) require finding $\Sigma^{-1}(\mathbf{x} - \mu\mathbf{1})$. Note that the kth iterate $\mathbf{x}^{(k)}$ (of the log barrier method) has the form

$$\begin{aligned}(\mathbf{x}^{(k)} - \mu\mathbf{1}) &= \mathbf{x}^{(k-1)} + t^{(k-1)}\mathbf{x}_{nt}^{(k-1)} - \mu\mathbf{1} \\ &= \sum_{j=1}^{k-1} t^{(j)}\mathbf{x}_{nt}^{(j)} + (\mathbf{x}^{(0)} - \mu\mathbf{1}) \quad (12)\end{aligned}$$

where $t^{(j)}$ and $\mathbf{x}_{nt}^{(j)}$ represent the jth iterates of the Newton step size t and the step $\mathbf{x}_{nt}$, and $\mathbf{x}^{(0)}$ is the algorithm initial point. The most logical starting point $\mathbf{x}^{(0)}$ is $\mu\mathbf{1}$, in which case the rightmost term in Eq. 12 drops out. Thus, letting $\mathbf{x}^{(0)} = \mu\mathbf{1}$ and using the form of $\mathbf{x}_{nt} = -H^{-1}\mathbf{g}$ with $-H^{-1}$ defined as in Eq. 7, we write:

$$\Sigma^{-1}(\mathbf{x}^{(k)} - \mu\mathbf{1}) = \sum_{j=1}^{k-1} t^{(j)}\Big(-\mathbf{g}^{(j)} + R^{(j)}(I + R^{(j)T}\Sigma R^{(j)})^{-1}R^{(j)T}\Sigma\mathbf{g}^{(j)}\Big). \quad (13)$$

In the earlier calculation of $\mathbf{x}_{nt}$ (Section 4.1), both of the right hand side arguments in Eq. 13 have already been found. As such, we have a recurrence that obviates the invertion of Σ, with no additional memory demands (Rasmussen & Williams, 2006).

The above steps reduce a naive MAP estimation (of any log concave renewal process) that requires cubic effort and quadratic storage to an algorithm that is modestly superlinear in run time and linear in memory requirements.

5. Model Selection Problem

Having now found $\mathbf{x}^*$ for any hyperparameters θ, the second major part of the problem is to find the negative logarithm of our approximation to the evidence $p(\mathbf{y} \mid \theta)$ in Eq. 2, and its gradients with respect to θ. The approximated log evidence can be written as:

$$\begin{aligned}&-\log\ p(\mathbf{y} \mid \theta) \approx -\log\ p(\mathbf{y} \mid \mathbf{x}^*) \\ &+\ \frac{1}{2}(\mathbf{x}^* - \mu\mathbf{1})^T\Sigma^{-1}(\mathbf{x}^* - \mu\mathbf{1})\ +\ \frac{1}{2}\log|I + \Sigma\Lambda^*| \quad (14)\end{aligned}$$

(ignoring constants). Each of these terms has an explicit and an implicit gradient with respect to θ, where the latter result from the dependence of the MAP estimate $\mathbf{x}^*$ on the hyperparameters (such implicit gradients are typical for the use of Laplace approximation in GP learning; see Rasmussen & Williams, 2006, section 5.5.1). The implicit gradients in this problem are extremely computationally burdensome to calculate (requiring the trace of matrix inversions and matrix-matrix products for each element of $\mathbf{x}$). In empirical tests, we find implicit gradients to be quite small relative to the explicit gradients (often by several orders of magnitude). Ignoring these gradients is undesirable but essential to make this problem computationally feasible. Thus we consider only explicit gradients. This is a common approach for GP methods; see Rasmussen and Williams (2006).

Efficient computation of the first two terms of Eq. 14, as well as their gradients with respect to θ, can be achieved by the fast multiplication method and the recursion derived in Sec. 4. Specifically, the values of the first and second terms of Eq. 14 are calculated during the MAP estimation, so no additional memory or computation is necessary for them. The gradient of the first term is nonzero only with respect to γ and is linear in $\mathbf{x}$ (no matrix multiplications are required). Thus it can be quickly calculated with no additional memory demands. Computation of the gradient of the second term (the prior) can exploit the fact that we calculated $\Sigma^{-1}(\mathbf{x}^* - \mu\mathbf{1})$ in the final step of the MAP estimation. The gradient of this term with respect to μ is a simple inner product $\mathbf{1}^T(\Sigma^{-1}(\mathbf{x}^* - \mu\mathbf{1}))$ (since we have already calculated the right side of this inner product, this computation is $\mathcal{O}(n)$ in run time and requires no additional memory). The gradient of this term with respect to a kernel hyperparameter θ_i (*e.g.* a lengthscale or variance) is:

$$\frac{d}{d\theta_i}\Big[\frac{1}{2}(\mathbf{x}^* - \mu\mathbf{1})^T\Sigma^{-1}(\mathbf{x}^* - \mu\mathbf{1})\Big] = \frac{1}{2}\big(\Sigma^{-1}(\mathbf{x}^* - \mu\mathbf{1})\big)^T\Big(\frac{d\Sigma}{d\theta_i}\Big)\big(\Sigma^{-1}(\mathbf{x}^* - \mu\mathbf{1})\big). \quad (15)$$

Since we have $\Sigma^{-1}(\mathbf{x}^* - \mu\mathbf{1})$, this gradient only requires one matrix-vector multiplication. $\frac{d\Sigma}{d\theta_i}$ has the same Toeplitz structure as Σ and can thus be quickly multiplied. Thus, calculating the first two terms of Eq. 14 and their gradients adds no complexity to the method developed so far.

Only the term $\frac{1}{2}\log|I + \Sigma\Lambda^*|$ presents difficulty. Determinants in general require $\mathcal{O}(n^2)$ memory and $\mathcal{O}(n^3)$ solve time using a Cholesky or PLU factorization, so we must consider the problem more carefully. We examine the eigenstructure of $(I + \Sigma\Lambda^*)$. Since we are not trying to find a MAP estimate, there is no log barrier term (*i.e.* let $\tau \to \infty$); thus D (from Eq. 5) is rank N only. This means that $\Lambda^* = B + D$ (Eq. 6) is block outer product plus sub rank diagonal, so it is also rank deficient with block rank 2. Thus, it has $2N$ nonzero eigenvalues (two corresponding to each of the N events, one in each block from B and one in each block from D). Using the eigenvalue decomposition

$\Lambda^* = USU^T$, we see

$$\begin{aligned} \log|I + \Sigma\Lambda^*| &= \log|I + \Sigma USU^T| \\ &= \log|U^T||I + \Sigma USU^T||U| \\ &= \log|I + U^T\Sigma US|, \end{aligned} \tag{16}$$

since the orthogonal matrix U has determinant 1 and $U^TU = I$ by definition. Since Λ^* has rank $2N$, we know that S is diagonal with zeros on the last $n - 2N$ entries. By construction, the number of events N is much smaller than the total data size n. Since the determinant of a matrix is the product of its eigenvalues, the unit eigenvalue dimensions of $I + U^T\Sigma US$ can be ignored. We define $\overline{S}$ as the $2N \times 2N$ submatrix of S that is made up of the diagonal block with nonzero diagonal entries. Further define $\overline{U}$ as the corresponding $2N$ eigenvectors. Then, since the other dimensions of $U^T\Sigma US$ contribute nothing to the determinant, we have

$$\begin{aligned} \log|I + \Sigma\Lambda^*| &= \log|I + U^T\Sigma US| \\ &= \log|I + \overline{U}^T\Sigma\overline{U}\,\overline{S}| \\ &= \log|I + \overline{\Sigma}\,\overline{S}|, \end{aligned} \tag{17}$$

where I is now the $2N \times 2N$ identity, and we have further defined $\overline{\Sigma} = \overline{U}^T\Sigma\overline{U}$. Computationally, $\overline{\Sigma}$ is formed by multiplying Σ with the columns of $\overline{U}$. Since Λ^* is block rank 2, both matrices $\overline{S}$ and $\overline{U}$ can be found in closed form (N rank 2 eigendecompositions, one decomposition per block). This calculation of Eq. 17 requires $2N$ matrix multiplications which each have a run time cost of $\mathcal{O}(n\log n)$.

We can make a small approximation that simplifies this problem even further. Typically, N of these $2N$ eigenvalues are substantially larger than the other N. Each block of Λ^* contributes two nonzero eigenvalues. The larger is due to the diagonal entry $x_{y_i}^{-2}$ (from the matrix D) and is nearly axis aligned. The smaller eigenvalue is due to the outer product vector from block $\hat{B}_i$. Examination of the denominators in the definition of $\hat{B}_i$ and D in Eqs. 5 and 6 explains the difference in magnitude, since $x_{y_i}^2$ is much smaller than the square of sums denominator in $\hat{B}_i$. We approximate the eigenvector as the y_i axis and approximate its eigenvalue as the corresponding value in Λ^*. Then $\overline{S}$ is size $N \times N$. This savings is small, but importantly we can form $\overline{\Sigma} = \overline{U}^T\Sigma\overline{U}$ simply by picking out the N rows and columns of Σ corresponding to the event times y_i.

In this formulation, we are left with matrices of size $N \times N$ only, so we have some modest number of $\mathcal{O}(N^3)$ operations; this approach is considerably faster and scales better than the exact method above. We have also reduced $\mathcal{O}(n^2)$ storage to $\mathcal{O}(N^2)$. The following section elucidates the quality of this approximation.

To calculate the gradients with respect to this log determinant term, we also use the approximation of Eq.17. We call our approximate gradient of this term the gradient of the approximation in Eq. 17. This approximation can readily be differentiated with respect to the hyperparameters (again, typical for GP; see Rasmussen & Williams, 2006). Since these approximations are matrices in the event space N (not time space n), these gradients are quickly calculated with a handful of $\mathcal{O}(N^3)$ operations and with storage of $\mathcal{O}(N^2)$.

6. Results and Discussion

The methods developed here maintain computational accuracy while achieving massive speed-up and the elimination of memory burden. First, we have shown a fast method that achieves an accurate approximation of the MAP estimate $\mathbf{x}^*$ in much less time than a naive method. We have made all matrix multiplications implicit, thereby eliminating the memory burden of representing full matrices. We call this piece the "MAP Estimation." Second, we found the approximate model evidence, as well as its gradients, so as to perform model selection on the hyperparameters θ. These calculations, which involved the calculation of a log determinant and its gradients (Eq. 17), were achieved with matrices of significantly reduced dimension, again removing the storage demands of teh naive method. We call this piece the "log determinant approximation." These two pieces must be iterated (as described before Eq. 2) to find both the optimal model $\hat{\theta}$ and the optimal intensity $\mathbf{x}^*$. We call this iterative method (combining the two pieces above) the "full GP intensity estimation." We show here that each piece is fast and accurate, and finally that they combine to make an overall method that is considerably faster than a standard implementation, with minimal sacrifice to accuracy.

To demonstrate results, we pick six representative intensity functions, consisting of sinusoids of various amplitudes (5-100 events/second), means (15-150 events/second), frequencies (1-2 Hz), and lengths (0.5-10 seconds of millisecond resolution data, implying data sizes n of 500 to 10000). This set is by no means exhaustive, but it does indicate how this method outperforms a naive implementation in a range of scenarios. Our testing over many different intensity functions (including those in Cunningham et al., 2008) agrees with the results shown here. We simulate point process data $\mathbf{y}$ from these intensities, and we implement both the naive and the fast method on these process realizations.

All results are given for 2006era Linux (FC4) 64 bit workstations with 2-4GB of RAM running MATLAB (R14sp3, BLAS ATLAS 3.2.1 on AMD processors). The naive method was implemented in MATLAB. The fast method was similarly implemented in MATLAB with some use of the C-MEX interface for linear operations such as multiplication of a vector by the (implicitly represented) matrix R.

Table 1. Performance for fast and naive methods. Results averaged over 10 independent trials.

[1] Entries show a range of data used.
[2] Squared norm of $x(t)$ is roughly 10^3 to 10^5, so these errors are insignificant.
[3] Unable to complete naive method; numbers estimated from cubic scaling.

First we demonstrate the utility of our fast MAP estimation method on problems of several different sizes and with different $\mathbf{x}$. We compare the fast MAP estimation to a naive implementation, demonstrating the average mean squared (MS) error (between the fast and naive estimates) and the average solve time. These results are found in the first part of Table 1. The squared norm of $\mathbf{x}$ is roughly 10^3 to 10^5, so the errors shown (the difference between the naive and fast methods) are vanishingly small. Thus, the fast MAP estimation gives an extremely accurate approximation of the naive MAP estimate. For all practical purposes, the fast MAP estimation method is exact.

The naive method scales in run time as the cube of data size n, as expected. The fast method and the speed-up factor do not appear to scale linearly in the data size. Indeed, run time depends heavily on the number of CG iterations required to solve the MAP estimation. This number of CG steps depends on problem size n, number of events N, and hyperparameters such as the lengthscale of the covariance matrix. Even so, major gains are achieved.

Second, we demonstrate our model selection accuracy and speed-up (the log determinant approximation). We run the full iterative fast method with both MAP estimation and evidence model selection. At each iterate of θ, we calculate evidence and its gradients using both the fast and naive methods. In the second section of Table 1, we show average solution times for calculating the log determinant in both naive and fast methods, and we compare their accuracy. For the sake of brevity, we demonstrate only the calculation of $\log |I + \Sigma\Lambda^*|$, not its gradients with respect to the hyperparameters. Those calculations show very similar speed-ups and are as well approximated. Thus, the log determinant is calculated to 99-100% accuracy with the naive method, and we have a highly accurate approximation.

Finally, the full intensity estimation problem requires iterative evidence calculations and MAP estimations, so we must also demonstrate the accuracy of the full fast method versus the full naive method. The last part of Table 1 shows this result (Full GP Intensity Estimation). We see that all data sets converge to quite similar results in both the fast and the naive methods, and the fast method enjoys significant speed-up. The MS errors shown compare the result

of the fast method to the result of the naive method and are very small compared to the squared norm of $\mathbf{x}$ (10^3 to 10^5).

We have demonstrated a method for inferring optimal intensity estimates from an observation of renewal process data, and we have exploited problem structure to make this method computationally attractive. As an extension, we also developed this fast GP technique for multiple observations $\mathbf{y}^{(i)}$ of the same underlying $\mathbf{x}$. It uses the same approach with comparable performance improvements. As such, we do not report it here.

Since we avoid all explicit representations of $n \times n$ matrices, our memory requirements are very minor for a problem of this size. The major run time improvements in Table 1 require effectively no loss of accuracy from an exact naive approach, and thus the additional technical complexity of this approach is well justified. Having fast, scalable methods for point process intensity estimation problems may mean the difference between theoretically interesting approaches and methods that become well used in practice.

Abstract

This paper focuses on a new clustering task, called *self-taught clustering*. Self-taught clustering is an instance of *unsupervised transfer learning*, which aims at clustering a small collection of target unlabeled data with the help of a large amount of *auxiliary* unlabeled data. The target and auxiliary data can be different in topic distribution. We show that even when the target data are not sufficient to allow effective learning of a high quality feature representation, it is possible to learn the useful features with the help of the auxiliary data on which the target data can be clustered effectively. We propose a co-clustering based self-taught clustering algorithm to tackle this problem, by clustering the target and auxiliary data simultaneously to allow the feature representation from the auxiliary data to influence the target data through a common set of features. Under the new data representation, clustering on the target data can be improved. Our experiments on image clustering show that our algorithm can greatly outperform several state-of-the-art clustering methods when utilizing irrelevant unlabeled auxiliary data.

1. Introduction

Clustering (Jain & Dubes, 1988) aims at partitioning objects into groups, so that the objects in the same groups are relatively similar, while the objects in different groups are relatively dissimilar. Clustering has a long history in machine learning (MacQueen, 1967), and recent works on clustering research have focused on improving the clustering performance using the prior knowledge in semi-supervised clustering (Wagstaff et al., 2001) and supervised clustering (Finley & Joachims, 2005).

In the past, semi-supervised clustering incorporates pairwise supervision, such as *must-link* or *cannot-link* constraints (Wagstaff et al., 2001), to bias clustering results. Supervised clustering methods learn distance functions from a small sample of auxiliary *labeled* data (Finley & Joachims, 2005). Different from these clustering problems, in this paper, we address a new clustering task where we use a large amount of *auxiliary unlabeled* data to enhance the clustering performance of a small amount of *target* unlabeled data. In our problem, we do not have any labeled data or pairwise supervisory constraint knowledge. All we have are the auxiliary data which are totally unlabeled and may be irrelevant to the target data. Our target data consist of a collection of unlabeled data from which it may be insufficient to learn a good feature representation. Thus, applying clustering directly on these target data may give very poor performance. However, with the help of auxiliary data, we are able to uncover a good feature set to enable high quality clustering on the target data.

Our problem can be considered as an instance of transfer learning, which makes use of knowledge gained from one learning task to improve the performance of another, even when these learning tasks or domains follow different distributions (Caruana, 1997). However, since all the data are unlabeled, we can consider it as an instance of *unsupervised transfer learning* (Teh et al., 2006). This unsupervised transfer learning problem could also be viewed as a clustering version of the self-taught learning (Raina et al., 2007), which uses irrelevant unlabeled data to help supervised learning. Thus, we refer to our problem as *self-taught clustering*

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

(a) diamond (b) platinum

(c) ring (d) titanium

Figure 1. Example for common features among different types of objects, using images as the instance.

(or STC for abbreviation).

To tackle the problem, we observe that the performance of clustering highly relies on data representation when the objective function and the distance measure are fixed. Therefore, to improve the clustering performance, one alternative way is to seek a better data representation. We observe that different objects may share some common or relevant features. For example, in Figure 1, `diamond` and `ring` share quite a lot of features about "diamond"; `ring` and `platinum` share quite a lot of features about "platinum"; moreover, `platinum` and `titanium` share quite a lot of features about "metal". In this situation, the auxiliary data can be used to help uncover a better data representation to benefit the target data set. Our approach to tackling this problem is by using co-clustering (Dhillon et al., 2003), so that the commonality can be found in the feature spaces that corresponds to similar semantic meanings.

In our solution to the self-taught clustering problem, two clustering operations, on the target data and the auxiliary data are respectively performed together. This is done through co-clustering. We extend the information theoretic co-clustering algorithm (Dhillon et al., 2003) which minimizes *loss in mutual information* before and after co-clustering. An iterative algorithm is proposed to monotonically reduce the objective function. The experimental results show that our algorithm can greatly improve the clustering performance by effectively using auxiliary unlabeled data, as compared to several other state-of-the-art clustering algorithms.

2. Problem Formulation

For clarity, we first define the self-taught clustering task. Let X and Y be two discrete random variables, taking values from two value sets $\{x_1, \ldots, x_n\}$ and $\{y_1, \ldots, y_m\}$, respectively. X and Y correspond to the target and auxiliary data. Let Z be a discrete random variable, taking values from the value set $\{z_1, \ldots, z_k\}$, that corresponds to the *common* feature space of both target and auxiliary data.

Let $p(X, Z)$ be the joint probability distribution with respect to X and Z, and $q(Y, Z)$ be the joint probability distribution with respect to Y and Z. In general, $p(X, Z)$ and $q(Y, Z)$ can be considered as two $n \times k$ and $m \times k$ matrices respectively, which can be estimated from data observations. For example, consider the case that $x_1 = \{z_1, z_3\}$, $x_2 = \{z_2\}$, and $x_3 = \{z_2, z_3\}$. Then, the joint probability distribution $p(X, Z)$ can be estimated as

$$p(X, Z) = \begin{bmatrix} 0.2 & 0.0 & 0.2 \\ 0.0 & 0.2 & 0.0 \\ 0.0 & 0.2 & 0.2 \end{bmatrix}. \quad (1)$$

We wish to cluster X into N partitions $\tilde{X} = \{\tilde{x}_1, \ldots, \tilde{x}_N\}$ and Y into M clusters $\tilde{Y} = \{\tilde{y}_1, \ldots, \tilde{y}_M\}$. Furthermore, Z can be clustered into K feature clusters $\tilde{Z} = \{\tilde{z}_1, \ldots, \tilde{z}_K\}$. We use $C_X : X \mapsto \tilde{X}$, $C_Y : Y \mapsto \tilde{Y}$ and $C_Z : Z \mapsto \tilde{Z}$ to denote three clustering functions, which map variables in the three value sets to their corresponding clusters. For brevity, in the following, we will use $\tilde{X}$, $\tilde{Y}$ and $\tilde{Z}$ to denote $C_X(X)$, $C_Y(Y)$ and $C_Z(Z)$, respectively.

Our objective is to find a good clustering function C_X for the target data, with the help of the clusters C_Y on the auxiliary data and C_Z on the common feature space.

3. The Self-taught Clustering Algorithm

In this section, we present our co-clustering based *self-taught clustering* (STC) algorithm, and then discuss its theoretical properties based on information theory.

3.1. Objective Function for Self-taught Clustering

We extend the information theoretic co-clustering (Dhillon et al., 2003) to model our self-taught clustering algorithm. In the information theoretic co-clustering, the objective function of co-clustering is defined as minimizing *loss in mutual information* between instances and features, before and after co-clustering. Formally, using the target data X and their feature space Z for illustration, the objective function can be expressed as

$$I(X, Z) - I(\tilde{X}, \tilde{Z}), \quad (2)$$

where $I(\cdot\,;\,\cdot)$ denotes the mutual information between two random variables (Cover & Thomas, 1991) that $I(X; Z) = \sum_{x \in X} \sum_{z \in Z} p(x, z) \log \frac{p(x,z)}{p(x)p(z)}$. Moreover, $I(\tilde{X}, \tilde{Z})$ corresponds to the joint probability distribu-

tion $p(\tilde{X}, \tilde{Z})$ which is defined as

$$p(\tilde{x}, \tilde{z}) = \sum_{x \in \tilde{x}} \sum_{z \in \tilde{z}} p(x, z). \quad (3)$$

For example, for the joint probability $p(X, Z)$ in Equation (1), suppose that the clustering on X is $\tilde{X} = \{\tilde{x}_1 = \{x_1, x_2\}, \tilde{x}_2 = \{x_3\}\}$, and the clustering on Z is $\tilde{Z} = \{\tilde{z}_1 = \{z_1, z_2\}, \tilde{z}_2 = \{z_3\}\}$. Then,

$$p(\tilde{X}, \tilde{Z}) = \begin{bmatrix} 0.4 & 0.2 \\ 0.2 & 0.2 \end{bmatrix}. \quad (4)$$

In this work, we model our self-taught clustering algorithm (STC) as performing co-clustering operations on the target data X and auxiliary data Y, simultaneously, while the two co-clusters share the same features clustering $\tilde{Z}$ on the feature set Z. Thus, the objective function can be formulated as

$$\mathcal{J} = I(X, Z) - I(\tilde{X}, \tilde{Z}) + \lambda \Big[I(Y, Z) - I(\tilde{Y}, \tilde{Z}) \Big]. \quad (5)$$

In Equation (2), $I(X, Z) - I(\tilde{X}, \tilde{Z})$ is computed on the co-clusters on the target data X, while $I(Y, Z) - I(\tilde{Y}, \tilde{Z})$ on the auxiliary data Y. λ is a trade-off parameter to balance the influence between the target data and the auxiliary data which we will test in our experiments. From Equation (5), we can see that, although the two co-clustering objective functions $I(X, Z) - I(\tilde{X}, \tilde{Z})$ and $I(Y, Z) - I(\tilde{Y}, \tilde{Z})$ are performed separately, they share the same feature clustering $\tilde{Z}$. This is the "bridge" to transfer the knowledge between the target and auxiliary data.

Our remaining task is to minimize the value of the objective function in Equation (5)[1]. However, minimizing Equation (5) is not an easy task, since it is non-convex and there are no good solutions currently to directly optimize this objective function. In the following, we will rewrite the objective function in Equation (5) into the form of Kullback-Leibler divergence (Cover & Thomas, 1991) (KL divergence), and minimize the reformulated objective function.

3.2. Optimization for Co-clustering

We first define two new probability distributions $\tilde{p}(X, Z)$ and $\tilde{q}(Y, Z)$ as follows.

Definition 1 *Let $\tilde{p}(X, Z)$ denote the joint probability distribution of X and Z with respect to the co-clusters (C_X, C_Z); formally,*

$$\tilde{p}(x, z) = p(\tilde{x}, \tilde{z}) \frac{p(x)}{p(\tilde{x})} \frac{p(z)}{p(\tilde{z})}, \quad (6)$$

where $x \in \tilde{x}$ and $z \in \tilde{z}$. Therefore, with regard to Equations (1) and (4), $\tilde{p}(X, Z)$ is given by

$$\tilde{p}(X, Z) = \begin{bmatrix} 0.089 & 0.178 & 0.133 \\ 0.044 & 0.089 & 0.067 \\ 0.067 & 0.133 & 0.200 \end{bmatrix}. \quad (7)$$

Likewise, let $\tilde{q}(Y, Z)$ denote the joint probability distribution of Y and Z with respect to the co-clusters (C_Y, C_Z). We have

$$\tilde{q}(y, z) = q(\tilde{y}, \tilde{z}) \frac{q(y)}{q(\tilde{y})} \frac{q(z)}{q(\tilde{z})}, \quad (8)$$

where $y \in \tilde{y}$ and $z \in \tilde{z}$.

Using the probability distributions $\tilde{p}(X, Z)$ and $\tilde{q}(Y, Z)$ defined above, we can reformulate the objective function in Equation (5) into a form based on KL divergence (Cover & Thomas, 1991).

Lemma 1 *When the clusters C_X, C_Y and C_Z are fixed, the objective function in Equation (5) can be reformulated as*

$$\begin{aligned} & I(X; Z) - I(\tilde{X}; \tilde{Z}) + \lambda \Big[I(Y; Z) - I(\tilde{Y}; \tilde{Z}) \Big] \quad (9) \\ & = D(p(X, Z) || \tilde{p}(X, Z)) + \lambda \, D(q(Y, Z) || \tilde{q}(Y, Z)), \end{aligned}$$

where $D(\cdot||\cdot)$ denotes the KL divergence between two probability distributions (Cover & Thomas, 1991), where $D(p||q) = \sum_x p(x) \log \frac{p(x)}{q(x)}$.

Proof Based on the Lemma 2.1 in (Dhillon et al., 2003), $I(X, Z) - I(\tilde{X}, \tilde{Z}) = D(p(X, Z)||\tilde{p}(X, Z))$. Similarly, $I(Y, Z) - I(\tilde{Y}, \tilde{Z}) = D(q(Y, Z)||\tilde{q}(Y, Z))$. Therefore, Lemma 1 can be proved straightforwardly. □

Lemma 1 converts the loss in mutual information to the KL divergence between the distributions p and $\tilde{p}$, and between q and $\tilde{q}$, respectively. However, the probability distributions in Lemma 1 are joint distributions, and are therefore difficult to optimize. Hence, in Lemma 2, we rewrite the objective function in Lemma 1 as a conditional probability form. We then show how to optimize the objective function in the new form.

Lemma 2 *The KL divergence with respect to joint probability distributions can be reformulated as*

$$\begin{aligned} & D(p(X, Z)||\tilde{p}(X, Z)) \\ & = \sum_{\tilde{x} \in \tilde{X}} \sum_{x \in \tilde{x}} p(x) D(p(Z|x)||\tilde{p}(Z|\tilde{x})) \quad (10) \\ & = \sum_{\tilde{z} \in \tilde{Z}} \sum_{z \in \tilde{z}} p(z) D(p(X|z)||\tilde{p}(X|\tilde{z})). \quad (11) \end{aligned}$$

[1] To be mentioned, in this paper, our minimization is for a fixed numbers of clusters N, M and K.

Similarly,

$$D(q(Y,Z)||\tilde{q}(Y,Z)) = \sum_{\tilde{y}\in\tilde{Y}}\sum_{y\in\tilde{y}} q(y)D(q(Z|y)||\tilde{q}(Z|\tilde{y})) \quad (12)$$

$$= \sum_{\tilde{z}\in\tilde{Z}}\sum_{z\in\tilde{z}} q(z)D(q(Y|z)||\tilde{q}(Y|\tilde{z})). \quad (13)$$

Proof We only give the proof to Equation (10). Using an identical argument, Equations (11), (12) and (13) can be easily derived.

$$D(p(X,Z)||\tilde{p}(X,Z)) = \sum_{\tilde{x}\in\tilde{X}}\sum_{\tilde{z}\in\tilde{Z}}\sum_{x\in\tilde{x}}\sum_{z\in\tilde{z}} p(x,z)\log\frac{p(x,z)}{\tilde{p}(x,z)}.$$

Since $\tilde{p}(x,z) = p(x)\frac{p(\tilde{x},\tilde{z})}{p(\tilde{x})}\frac{p(z)}{p(\tilde{z})} = p(x)\tilde{p}(z|\tilde{x})$, we have

$$\begin{aligned} &D(p(X,Z)||\tilde{p}(X,Z)) \\ &= \sum_{\tilde{x}\in\tilde{X}}\sum_{\tilde{z}\in\tilde{Z}}\sum_{x\in\tilde{x}}\sum_{z\in\tilde{z}} p(x)p(z|x)\log\frac{p(x)p(z|x)}{p(x)\tilde{p}(z|\tilde{x})} \\ &= \sum_{\tilde{x}\in\tilde{X}}\sum_{x\in\tilde{x}} p(x)\sum_{\tilde{z}\in\tilde{Z}}\sum_{z\in\tilde{z}} p(z|x)\log\frac{p(z|x)}{\tilde{p}(z|\tilde{x})} \\ &= \sum_{\tilde{x}\in\tilde{X}}\sum_{x\in\tilde{x}} p(x)D(p(Z|x)||\tilde{p}(Z|\tilde{x})). \end{aligned}$$

□

From Lemma 2 and Equation (10), we can see that minimizing $D(p(Z|x)||\tilde{p}(Z|\tilde{x}))$ for a single x can reduce the value of $D(p(X,Z)||\tilde{p}(X,Z))$ and thus can then decrease global optimization function in Equation (9). Therefore, if we iteratively choose the best cluster $\tilde{x}$ for each x to minimize $D(p(Z|x)||\tilde{p}(Z|\tilde{x}))$, the objective function will be minimized monotonically. Formally,

$$C_X(x) = \arg\min_{\tilde{x}\in\tilde{X}} D(p(Z|x)||\tilde{p}(Z|\tilde{x})). \quad (14)$$

Using a similar argument on Y and Z, we have

$$C_Y(y) = \arg\min_{\tilde{y}\in\tilde{Y}} D(q(Z|y)||\tilde{q}(Z|\tilde{y})), \quad (15)$$

and

$$C_Z(z) = \arg\min_{\tilde{z}\in\tilde{Z}} p(z)D(p(X|z)||\tilde{p}(X|\tilde{z})) + \lambda\, q(z)D(q(Y|z)||\tilde{q}(Y|\tilde{z})). \quad (16)$$

Based on Equation (14), (15) and (16), an alternative way to minimize the objective function in Equation (9) is derived, as shown in Algorithm 1.

In Algorithm 1, in each iteration, our self-taught clustering algorithm (STC) minimizes the objective function by choosing the best $\tilde{x}$, $\tilde{y}$ and $\tilde{z}$ for each x, y and z based on Equations (14), (15) and (16). As we discussed above, this can reduce the value of the global objective function in Equation (9). In the following theorem, we show the monotonically decreasing property of the objective function of the STC algorithm.

Algorithm 1 The Self-taught Clustering Algorithm: STC

Input: A target unlabeled data set X; an auxiliary unlabeled data set Y; the feature space Z shared by both X and Y; the initial clustering functions $C_X^{(0)}$, $C_Y^{(0)}$ and $C_Z^{(0)}$; the number of iterations T.

Output: The final clustering function $C_X^{(T)}$ on the target data X.

Procedure STC

1: Initialize $p(X,Z)$ and $q(Y,Z)$ based on the data observations on X, Y, and Z.
2: Initialize $\tilde{p}^{(0)}(X,Z)$ based on $p(X,Z)$, $C_X^{(0)}$, $C_Z^{(0)}$, and Equation (6).
3: Initialize $\tilde{q}^{(0)}(Y,Z)$ based on $q(Y,Z)$, $C_Y^{(0)}$, $C_Z^{(0)}$, and Equation (8).
4: **for** $t \leftarrow 1,\ldots,T$ **do**
5: Update $C_X^{(t)}(X)$ based on p, $\tilde{p}^{(t-1)}$, and Equation (14).
6: Update $C_Y^{(t)}(Y)$ based on q, $\tilde{q}^{(t-1)}$, and Equation (15).
7: Update $C_Z^{(t)}(Z)$ based on p, q, $\tilde{p}^{(t-1)}$, $\tilde{q}^{(t-1)}$, and Equation (16).
8: Update $\tilde{p}^{(t)}$ based on based on $p(X,Z)$, $C_X^{(t)}$, $C_Z^{(t)}$, and Equations (6).
9: Update $\tilde{q}^{(t)}$ based on based on $q(Y,Z)$, $C_Y^{(t)}$, $C_Z^{(t)}$, and Equations (8).
10: **end for**
11: Return $C_X^{(T)}$ as the final clustering function on the target data X.

Theorem 1 *In Algorithm 1, let the value of objective function $\mathcal{J}$ in the t-th iteration be*

$$\mathcal{J}(C_X^{(t)},C_Y^{(t)},C_Z^{(t)}) = D(p(X,Z)||\tilde{p}^{(t)}(X,Z)) + \lambda\, D(q(Y,Z)||\tilde{q}^{(t)}(Y,Z)). \quad (17)$$

Then,

$$\mathcal{J}(C_X^{(t)},C_Y^{(t)},C_Z^{(t)}) \geq \mathcal{J}(C_X^{(t+1)},C_Y^{(t+1)},C_Z^{(t+1)}). \quad (18)$$

Proof (Sketch) Since in each iteration, the clustering functions are updated based on Equations (14), (15) and (16), which locally minimize the values of $D(p(X,Z)||\tilde{p}(X,Z))$ and $D(q(Y,Z)||\tilde{q}(Y,Z))$, the objective function is monotonically non-increasing as a result. Theorem 1 follows as a consequence. □

Note that, although STC is able to minimize the objective function value in Equation (9), it is only able to find a locally optimal one. Finding the global optimal solution is NP-hard. The next corollary emphasizes the convergence property of our algorithm STC.

Corollary 1 *Algorithm 1 converges in a finite number of iterations.*

Proof (Sketch) The convergence of our algorithm STC can be proved straightforwardly based on the monotonical decreasing property in Theorem 1, and the finiteness of the solution space. □

3.3. Complexity Analysis

We now analyze the computational cost of our algorithm STC. Suppose that the total number of (x, z) co-occurrences in the target data set X is L_1, and the total number of (y, z) co-occurrences in the auxiliary data set Y is L_2. In each iteration, updating the target instance clustering C_X takes $O(N \cdot L_1)$. Updating the auxiliary instance clustering C_Y takes $O(M \cdot L_2)$. Moreover, updating the feature clustering C_Z takes $O(K \cdot (L_1 + L_2))$. Since the number of iterations is T, the time complexity of our algorithm is $O(T \cdot ((K + N) \cdot L_1 + (K + M) \cdot L_2)))$. In the following experiments, it is shown that $T = 10$ is enough for convergence. Usually, the number of clusters N, M and K can be considered as constants, so that the time complexity of STC is $O(L_1 + L_2)$.

Considering space complexity, our algorithm needs to store all the (x, z) and (y, z) co-occurrences and their corresponding probabilities. Thus, the space complexity is $O(L_1 + L_2)$. This indicates that the time complexity and the space complexity of our algorithm are all linear on the input. We conclude that the algorithm scales well.

4. Experiments

In this section, we evaluate our self-taught clustering algorithm STC on the image clustering tasks, and show effectiveness of STC.

4.1. Data Sets

We conduct our experiments on eight clustering tasks generated based on the Caltech-256 image corpus (Griffin et al., 2007). There are a total of 256 categories in the Caltech-256 data set, where we randomly chose 20 categories from this corpus. For each category, 70 images are randomly selected to form our clustering tasks. Six binary clustering tasks, one 3-way clustering task, and one 5-way clustering task were generated using these 20 categories, as shown in Table 1. The first column in Table 1 presents the categories with respect to the target unlabeled data. For each clustering task, we used the data from the corresponding categories as target unlabeled data, while the data from the remaining categories as the auxiliary unlabeled data.

For data preprocessing, we used the "bag-of-words" method (Li & Perona, 2005) to represent images in our experiments. Interesting points in images are found and described by SIFT descriptor (Lowe, 2004). Then, we clustered all the interesting points to get the codebook, and set the number of clusters to 800. Using this codebook, each image can be represented as a vector in the subsequent learning processes.

4.2. Evaluation Criteria

In these experiments, we used *entropy* to measure the quality of clustering results, which reveals the purity of clusters. Specifically, the entropy for a cluster $\tilde{x}$ is defined as $H(\tilde{x}) = -\sum_{c \in C} p(c|\tilde{x}) \log_2 p(c|\tilde{x})$, where c represents a category label in the evaluation corpus, and $p(c|\tilde{x})$ is defined as $p(c|\tilde{x}) = \frac{|\{x|\ell(x)=c \wedge x \in \tilde{x}\}|}{|\tilde{x}|}$, where $\ell(x)$ denotes the *true* label of x in the evaluation corpus. The *total entropy* for the whole clustering is defined as the weighted sum of the entropy with respect to all the clusters; formally, $H(\tilde{X}) = \sum_{\tilde{x} \in \tilde{X}} \frac{|\tilde{x}|}{n} H(\tilde{x})$. The quality of clustering $\tilde{X}$ is evaluated using the entropy $H(\tilde{X})$.

4.3. Empirical Analysis

We compared our algorithm STC to several state-of-the-art clustering methods as baseline methods. For each baseline method considered below, we have two different options: one is to apply the baseline method on the target data only, which we refer to as `separate`, and the other is to apply on the combined data consisting of target data and the auxiliary data, which we refer as `combined`. The first baseline method is a traditional 1D-clustering solution `CLTUO` (Zhao & Karypis, 2002) using its default parameter. The second baseline method is clustering on the target data under a new feature representation that is first constructed through feature clustering (on the target or the combined data set); this baseline is designed to evaluate the effectiveness of co-clustering based method as opposed to naively constructing new data representation for clustering. We refer to this class of baseline methods as `Feature Clustering`. The third baseline method is an information theoretic co-clustering method applied to the target (or the combined) data set (Dhillon et al., 2003), which we refer to as `Co-clustering`. This base-

Table 1. Performance in terms of entropy for each data set and evaluation method.

Data Set	CLUTO		Feature Clustering		Co-clustering		STC
	separate	combined	separate	combined	separate	combined	
eyeglass vs sheet-music	0.527	0.966	0.669	0.669	0.630	0.986	0.187

line is designed to test the effectiveness of our special co-clustering model for self-taught clustering.

Table 1 presents the clustering performance in entropy according to each data set and each evaluation method. From this table, we can see that `Feature Clustering` and `Co-clustering` perform somewhat worse than `CLUTO`. This is a little different from the results shown in the previous literatures such as (Dhillon et al., 2003). In our opinion, it is because our self-taught clustering problem focuses on a different situation from the previous ones; that is, the target data are insufficient for traditional clustering algorithms. In our experiments, there are only 70 instances in each category, which is too few to build a good feature clustering partition. Therefore, the performance of `Feature Clustering` and `Co-clustering` declines. Moreover, the performance with respect to `combined` is worse than that with respect to `separate` in general. We believe that it is because the target data and the auxiliary data are more or less independent of each other, and thus the topics in the combined data set may be biased towards the auxiliary data and thus harm the clustering performance on the target data. In general, our algorithm STC greatly outperforms the three baseline methods. We observe that the reason for the outstanding performance of STC is that the co-clustering part of STC makes feature clustering result consistent with the clustering result on both the target data and the auxiliary data. Therefore, using this feature clustering as the new data representation, the clustering performance of the target data is improved.

In our STC algorithm, it is assumed that we have already known the number of feature clusters K. However, in reality, this number should be carefully tuned. In these experiments, we tuned this parameter empirically. Figure 2 presents the entropy curves with respect to different number of feature clusters given by `CLUTO`, `Feature Clustering`, `Co-clustering` and STC respectively. The entropy in Figure 2 is the average over 6 binary image clustering tasks. Note that the curve given by `CLUTO` never changes, since `CLUTO` does not incorporate feature clustering. From this figure, we can see `Feature Clustering` and `Co-clustering` perform somewhat unstably as a function of the increasing number of feature clustering. We believe the reason is that there are only too few instances in each clustering task, which makes the traditional clustering results unreliable. Our algorithm STC incorporates a large amount of auxiliary unlabeled data, so that its variance is much smaller than that of traditional clustering algorithms. STC performs increasingly better in general, along with the increasing number of feature clustering, until the number of feature clusters reaches 32. When the number of feature clusters is greater than 32, the performance of STC becomes insensitive to the number of feature clusters. We believe a number of feature clustering which is no less than 32 will be sufficient to make STC perform well. In these experiments, we set the number of feature clustering

to 32.

We next tested the choice for the trade-off parameter λ in our algorithm STC (refer to Equation (5)). Generally, it is difficult to theoretically determine the value of the trade-off parameter λ. Instead, in this work, we tuned this parameter empirically on the data set `fern vs starfish`. Figure 3 presents the entropy curve given by STC along with changing trade-off parameter λ. From this figure, it can be seen that, when λ decreases, which implies that the weights of the auxiliary unlabeled data lower, the performance of STC declines rapidly. On the other hand, when λ is sufficiently large, i.e. $\lambda > 1$, the performance of STC is relatively insensitive to the parameter λ. This indicates the auxiliary data can help the clustering on the target data in our clustering tasks. In these experiments, we set the trade-off parameter λ to one, which is the best point in Figure 3.

Since our algorithm STC is iterative, the convergence property is also important to evaluate. Theorem 1 and Corollary 1 have already proven the convergence of STC theoretically. Here, we analyze the convergence of STC empirically. Figure 4 shows the entropy curve given by STC corresponding to different number of iterations on the data set `fern vs starfish`. From this figure, we can see that STC converges very well after 7 iterations, while the performance of STC reaches the lowest point when STC converges. This indicates that our algorithm STC converges very fast and very well. In these experiments, we set the number of iterations T to 10. We believe 10 iterations are enough for STC to converge.

5. Related Work

In this section, we review several past research works that are related to our work, including semi-supervised clustering, supervised clustering and transfer learning.

Semi-supervised clustering improves clustering performance by incorporating additional constraints provided by a few labeled data, in the form of *must-links* (two examples must in the same cluster) and *cannot-links* (two examples cannot in the same cluster) (Wagstaff et al., 2001). It finds a balance between satisfying the pairwise constraints and optimizing the original clustering criteria function. In addition to (Wagstaff et al., 2001), Basu et al. (2002) used a small amount of labeled data to generate initial seed clusters in K-means and constrained K-means algorithm by labeled data. Basu et al. (2004) generalized the previous semi-supervised clustering algorithms and proposed a probabilistic framework based on *hidden Markov random fields* that combines the constraints and clustering distortion measures in a general framework. Recent semi-supervised clustering works include (Nelson & Cohen, 2007; Davidson & Ravi, 2007).

Supervised clustering is another branch of work designed to improve clustering performance with the help of a collection of auxiliary labeled data. To address the supervised clustering problem, Finley and Joachims (2005) proposed an SVM-based supervised clustering algorithm by optimizing a variety of different clustering functions. Daumé III and Marcu (2005) developed a Bayesian framework for supervised clustering based on Dirichlet process prior.

Transfer learning emphasizes the transferring of knowledge across different domains or tasks. For example, multi-task learning (Caruana, 1997) or clustering (Teh et al., 2006) learns the common knowledge among different related tasks. Wu and Dietterich (2004) investigated methods for improving SVM classifiers with *auxiliary* training data sources. Raina et al. (2006) proposed to learn logistic regression classifiers by incorporating labeled data from irrelevant categories through constructing informative prior from the irrelevant labeled data. Raina et al. (2007) proposed a new learning strategy known as *self-taught learning*, which utilizes irrelevant unlabeled data to enhance the classification performance.

In this paper, we propose a new clustering framework called *self-taught clustering* which is an instance of *unsupervised transfer learning*. The basic idea is to use irrelevant unlabeled data to help the clustering of a small amount of target data. To our best knowledge, our self-taught clustering problem is novel in capturing a large class of machine learning problems.

6. Conclusions and Future Work

In this paper, we investigated an unsupervised transfer learning problem called *self-taught clustering*, and developed a solution by using an unlabeled auxiliary data to help improve the target clustering results. We proposed a co-clustering based self-taught clustering algorithm (STC) to solve this problem. In our algorithm, two co-clusterings are performed simultaneously on the target data and the auxiliary data to uncover the shared feature clusters. Our empirical results show that the auxiliary data can help the target data to construct a better feature clustering as data representation. Under the new data representation, the clustering performance on the target data is indeed enhanced, and our algorithm can greatly outperform several state-of-the-art clustering methods in the ex-

periments.

In this work, we tackled the self-taught clustering by finding a better feature representation using co-clustering. In the future, we will explore several other ways in finding common feature representations.

Abstract

We present an active learning scheme that exploits cluster structure in data.

1. Introduction

The *active learning* model is motivated by scenarios in which it is easy to amass vast quantities of unlabeled data (images and videos off the web, speech signals from microphone recordings, and so on) but costly to obtain their labels. It shares elements with both supervised and unsupervised learning. Like supervised learning, the goal is ultimately to learn a classifier. But like unsupervised learning, the data come unlabeled. More precisely, the labels are hidden, and each of them can be revealed only at a cost. The idea is to query the labels of just a few points that are especially informative about the decision boundary, and thereby to obtain an accurate classifier at significantly lower cost than regular supervised learning. Indeed, there are canonical examples in which active learning provably yields exponentially lower label complexity than supervised learning (Cohn et al., 1994; Freund et al., 1997; Dasgupta, 2005; Balcan et al., 2006; Balcan et al., 2007; Castro & Nowak, 2007; Hanneke, 2007; Dasgupta et al., 2007). However, these examples are highly specific, and the wider efficacy of active learning remains to be characterized.

Sampling bias. A typical active learning heuristic might start by querying a few randomly-chosen points, to get a very rough idea of the decision boundary. It might then query points that are increasingly closer to its current estimate of the boundary, with the hope of rapidly honing in. Such heuristics immediately bring to the forefront the unique difficulty of active learning, the fundamental characteristic that separates it from other learning models: *sampling bias*. As training proceeds, and points are queried based on increasingly confident assessments of their informativeness, the training set quickly diverges from the underlying data distribution. It consists of an unusual subset of points, hardly a representative subsample; why should a classifier trained on these strange points do well on the overall distribution? In section 2, we make this intuition concrete, and show how ill-managed sampling bias causes many active learning heuristics to not be consistent: even with infinitely many labels, they fail to converge to a good hypothesis.

The two faces of active learning. The recent literature offers two distinct narratives for explaining when active learning is helpful. The first has to do with *efficient search through the hypothesis space*. Each time a new label is seen, the set of plausible classifiers (those roughly consistent with the labels seen so far) shrinks somewhat. Using active learning, one can explicitly select points whose labels will shrink this set as fast as possible. Most theoretical work in active learning attempts to formalize this intuition.

The second argument for active learning has to do with *exploiting cluster structure in data*. Suppose, for instance, that the unlabeled points form five nice clusters; with luck, these clusters will be "pure" and only five labels will be necessary! Of course, this is hopelessly optimistic. In general, there may be no nice clusters, or there may be viable clusterings at many different resolutions. The clusters themselves may only be mostly-pure, or they may not be aligned with labels at all. In this paper, we present a scheme for cluster-based active learning that is statistically consistent and never has worse label complexity than supervised learning. In cases where there exists cluster structure (at whatever resolution) that is loosely aligned with class labels, the scheme detects and exploits it.

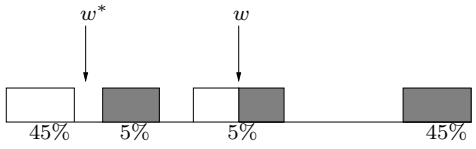
Our model. We start with a hierarchical clustering of the unlabeled points. This should be constructed so that some pruning of it is weakly informative of the

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

class labels. We describe an active learning strategy with good statistical properties, that will discover and exploit any informative pruning of the cluster tree. For instance, suppose it is possible to prune the cluster tree to m leaves (m unknown) that are fairly pure in the labels of their constituent points. Then, after querying just $O(m)$ labels, our learner will have a fairly accurate estimate of the labels of the *entire* data set. These can then be used as is, or as input to a supervised learner. Thus, our scheme can be used in conjunction with any hypothesis class, no matter how complex.

2. Active Learning and Sampling Bias

Many active learning heuristics start by choosing a few unlabeled points at random and querying their labels. They then repeatedly do something like this: fit a classifier $h \in H$ to the labels seen so far; and query the label of the unlabeled point closest to the decision boundary of h (or the one on which h is most uncertain, or something similar). Such schemes make intuitive sense, but do not correctly manage the bias introduced by adaptive sampling. Consider this 1-d example:



Here the data lie in four groups on the line, and are (say) distributed uniformly within each group. Filled blocks have a + label, while clear blocks have a − label. Most of the data lies in the two extremal groups, so an initial random sample has a good chance of coming entirely from these. Suppose the hypothesis class consists of thresholds on the line: $H = \{h_w : w \in \mathbb{R}\}$ where $h_w(x) = \mathbf{1}(x \geq w)$. Then the initial boundary will lie somewhere in the center group, and the first query point will lie in this group. So will every subsequent query point, forever. As active learning proceeds, the algorithm will gradually converge to the classifier shown as w. But this has 5% error, whereas classifier w^* has only 2.5% error. Thus the learner is not consistent: even with infinitely many labels, it returns a suboptimal classifier.

The problem is that the second group from the left gets overlooked. It is not part of the initial random sample, and later on, the learner is mistakenly confident that the entire group has a − label. And this is just in one dimension; in high dimension, the problem can be expected to be worse, since there are more places for this troublesome group to be hiding out. For a discussion of this problem in text classification, see the recent paper of Schutze et al. (2006).

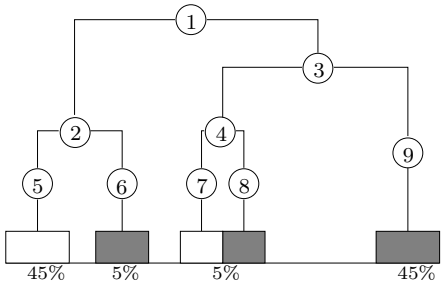


Figure 1. The top few nodes of a hierarchical clustering.

Sampling bias is the most fundamental challenge posed by active learning. This paper presents a broad framework for managing this bias that is provably sound.

3. A Clustering-Based Framework for Guiding Sampling

Our active learner starts with a hierarchical clustering of the data. Figure 1 shows how this might look for the example of the previous section.

Here only the top few nodes of the hierarchy are shown; their numbering is immaterial. At any given time, the learner works with a particular partition of the data set, given by a pruning of the tree. Initially, this is just $\{1\}$, a single cluster containing everything. Random points are drawn from this cluster and their labels are queried. Suppose one of these points, x, lies in the rightmost group. Then it is a random sample from node 1, but also from nodes 3 and 9. Based on these random samples, each node of the tree maintains statistics about the relative numbers of positive and negative instances seen. A few samples reveal that the top node 1 is very mixed while nodes 2 and 3 are substantially more pure. Once this transpires, the partition $\{1\}$ will be replaced by $\{2, 3\}$. Subsequent random samples will be chosen from either 2 or 3, according to a sampling strategy favoring the less-pure node. A few more queries down the line, the pruning will likely be refined to $\{2, 4, 9\}$. This is when the benefits of the partitioning scheme become most obvious; based on the samples seen, it can be concluded that cluster 9 is (almost) pure, and thus (almost) no more queries will be made from it until the rest of the space has been partitioned into regions that are similarly pure.

The querying can be stopped at any stage; then, each cluster in the current partition gets assigned the majority label of the points queried from it. In this way,

the *entire* data set gets labeled, and the number of erroneous labels induced is kept to a minimum. If desired, these labels can be used for a subsequent round of supervised learning, with any learning algorithm and any hypothesis class.

3.1. Preliminary Definitions

The cost of a pruning. Say there are n unlabeled points, and we have a hierarchical clustering represented by a binary tree T with n leaves. For any node v of the tree, denote by T_v both the subtree rooted at v and also the data points contained in this subtree (at its leaves). A *pruning* of the tree is a subset of nodes $\{v_1, \ldots, v_m\}$ such that the T_{v_i} are disjoint and together cover all the data. At any given stage, the active learner will work with a partition of the data set given by a pruning of T. In the analysis, we will also deal with a *partial pruning*: a subset of a pruning.

A weight of a node $v \in T$ is the proportion of the data set in T_v: $w_v =$ (number of leaves of T_v)$/n$. Likewise, the weight of a partial pruning is the fraction of the data set that it covers, $w(P) = \sum_{v \in P} w_v$. A full pruning has weight 1.

Suppose there are k possible labels, and that their proportions in T_v are $p_{v,l}$ for $l = 1, \ldots, k$. Then the error introduced by assigning all points in T_v their majority label is $\epsilon_v = 1 - \max_l p_{v,l}$. Consequently, the error induced by a particular pruning (or partial pruning) P—that is, the fraction of incorrect labels when each cluster of P is assigned its majority label—is

$$\epsilon(P) = \frac{1}{w(P)} \sum_{v \in P} w_v \epsilon_v$$

In pruning the tree, it always helps to go as far down as possible, *provided* we can accurately estimate the majority labels in those nodes.

Empirical estimates for individual nodes. Due of limited sampling, we will only have labels from some of the nodes, and even for those, we may not be able to correctly determine the majority label. If we assign label l to all the points in T_v, the induced error is $\epsilon_{v,l} = 1 - p_{v,l}$. Likewise, when each cluster v of pruning (or partial pruning) P is assigned label $L(v) \in \{1, 2, \ldots, k\}$, the error induced is

$$\epsilon(P, L) = \frac{1}{w(P)} \sum_{v \in P} w_v \epsilon_{v,L(v)}.$$

We will at any given time have only very imperfect estimates of the $p_{v,l}$'s and thus of these various error probabilities. Fix any node v, and suppose that at time t, we have queried $n_v(t)$ random points contained in that node. This gives us estimates of its class probabilities, $p_{v,l}(t)$. Correspondingly, our estimate of $\epsilon_{v,l}$ will be $\epsilon_{v,l}(t) = 1 - p_{v,l}(t)$.

Table 1. Key quantities in the algorithm and analysis. The indexing (t) specifies the empirical quantity at time t.

d_v	depth of node v in tree
d_P	maximum depth of nodes in P
w_v	weight of node v
$p_{v,l}$	fraction of label l in node v
$L^*(v)$	majority label of node v (that is, $\arg\max_l p_{v,l}$)
$n_v(t)$	number of points sampled from node v
$p_{v,l}(t)$	fraction of label l in points sampled from T_v
$\mathcal{A}(t)$	admissible (node,label) pairs
$\epsilon_{v,l}(t)$	$1 - p_{v,l}(t)$
$\widetilde{\epsilon}_{v,l}(t)$	$\epsilon_{v,l}(t)$ if $(v,l) \in \mathcal{A}(t)$; otherwise 1

The quality of these estimates can be assessed using generalization bounds. At any given time t, we can associate with each node v and label l a confidence interval $[p_{v,l}^{\mathrm{LB}}, p_{v,l}^{\mathrm{UB}}]$ within which we expect the true probability $p_{v,l}$ to lie. One possibility is to use $[\max(p_{v,l}(t) - \Delta_{v,l}(t), 0), \min(p_{v,l}(t) + \Delta_{v,l}, 1)]$, for $\Delta_{v,l}(t) \approx \frac{1}{n_v(t)} + \sqrt{\frac{p_{v,l}(t)(1-p_{v,l}(t))}{n_v(t)}}$. In Lemma 1, we will give a precise value for $\Delta_{v,l}(t)$ for which we are able to assert that (with high probability) *every* $p_{v,l}$ is *always* within this interval. However, there are other ways of constructing confidence intervals as well. The most accurate is simply to use the binomial (or hypergeometric) distribution directly.

When are we confident about the majority label of a subtree? As mentioned above, it is advantageous to descend as far as possible in the tree, provided we are confident about our estimate of the majority label. To this end, define

$$A_{v,l}(t) = \text{true} \quad \Leftrightarrow \quad (1 - p_{v,l}^{\mathrm{LB}}(t)) < \beta \cdot \min_{l' \neq l} (1 - p_{v,l'}^{\mathrm{UB}}(t)). \tag{1}$$

$A_{v,l}$ asserts that l is an *admissible* label for node v, in the weak sense that it incurs at most β times as much error as any other label. To see this, notice that label l gets at most $1 - p_{v,l}^{\mathrm{LB}}(t)$ fraction of the points wrong, whereas l' gets at least $1 - p_{v,l'}^{\mathrm{UB}}(t)$ fraction of the points wrong. In our experiments, we use $\beta = 2$, in which case

$$A_{v,l}(t) = \text{true} \quad \Leftrightarrow \quad p_{v,l}^{\mathrm{LB}}(t) > 2 p_{v,l'}^{\mathrm{UB}}(t) - 1 \ \forall l' \neq l.$$

For any given v, t, several different labels l might satisfy this criterion, for instance if $p_{v,l}^{\mathrm{LB}}(t) = p_{v,l}^{\mathrm{UB}}(t) = 1/k$ for all labels l. When there are only two possible labels, the criterion further simplifies to $p_{v,l}^{\mathrm{LB}}(t) > 1/3$.

We will maintain a set of (v, l) pairs for which the condition $A_{v,l}(t)$ is either true or was true sometime in the past:

$$\mathcal{A}(t) = \{(v, l) : A_{v,l}(t') \text{ for some } t' \leq t\}.$$

$\mathcal{A}(t)$ is the set of admissible (v, l) pairs at time t. We use it to stop ourselves from descending too far down tree T when only a few samples have been drawn. Specifically, we say pruning P and labeling L are *admissible* in tree T at time t if:

- $L(v)$ is defined for P and ancestors of P in T.
- $(v, L(v)) \in \mathcal{A}(t)$ for any node v that is a strict ancestor of P in T.
- For any node $v \in P$, there are two options:
  - either $(v, L(v)) \in \mathcal{A}(t)$;
  - or there is no l for which $(v, l) \in \mathcal{A}(t)$. In this case, if v has parent u, then $(u, L(v)) \in \mathcal{A}(t)$.

This final condition implies that if a node in P is not admissible (with any label), then it is forced to take on an admissible label of its parent.

Empirical estimate of the error of a pruning. For any node v, the empirical estimate of the error induced when all of subtree T_v is labeled l is $\epsilon_{v,l}(t) = 1 - p_{v,l}(t)$. This extends to a pruning (or partial pruning) P and a labeling L:

$$\epsilon(P, L, t) = \frac{1}{w(P)} \sum_{v \in P} w_v \epsilon_{v,L(v)}(t).$$

This can be a bad estimate when some of the nodes in P have been inadequately sampled. Thus we use a more conservative adjusted estimate:

$$\widetilde{\epsilon}_{v,l}(t) = \begin{cases} 1 - p_{v,l}(t) & \text{if } (v, l) \in \mathcal{A}(t) \\ 1 & \text{if } (v, l) \notin \mathcal{A}(t) \end{cases}$$

with $\widetilde{\epsilon}(P, L, t) = (1/w(P)) \sum_{v \in P} w_v \widetilde{\epsilon}_{v,L(v)}(t)$. The various definitions are summarized in Table 1.

Picking a good pruning. It will be convenient to talk about prunings not just of the entire tree T but also of subtrees T_v. To this end, define the *score of v at time t*—denoted $s(v, t)$—to be the adjusted empirical error of the best admissible pruning and labeling (P, L) of T_v. More precisely, $s(v, t)$ is

$$\min\{\widetilde{\epsilon}(P, L, t) : (P, L) \text{ admissible in } T_v \text{ at time } t\}.$$

Written recursively, $s(v, t)$ is the minimum of

- $\widetilde{\epsilon}_{v,l}(t)$, for all l;
- $\frac{w_a}{w_v} s(a, t) + \frac{w_b}{w_v} s(b, t)$, whenever v has children a, b and $(v, l) \in \mathcal{A}(t)$ for some l.

Algorithm 1 Cluster-adaptive active learning

Input: Hierarchical clustering of n unlabeled points; batch size B
$P \leftarrow \{\text{root}\}$ (current pruning of tree)
$L(\text{root}) \leftarrow 1$ (arbitrary starting label for root)
for time $t = 1, 2, \ldots$ until the budget runs out **do**
  for $i = 1$ to B **do**
    $v \leftarrow \text{select}(P)$
    Pick a random point z from subtree T_v
    Query z's label l
    Update empirical counts and probabilities $(n_u(t), p_{u,l}(t))$ for all nodes u on path from z to v
  end for
  In a bottom-up pass of T, update $\mathcal{A}$ and compute scores $s(u, t)$ for all nodes $u \in T$ (see text)
  for each (selected) $v \in P$ **do**
    Let (P', L') be the pruning and labeling of T_v achieving scores $s(v, t)$
    $P \leftarrow (P \setminus \{v\}) \cup P'$
    $L(v) \leftarrow L'(u)$ for all $u \in P'$
  end for
end for
for each cluster $v \in P$ **do**
  Assign each point in T_v the label $L(v)$
end for

Starting from the empirical estimates $p_{v,l}(t), p^{\text{LB}}_{v,l}, p^{\text{UB}}_{v,l}$, it is possible to update the set $\mathcal{A}(t)$ and to compute all the $\widetilde{\epsilon}_{v,l}(t)$ and $s(v, t)$ values in a single linear-time, bottom-up pass through the tree.

3.2. The Algorithm

Algorithm 1 contains the active learning strategy. It remains to specify the the manner in which the hierarchical clustering is built and the procedure **select**. *Regardless of how these decisions are made*, the algorithm is statistically sound in that the confidence intervals $p_{v,l} \pm \Delta_{v,l}(t)$ are valid, and these in turn validate the guarantees for admissible prunings/labelings. This leaves a lot of flexibility to explore different clustering and sampling strategies.

The select procedure. This controls the selective sampling. Some options:

(1) Choose $v \in P$ with probability $\propto w_v$. This is similar to random sampling.

(2) Choose v with probability $\propto w_v(1 - p^{\text{UB}}_{v,L(v)}(t))$. This is an active learning rule that reduces sampling

in regions of the space that have already been observed to be fairly pure in their labels.

(3) For each subtree $(T_z, z \in P)$, find the observed majority label, and assign this label to all points in the subtree; fit a classifier h to this data; and choose $v \in P$ with probability $\propto \min\{|\{x \in T_v : h(x) = +1\}|, |\{x \in T_v : h(x) = -1\}|\}$. This biases sampling towards regions close to the current decision boundary.

Building a hierarchical clustering. The scheme works best when there is a pruning P of the tree such that $|P|$ is small and a significant fraction of its constituent clusters are almost-pure. One option is to run a standard hierarchical clustering algorithm, like average linkage, perhaps with a domain-specific distance function (or one generated from a neighborhood graph). Another option is to use a bit of labeled data to guide the construction of the hierarchy.

3.3. Naive Sampling

First consider the naive sampling strategy in which a node $v \in P$ is selected in proportion to its weight w_v. We'll show that if there is an almost-pure pruning with m nodes, then only $O(m)$ labels are needed before the entire data is labeled almost-perfectly. Proofs are deferred to the full version of the paper.

Theorem 1 *Pick any $\delta, \eta > 0$ and any pruning Q with $\epsilon(Q) \leq \eta$. With probability at least $1 - \delta$, the learner induces a labeling (of the data set) with error $\leq (\beta + 1)\epsilon(Q) + \eta$ when the number of labels seen is*

$$Bt = O\left(\frac{\beta+1}{\beta-1} \cdot \frac{|Q|}{\eta} \log \frac{2^{d_Q} kB|Q|}{\eta\delta}\right).$$

Recall that β is used in the definition of an admissible label (equation (1)); we use $\beta = 2$ in our experiments.

The number of prunings with m nodes is about 4^m; and these correspond to roughly $(4k)^m$ possible classifications (each of the m clusters can take on one of k labels). Thus this result is what one would expect if one of these classifiers were chosen by supervised learning. In our scheme, we do not evaluate such classifiers directly, but instead evaluate the subregions of which they are composed. We start our analysis with confidence intervals for $p_{v,l}$ and n_v.

Lemma 1 *Pick any $\delta > 0$. With probability at least $1 - \delta$, the following holds for all nodes $v \in T$, all labels l, and all times t.*

(a) $|p_{v,l} - p_{v,l}(t)| \leq \Delta_{v,l} \leq \Delta_{v,l}(t)$, where

$$\Delta_{v,l} = \frac{2}{3n_v(t)} \log \frac{1}{\delta'} + \sqrt{\frac{2p_{v,l}(1-p_{v,l})}{n_v(t)} \log \frac{1}{\delta'}}.$$

$$\Delta_{v,l}(t) = \frac{5}{n_v(t)} \log \frac{1}{\delta'} + \sqrt{\frac{9p_{v,l}(t)(1-p_{v,l}(t))}{2n_v(t)} \log \frac{1}{\delta'}}.$$

for $\delta' = \delta/(kBt^2 d_v^2)$.

(b) $n_v(t) \geq Btw_v/2$ if $Btw_v \geq 8 \log(t^2 2^{2d_v}/\delta)$.

Our empirical assessment of the quality of a pruning P is a blend of sampling estimates $p_{v,l}(t)$ and perfectly known values w_v. Next, we examine the rate of convergence of $\epsilon(P, L, t)$ to the true value $\epsilon(P, L)$.

Lemma 2 *Assume the bounds of Lemma 1 hold. There is a constant c such that for all prunings (or partial prunings) $P \subset T$, all labelings L, and all t,*

$$w(P) \cdot |\epsilon(P, L, t) - \epsilon(P, L)| \leq c \cdot \left(\frac{|P|}{Bt} \log \frac{kBt^2 2^{d_P}}{\delta} + \sqrt{w(P)\epsilon(P, L)\frac{|P|}{Bt} \log \frac{kBt^2 2^{d_P}}{\delta}}\right).$$

Lemma 2 gives useful bounds on $\epsilon(P, L, t)$. Our algorithm uses the more conservative estimate $\widetilde{\epsilon}(P, L, t)$, which is identical to $\epsilon(P, L, t)$ except that it automatically assigns an error of 1 to any $(v, L(v)) \notin \mathcal{A}(t)$, that is to say, any (node, label) pair for which insufficiently many samples have been seen. We need to argue that for nodes v of reasonable weight, and their majority labels $L^*(v)$, we will have $(v, L^*(v)) \in \mathcal{A}(t)$.

Lemma 3 *There is a constant c' such that $(v, l) \in \mathcal{A}(t)$ for any node v with majority label l and*

$$w_v \geq \max\left(\frac{8}{Bt} \log \frac{t^2 2^{2d_v}}{\delta}, \frac{\beta+1}{\beta-1} \cdot \frac{c'}{Bt} \log \frac{kBt^2 d_v^2}{\delta}\right).$$

The purpose of the set $\mathcal{A}(t)$ is to stop the algorithm from descending too far in the tree. We now quantify this. Suppose there is a good pruning that contains a node q whose majority label is $L^*(q)$. However, our algorithm descends far below q, to some pruning P (and associated labeling L) of T_q. By the definition of admissible pruning, this can only happen if $(q, L(q))$ lies in $\mathcal{A}(t)$. Under such circumstances, it can be proved that (P, L) is not too much worse than $(q, L^*(q))$.

Lemma 4 *For any node q, let (P, L) be the admissible pruning and labeling of T_q found by our algorithm at time t. If $(q, L(q)) \in \mathcal{A}(t)$, then $\epsilon(P, L) \leq (\beta + 1)\epsilon_q$.*

Proof sketch of Theorem 1. Let Q, t be as in the theorem statement, and let L^* denote the optimal labeling (by majority label) of each node. Define V to be the set of all nodes v with weight exceeding the bound in Lemma 3. As a result, $(v, L^*(v)) \in \mathcal{A}(t)$ for all $v \in V$.

Suppose that at time t, the learning scheme is using some pruning P with labeling L. We will decompose P and Q into three groups of nodes each: (i) $P_a \subset P$ are strict ancestors of $Q_a \subset Q$; (ii) $P_d \subset P$ are strict descendants of $Q_d \subset Q$; and (iii) the remaining nodes are common to P and Q.

Since nodes of P_a were never expanded to Q_a, we can show $w(P_a)\epsilon(P_a, L) \leq w(P_a)\epsilon(Q_a, L^*) + 2\eta/3 + w(Q_a \setminus V)$. Meanwhile, from Lemma 4 we have $w(P_d)\epsilon(P_d, L) \leq (\beta+1)w(Q_d)\epsilon(Q_d, L^*) + w(Q_d \setminus V)$. Putting it all together, we get $\epsilon(P, L) - \epsilon(Q, L^*) \leq \eta + (\beta+1)\epsilon(Q)$, under the conditions on t. ∎

3.4. Active Sampling

Suppose our current pruning and labeling are (P, L). So far we have only discussed the naive strategy of choosing query nodes $u \in P$ with probability proportional to w_u. For active learning, a more intelligent and adaptive strategy is needed. A natural choice is to pick u with probability proportional to $w_u \epsilon^{\mathrm{UB}}_{u,L(u)}(t)$, where $\epsilon^{\mathrm{UB}}_{u,l} = 1 - p^{\mathrm{LB}}_{u,l}(t)$ is an upper bound on the error associated with node u. This takes advantage of large, pure clusters: as soon as their purity becomes evident, querying is directed elsewhere.

Fallback analysis. Can the adaptive strategy perform worse than naive random sampling? There is one problematic case. Suppose there are only two labels, and that the current pruning P consists of two nodes (clusters), each with 50% probability mass; however, cluster A has impurity (minority label probability) 5% while B has impurity 50%. Under our adaptive strategy, we will query 10 times more from B than from A. But suppose B cannot be improved: any attempts to further refine it lead to subclusters which are also 50% impure. Meanwhile, it might be possible to get the error in A down to zero by splitting it further. In this case, random sampling, which weighs A equally to B, does better than the active learning scheme.

Such cases can only occur if the best pruning has high impurity, and thus active learning still yields a pruning that is not much worse than optimal. To see this, pick any good pruning Q (with optimal labeling L^*), and let's see how adaptive sampling fares with respect to Q. Suppose our scheme is currently working with a pruning P and labeling L. Divide P into two regions: $P_0 = \{p \in P : p \in T_v \text{ for some } v \in Q\}$ and $P_1 = P \setminus P_0$. The danger is that we will sample too much from P_0, where no further improvement is needed (relative to Q), and not enough from P_1. But it can be shown that *either* the active strategy samples from P_1 at least half as often as the random strategy would, *or* the current pruning is already pretty good, in that

$$\epsilon(P, L) \leq 2\epsilon(Q, L^*) + \text{terms involving sampling error.}$$

Benefits of active learning. Active sampling is sure to help when the hierarchical clustering has some large, fairly-pure clusters near the top of the tree. These will be quickly identified, and very few queries will subsequently be made in those regions. Consider an idealized example in which there are only two possible labels and each node in the tree is either pure or $(1/3, 2/3)$-impure. Specifically: (i) each node has two children, with equal probability mass; and (ii) each impure node has a pure child and an impure child. In this case, active sampling can be seen to yield a convergence rate $1/n^2$ in contrast to the $1/n$ rate of random sampling.

The example is set up so that the selected pruning P (with labeling L) always consists of pure nodes $\{a_1, a_2, \ldots, a_d\}$ (at depths $1, 2, \ldots, d$) and a single impure node b (at depth d). These nodes have weights $w_{a_i} = 2^{-i}$, $i = 1, \ldots, d$, and $w_b = 2^{-d}$; the impure node causes the error of the best pruning to be $\varepsilon = 2^{-d}/3$. The goal, then, is to sample enough from node b to cut this error in half (say, because the target error is $\varepsilon/2$). This can be achieved with a constant number of queries from node b, since this is enough to render the majority label of its pure child admissible and thus offer a superior pruning.

If we were to completely ignore the pure nodes, then the next several queries could all be made in node b; we thus halve the error with only a constant number of queries. Continuing this way leads to an exponential improvement in convergence rate. Such a policy of neglect is fine in our present example, but this would be imprudent in general: after all, the nodes we ignore may actually turn out impure, and only further sampling would reveal them as such. We instead select a node u with probability proportional to $w_u \epsilon^{\mathrm{UB}}_{u,L(u)}(t)$, and thus still select a pure node a_i with probability roughly proportional to $w_{a_i}/n_{a_i}(t)$. This allows for some cautionary exploration while still affording an improved convergence rate.

The chance of selecting the impure node b is

$$\frac{w_b \epsilon^{\mathrm{UB}}_{b,L(b)}}{w_b \epsilon^{\mathrm{UB}}_{b,L(b)} + \sum_{i=1}^{d} w_{a_i} \epsilon^{\mathrm{UB}}_{a_i,L(a_i)}} \geq \Omega\left(\frac{\varepsilon}{\varepsilon + \frac{d}{\sum_{i=1}^{d} n_{a_i}(t)}}\right).$$

The inequality follows (with high probability) because the error bound for b is always at least the true error ε (up to constants), while another argument shows that

$$\sum_{i=1}^{d} w_{a_i} \epsilon^{\mathrm{UB}}_{a_i, L(a_i)} = O\left(\sum_{i=1}^{d} \frac{w_{a_i}}{n_{a_i}(t)}\right) = O\left(\frac{d}{\sum_{i=1}^{d} n_{a_i}(t)}\right).$$

We need to argue that the pure nodes do not get queried too much. Well, if they have been queried at least $\sqrt{d/\varepsilon} = O(\sqrt{(1/\varepsilon)\log 1/\varepsilon})$ times, the chance of selecting b is $\Omega(\sqrt{\varepsilon/d})$; another $O(\sqrt{d/\varepsilon})$ queries with active sampling suffice to land a constant number in node b—just enough to cut the error in half. Overall, the number of queries needed is then $O(\sqrt{(1/\varepsilon)\log(1/\varepsilon)})$, considerably less than the $O(1/\varepsilon)$ required of random sampling.

4. Experiments

How many label queries can we save by exploiting cluster structure with active learning? Our analysis suggests that the savings is tied to *how well the cluster structure aligns with the actual labels*. To evaluate how accommodating real world data is in this sense, we studied the performance of our active learner on several natural classification tasks.

4.1. Classification Tasks

When used for classification, our active learning framework decomposes into three parts: (1) unsupervised hierarchical clustering of the unlabeled data, (2) cluster-adaptive sampling (Algorithm 1, with the second variant of **select**), and (3) supervised learning on the resulting fully labeled data. We used standard statistical procedures, Ward's average linkage clustering and logistic regression, for the unsupervised and supervised components, respectively, in order to assess just the role of the cluster-adaptive sampling method.

We compared the performance of our active learner to two baseline active learning methods, random sampling and margin-based sampling, that only train a classifier on the subset of queried labeled data. Random sampling chooses points to label at random, and margin-based sampling chooses to label the points closest to the decision boundary of the current classifier (as described in Section 2). Again, we used logistic regression with both of these methods.

A few details: We ran each active learning method 10 times for each classification task, allowing the budget of labels to grow in small increments. For each budget size, we evaluated the resulting classifier on a test set, computed its misclassification error, and averaged this error over the repeated trials. Finally, we used

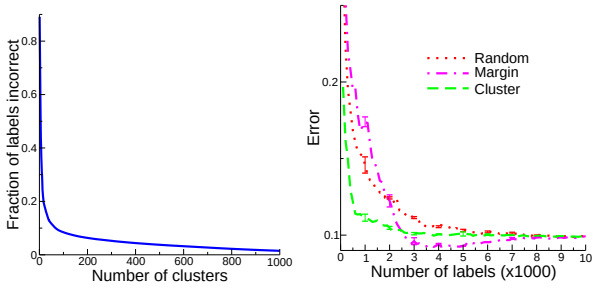

Figure 2. Results on OCR digits. Left: Errors of the best prunings in the OCR digits tree. Right: Test error curves on classification task.

ℓ_2-regularization with logistic regression, choosing the trade-off parameter with 10-fold cross validation.

OCR digit images. We first considered multi-class classification of the MNIST handwritten digit images.[1] We used 10000 training images and 2000 test images.

The tree produced by Ward's hierarchical clustering method was especially accommodating for cluster-adaptive sampling. Figure 2 (left) depicts this quantitatively; it shows the error of the best k-pruning of the tree for several values of k. For example, the tree had a pruning of 50 nodes with about 12% error. Our active learner found such a pruning using just 400 labels.

Figure 2 (right) plots the test errors of the three active learning methods on the multi-class classification task. Margin-based sampling and cluster-adaptive sampling both outperformed random sampling, with margin-based sampling taking over a little after 2000 label queries. The initial advantage of cluster-adaptive sampling reflects its ability to discover and subsequently ignore relatively pure clusters at the onset of sampling. Later on, it is left sampling from clusters of easily confused digits (e.g. 3's, 5's, and 8's).

The test error of the margin-based method appeared to actually dip below the test error of classifier trained using all of the training data (with the correct labels). This appears to be a case of fortunate sampling bias. In contrast, cluster-adaptive sampling avoids this issue by concentrating on converging to the same result as if it had all of the correct training labels.

Newsgroup text. We also considered four pairwise binary classification tasks with the 20 Newsgroups data set. Following Schohn and Cohn (2000), we chose four pairs of newsgroups that varied in difficulty. We used a version of the data set that removes duplicates and some newsgroup-identifying headers, but other-

wise represents each document as a simple word count vector.[2] Each newsgroup had about 1000 documents, and the data for each pair were partitioned into training and test sets at a 2:1 ratio. We length-normalized the count vectors before training the logistic regression models in order to speed up the training and improve classification performance.

The initial word count representation of the newsgroup documents yielded poor quality clusterings, so we tried various techniques for preprocessing text data before clustering with Ward's method: (1) normalize each document vector to unit length; (2) apply TF/IDF and length normalization to each document vector; and (3) infer a posterior topic mixture for each document using a Latent Dirichlet Allocation model trained on the same data (Blei et al., 2003). For the last technique, we used Kullback-Leibler divergence as the notion of distance between the topic mixture representations. Figure 3 (top) plots the errors of the best prunings. Indeed, the various changes-of-representation and specialized notions of distance help build clusterings of greater utility for cluster-adaptive active learning.

In all four pairwise tasks, both margin-based sampling and cluster-adaptive sampling outperformed random sampling. Figure 3 (bottom) shows the test errors on two of these newsgroup pairs. We observed the same effects regarding cluster-adaptive sampling and margin-based sampling as in the OCR digits data.

4.2. Rare Category Detection

To demonstrate its versatility, we applied our cluster-adaptive sampling method to a rare category detection task. We used the Statlog Shuttle data, a set of 43500 examples from seven different classes; the smallest class comprises a mere 0.014% of the whole. To discover at least one example from each class, random sampling needed over 8000 queries (averaged over several trials). In contrast, cluster-adaptive sampling needed just 880 queries; it sensibly avoided sampling much from clusters confidently identified as pure, and instead focused on clusters with more potential.

Abstract

After a classifier is trained using a machine learning algorithm and put to use in a real world system, it often faces noise which did not appear in the training data. Particularly, some subset of features may be missing or may become corrupted. We present two novel machine learning techniques that are robust to this type of classification-time noise. First, we solve an approximation to the learning problem using linear programming. We analyze the tightness of our approximation and prove statistical risk bounds for this approach. Second, we define the online-learning variant of our problem, address this variant using a modified Perceptron, and obtain a statistical learning algorithm using an online-to-batch technique. We conclude with a set of experiments that demonstrate the effectiveness of our algorithms.

1. Introduction

Supervised machine learning techniques often play a central role in solving complex real-world classification problems. First, we collect a training set of labeled examples and present this set to a machine learning algorithm. Then, the learning algorithm constructs a classifier, which can be put to use as a component in a working system. The process of collecting the training set and constructing the classifier is called the *training phase*, whereas everything that occurs after the hypothesis has been determined is called the *classification phase*. In many cases, the training phase can be performed under sterile and controlled conditions, and care can be taken to collect a high quality training set. In contrast, the classification phase often takes place in the noisy and uncertain conditions of the real world, and some of the features that were available during the training phase may be missing or corrupted. In this paper, we explore the possibility of anticipating and preparing for this type of classification-time noise.

The problem of corrupted and missing features occurs in a variety of different classification settings. For example, say that our goal is to learn an automatic medical diagnosis system. Each instance represents a patient, each feature contains the result of a medical test performed on that patient, and the purpose of the system is to detect a certain disease. When constructing the training set, we go to the trouble of carefully performing every possible test on each patient. However, when the learned classifier is eventually deployed as part of a diagnosis system, and applied to new patients, it is highly unlikely that all of the test results will be available. Technical difficulties may prevent certain tests from being performed. Different patients may have different insurance policies, each covering a different set of tests. A patient's blood sample may become contaminated, replacing the features that correspond to blood tests with random noise, while having no effect on other features. We would still like our diagnosis system to make accurate predictions. Alternatively, our goal may be to train a fingerprint recognition system that controls the lock on a door. After a few days of flawless operation, a user with greasy fingers comes along and leaves an oily smudge on the fingerprint scanner panel. From then on, all of the features measured from the area under the smudge are either distorted or cannot be extracted altogether. Ideally, the fingerprint recognition system should continue operating.

We take a worst-case approach to our problem, and assume that the set of affected features is chosen by an adversary individually per instance. More specifically, we assume that each feature is assigned an a-priori importance value and the adversary may remove or corrupt any feature subset whose total value is upper-bounded by a predefined parameter. In many natural settings, missing and damaged features are not actually chosen adversarially, but we find it beneficial to have our algorithm as robust as possible.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

We present two different learning algorithms for our problem, each with pros and cons. The first approach formulates the learning problem as a linear program (LP), in a way that closely resembles the quadratic programming formulation of the Support Vector Machine (Vapnik, 1998). However, the number of constraints in this LP grows exponentially with the number of features. Using tricks from convex analysis, we derive a related polynomial-size LP, and give conditions under which it is an exact reformulation of the original exponential-size LP. When these conditions do not hold, the polynomial-size LP still approximates the exponential-size LP, and we prove an upper bound on the approximation difference. Despite the fact that the distribution of training examples is different from the distribution of examples observed during the classification phase, we prove a statistical generalization bound for this approach.

Letting m denote the size of our training set and n the number of features, our polynomial LP formulation uses $O(mn)$ variables and $O(mn)$ sparse constraints. Depending on the dataset, this can still be rather large for off-the-shelf LP solvers. We see this as a shortcoming of our first approach, which brings us to our second algorithmic approach. We define an online learning problem, which is closely related to the original statistical learning problem. We devise a modified version of the Perceptron algorithm (Rosenblatt, 1958) for this online problem, and convert this Perceptron into a statistical learning algorithm using an online-to-batch conversion technique (Cesa-Bianchi et al., 2004). This approach benefits from the computational efficiency of the online Perceptron, and from the generalization properties and theoretical guarantees provided by the online-to-batch technique. Experimentally, we observe that the efficiency of our second approach seems to come at the price of accuracy.

Choosing an adequate regularization scheme is one of the keys to solving this problem successfully. Many existing machine learning algorithms, such as the Support Vector Machine, use L_2 regularization to promote statistical generalization. When L_2 regularization is used, the learning algorithm may put a large weight on one feature and compensate by putting a small weight on another feature. This promotes classifiers that focus their weight on the features that contribute the most. For example, in the degenerate case where one of the features actually equals the label, an L_2 regularized learning algorithm is likely to put most of its weight on that one feature. Some algorithms use L_1 regularization to further promote sparse solutions. In the context of our work, sparsity actually makes a classifier more susceptible to adversarial feature-corrupting noise. Here we prefer dense classifiers, which hedge their bets as much as possible. Both of the algorithms presented in this paper achieve this density by using a L_∞ regularization scheme. It is interesting to note that the choice of the L_∞ norm emerges as a natural one in the theoretical analysis of our first, LP-based learning approach.

1.1. Related Work

Previous papers on "noise-robust learning" mainly deal with the problem of learning with a noisy training set, a research topic which is entirely orthogonal to ours. The learning algorithms presented in (Dietterich & Bakiri, 1995) and (Gamble et al., 2007) try to be robust to general additive noise that appears at classification time, but not necessarily to feature deletion or corruption. (**?**) presents adversarial learning as a one-shot two-player game between the classifier and an adversary, and designs a robust learning algorithm from a Bayesian-learning perspective. Our approach shares the motivation of (**?**) but is otherwise significantly different. In the related field of online learning, where the training and classification phases are interlaced and cannot be distinguished, (Littlestone, 1991) proves that the Winnow algorithm can tolerate various types of noise, both adversarial and random.

Our work is most closely related to the work in (Globerson & Roweis, 2006), and its more recent enhancement in (Teo et al., 2008). Our motivation is the same as theirs, and the approaches share some similarities. Our experiments, presented in Sec. 4, suggest that our algorithms achieve considerably better performance, but we would also like to emphasize more fundamental differences between the two approaches: We allow features to have different a-priori importance levels, and we take this information into account in our algorithm and analysis. Our approach uses L_∞ regularization to promote a dense solution, where (Globerson & Roweis, 2006) uses L_2 regularization. Our second approach, which uses online-to-batch conversion techniques, is entirely novel. Finally, we prove statistical generalization bounds for our algorithms despite the change in distribution at classification time.

2. A Linear Programming Formulation

In this section, and throughout the paper, we use lowercase bold-face letters to denote vectors, and their plain-face counterparts to denote each vector's components. We also use the notation $[n]$ as shorthand for $\{1, \ldots, n\}$.

2.1. Feature Deleting Noise

We first examine the case where features are missing at classification time. Let $\mathcal{X} \subseteq \mathbb{R}^n$ be an instance space and let $\mathcal{D}$ be a probability distribution on the product space $\mathcal{X} \times \{\pm 1\}$. We receive a training set $S = \{(\mathbf{x}_i, y_i)\}_{i=1}^m$ sampled i.i.d. from $\mathcal{D}$, which we use to learn our classifier. We assign each feature $j \in [n]$ a value $v_j \geq 0$. Informally, we think of v_j as the a-priori *informativeness* of fea-

ture j, or as the importance of feature j to the classification task. It can also represent the cost of obtaining the feature (such as the price of a medical test). Next, we define the value of a subset J of features as the sum of values of the features in that subset, and we denote $V(J) = \sum_{j\in J} v_j$. For instance, we frequently use $V([n])$ when referring to $\sum_{j=1}^{n} v_j$ and $V([n] \setminus J)$ when referring to $\sum_{j\notin J} v_j$. Next, we fix a noise-tolerance parameter N in $[0, V([n])]$ and define $P = V([n]) - N$. During the classification phase, instances are generated in the following way: First, a pair $(\mathbf{x}, y)$ is sampled from $\mathcal{D}$. Then, an adversary selects a subset of features $J \subset [n]$ such that $V([n] \setminus J) \leq N$, and replaces x_j with 0 for all $j \notin J$. The adversary selects J for each instance individually, and with full knowledge of the inner workings of our classifier. The noise-tolerance parameter N essentially acts as an upper bound on the amount of damage the adversary is allowed to inflict. We would like to use the training set S (which does not have missing features) to learn a binary classifier that is robust to this specific type of classification-time noise.

We focus on learning linear margin-based classifiers. A linear classifier is defined by a weight vector $\mathbf{w} \in \mathbb{R}^n$ and a bias term $b \in \mathbb{R}$. Given an instance $\mathbf{x}$, which is sampled from $\mathcal{D}$, and a set of coordinates J left intact by the adversary, the linear classifier outputs $b + \sum_{j\in J} w_j x_j$. The sign of $b + \sum_{j\in J} w_j x_j$ constitutes the actual binary prediction, while $|b + \sum_{j\in J} w_j x_j|$ is understood as the degree of confidence in that prediction. A classification mistake occurs if and only if $y(b + \sum_{j\in J} w_j x_j) \leq 0$, so we define the *risk* of the linear classifier $(\mathbf{w}, b)$ as

$$\mathcal{R}(\mathbf{w}, b) = \Pr_{(\mathbf{x},y)\sim\mathcal{D}} \Big(\begin{array}{l} \exists J \text{ with } V([n] \setminus J) < N \\ \text{s.t. } y\big(b + \sum_{j\in J} w_j x_j\big) \leq 0 \end{array} \Big) \ . \quad (1)$$

Since $\mathcal{D}$ is unknown, we cannot explicitly minimize Eq. (1). Thus, we turn to the empirical estimate of Eq. (1), the *empirical risk*, defined as

$$\frac{1}{m}\sum_{i=1}^{m} \Big[\!\Big[\min_{J\,:\,V([n]\setminus J)\leq N} y_i\big(b + \textstyle\sum_{j\in J} w_j x_{i,j}\big) \leq 0 \Big]\!\Big], \quad (2)$$

where $[\![\pi]\!]$ denotes the indicator function of the predicate π. Minimizing the empirical risk directly constitutes a difficult combinatorial optimization problem. Instead, we formulate a linear program that closely resembles the formulation of the Support Vector Machine (Vapnik, 1998). We choose a margin parameter $\gamma > 0$ and a regularization parameter $C > 0$, and solve the problem

$$\begin{aligned} \min_{\mathbf{w},b,\boldsymbol{\xi}} \ & \tfrac{1}{m\gamma}\textstyle\sum_{i=1}^{m} \xi_i \quad (3) \\ \text{s.t. } & \forall\, i \in [m] \quad \forall J \,:\, V([n] \setminus J) \leq N \\ & \qquad y_i\big(b + \textstyle\sum_{j\in J} w_j x_{i,j}\big) \geq \tfrac{\gamma V(J)}{P} - \xi_i \ , \\ & \forall\, i \in [m] \ \ \xi_i \geq 0 \ , \quad \|\mathbf{w}\|_\infty \leq C \ . \end{aligned}$$

The objective function of Eq. (3) is called the *empirical hinge-loss* obtained on the sample S. Since ξ_i is constrained to be non-negative, each training example contributes a non-negative amount to the total loss. Moreover, the objective function of Eq. (3) upper bounds the empirical risk of $(\mathbf{w}, b)$. More specifically, for any feasible point $(\mathbf{w}, b, \boldsymbol{\xi})$ of Eq. (3), ξ_i upper bounds γ times the indicator function of the event

$$\min_{J\,:\,V([n]\setminus J)\leq N} y_i\big(b + \textstyle\sum_{j\in J} w_j x_{i,j}\big) \leq 0 \ .$$

To see this, note that for a given example $(\mathbf{x}_i, y_i)$, if there exists a feature subset J such that $V([n] \setminus J) \leq N$ and $y_i(b + \sum_{j\in J} w_j x_j) \leq 0$ then the first constraint in Eq. (3) enforces $\xi_i \geq \gamma V(J)/P$. The assumption $V([n] \setminus J) \leq N$ now implies that $V(J) \geq P$, and therefore $\xi_i \geq \gamma$. If such a set J does not exist, then the second constraint in Eq. (3) enforces $\xi_i \geq 0$.

The optimization problem above actually does more than minimize an upper bound on the empirical risk. It also requires the margin attained by the feature subset J to grow with proportion to $V(J)$. While a true adversary would always inflict the maximal possible damage, our optimization problem also prepares for the case where less damage is inflicted, requiring the confidence of our classifier to increase as less noise is introduced. We also restrict $\mathbf{w}$ to a hyper-box of radius C, which controls the complexity of the learned classifier and promotes dense solutions. Moreover, this constraint is easy to compute and makes our algorithms more efficient. Although Eq. (3) is a linear program, it is immediately noticeable that the size of its constraint set may grow exponentially with the number of features n. For example, if $v_j = 1$ for all $j \in [n]$ and if N is a positive integer, then the linear program contains over $\binom{n}{N}$ constrains per example. We deal with this problem below.

2.2. A Polynomial Approximation

Taking inspiration from (Carr & Lancia, 2000), we find an efficient approximate formulation of Eq. (3), which turns out to be an exact reformulation of Eq. (3) when $v_j \in \{0, 1\}$ for all $j \in [n]$. Specifically, we replace Eq. (3) with

$$\begin{aligned} \min \ & \tfrac{1}{m\gamma}\textstyle\sum_{i=1}^{m} \xi_i \quad (4) \\ \text{s.t. } & \forall\, i \in [m] \ \ P\lambda_i - \textstyle\sum_{j=1}^{n} \alpha_{i,j} + y_i b \geq -\xi_i \\ \forall\, i \in [m] \, \forall\, j \in [n] \ & \ y_i w_j x_{i,j} - \tfrac{\gamma v_j}{P} \geq \lambda_i v_j - \alpha_{i,j} \ , \\ \forall\, i \in [m] \, \forall\, j \in [n] \ & \ \alpha_{i,j} \geq 0 \ , \\ \forall\, i \in [m] \ & \ \lambda_i \geq 0 \text{ and } \xi_i \geq 0 \ , \\ & \ \|\mathbf{w}\|_\infty \leq C \ , \end{aligned}$$

where the minimization is over $\mathbf{w} \in \mathbb{R}^n$, $b \in \mathbb{R}$, $\boldsymbol{\xi} \in \mathbb{R}^m$, $\boldsymbol{\lambda} \in \mathbb{R}^m$, and $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_m$, each in $\mathbb{R}^n$. The number of

variables and the number of constraints in this problem are both $O(mn)$. The following theorem explicitly relates the optimization problem in Eq. (4) with the one in Eq. (3).

Theorem 1. *If $(\mathbf{w}^\star, b^\star, \boldsymbol{\xi}^\star, \boldsymbol{\lambda}^\star, \boldsymbol{\alpha}_1^\star, \ldots, \boldsymbol{\alpha}_m^\star)$ is an optimal solution to Eq. (4), then $(\mathbf{w}^\star, b^\star, \boldsymbol{\xi}^\star)$ is a feasible point of Eq. (3), and therefore the value of Eq. (4) upper-bounds the value of Eq. (3). Moreover, if $v_j \in \{0,1\}$ for all $j \in [n]$, then $(\mathbf{w}^\star, b^\star, \boldsymbol{\xi}^\star)$ is an optimal solution to Eq. (3). Finally, if it does not hold that $v_j \in \{0,1\}$ for all $j \in [n]$, and assuming $\|\mathbf{x}_i\| \leq 1$ for all i, then the difference between the value of Eq. (4) and the value of Eq. (3) is at most C/γ.*

As a first step towards proving Thm. 1, we momentarily forget about the optimization problem at hand and focus on another question: given a specific triplet $(\mathbf{w}, b, \boldsymbol{\xi})$, is it a feasible point of Eq. (3) or not? More concretely, for each training example $(\mathbf{x}_i, y_i)$, we would like to determine if for all J with $V([n] \setminus J) \leq N$ it holds that

$$y_i\big(b + \textstyle\sum_{j\in J} w_j x_{i,j}\big) \;\geq\; \frac{\gamma V(J)}{P} - \xi_i \;\;. \tag{5}$$

We can answer this question by comparing $-\xi_i$ with the value of the following integer program:

$$\begin{array}{ll} \min\limits_{\boldsymbol{\tau}\in\{0,1\}^n} & y_i b + \sum_{j=1}^n \tau_j \left(y_i w_j x_{i,j} - \frac{\gamma v_j}{P}\right) \\ \text{s.t.} & P \;\leq\; \sum_{j=1}^n \tau_j v_j \;\;. \end{array} \tag{6}$$

For example, if the value of this integer program is less than $-\xi_i$, then let $\boldsymbol{\tau}'$ be an optimal solution and we have that $y_i(b + \sum_{j=1}^n \tau'_j w_j x_{i,j}) < (\gamma \sum_{j=1}^n \tau'_j v_j)/P - \xi_i$. Namely, the set $J = \{j \in [n] : \tau'_j = 1\}$ violates Eq. (5). On the other hand, if there exists some J with $V([n] \setminus J) \leq N$ that violates Eq. (5) then its indicator vector is a feasible point of Eq. (6) whose objective value is less than $-\xi_i$.

Directly solving the integer program in Eq. (6) may be difficult, so instead we examine the properties of the following linear relaxation:

$$\begin{array}{ll} \min\limits_{\boldsymbol{\tau}} & y_i b + \sum_{j=1}^n \tau_j \left(y_i w_j x_{i,j} - \frac{\gamma v_j}{P}\right) \\ \text{s.t.} & \forall j \in [n] \;\; 0 \leq \tau_j \leq 1 \;\; \text{and} \;\; P \leq \sum_{j=1}^n \tau_j v_j \;\;. \end{array} \tag{7}$$

To analyze this relaxation we require the following lemma.

Lemma 1. *Fix an example $(\mathbf{x}_i, y_i)$, a linear classifier $(\mathbf{w}, b)$, and a scalar $\xi_i > 0$, and let θ be the value of Eq. (7) with respect to these choices. (a) If $\theta \geq -\xi_i$ then Eq. (5) holds. (b) In the special case where $v_j \in \{0,1\}$ for all $j \in [n]$ and where N is an integer, $\theta \geq -\xi_i$ if and only if Eq. (5) holds. (c) There exists a minimizer of Eq. (7) with at most one coordinate in $(0,1)$.*

The proof of the lemma is straightforward but technical, and is omitted due to lack of space. Lemma 1 tells us that comparing the value of the linear program in Eq. (7) with $-\xi_i$ provides a sufficient condition for Eq. (5) to hold for the example $(\mathbf{x}_i, y_i)$. Moreover, this condition becomes both sufficient and necessary in the special case where $v_j \in \{0,1\}$ for all $j \in [n]$. We now proceed with proving the first part of Thm. 1 using claim (a) in Lemma 1. The remaining parts of the theorem follow similarly from claims (b) and (c) in the lemma.

Proof of Theorem 1. Let $(\mathbf{w}^\star, b^\star, \boldsymbol{\xi}^\star, \boldsymbol{\lambda}^\star, \boldsymbol{\alpha}_1^\star, \ldots, \boldsymbol{\alpha}_m^\star)$ be an optimal solution to the linear program in Eq. (4). Specifically, it holds for all $i \in [m]$ that $\boldsymbol{\alpha}_i^\star$ and $\lambda_i^\star$ are non-negative, that $P\lambda_i^\star - \sum_{j=1}^n \alpha_{i,j}^\star + y_i b^\star \geq -\xi_i^\star$, and that

$$\forall\, j \in [n] \;\; y_i w_j^\star x_{i,j} - \frac{\gamma v_j}{P} \;\geq\; \lambda_i^\star v_j - \alpha_{i,j}^\star \;\;.$$

Therefore, it also holds that the value of the following optimization problem

$$\begin{array}{ll} \max\limits_{\boldsymbol{\alpha}_i, \lambda_i} & P\lambda_i \;-\; \sum_{j=1}^n \alpha_{i,j} + y_i b^\star \\ \text{s.t.} & \forall\, j \in [n] \;\; y_i w_j^\star x_{i,j} - \frac{\gamma v_j}{P} \geq \lambda_i v_j - \alpha_{i,j} \;, \\ & \forall\, j \in [n] \;\; \alpha_{i,j} \geq 0 \;\text{ and }\; \lambda_i \geq 0 \;\;, \end{array} \tag{8}$$

is at least $-\xi_i^\star$. The strong duality principle of linear programming (Boyd & Vandenberghe, 2004) states that the value of Eq. (8) equals the value of its dual optimization problem, which is:

$$\begin{array}{ll} \min\limits_{\boldsymbol{\tau}} & y_i b^\star + \sum_{j=1}^n \tau_j \left(y_i w_j^\star x_{i,j} - \frac{\gamma v_j}{P}\right) \\ \text{s.t.} & \forall\, j \in [n] \;\; 0 \leq \tau_j \leq 1 \quad \text{and} \quad P \;\leq\; \sum_{j=1}^n \tau_j v_j \;\;. \end{array} \tag{9}$$

In other words, the value of Eq. (9) is also at least $-\xi_i^\star$. Using claim (a) of Lemma 1, we have that

$$y_i\big(b^\star + \textstyle\sum_{j\in J} w_j^\star x_{i,j}\big) \;\geq\; \frac{\gamma V(J)}{P} - \xi_i^\star \;\;,$$

holds for all J with $V([n] \setminus J) \leq N$. The optimization problem in Eq. (4) also constrains $\|\mathbf{w}\|_\infty \leq C$ and $\xi_i \geq 0$ for all $i \in [m]$, thus, $(\mathbf{w}^\star, b^\star, \boldsymbol{\xi}^\star)$ satisfies the constraints in Eq. (3). Since Eq. (3) and Eq. (4) have the same objective function, the value of Eq. (3) is upper bounded by the value of Eq. (4). □

2.3. Generalization Bounds

We now prove a generalization bound on the risk of the classifier learned in our framework, using PAC-Bayesian techniques (McAllester, 2003). Throughout, we assume that $\|\mathbf{x}\|_\infty \leq 1$ with probability 1 over $\mathcal{D}$. For simplicity, we assume that the bias term b is 0, and that $v_j > 0$ for all j. These assumptions can be relaxed at the cost of a somewhat more complicated analysis. Given a classifier $\mathbf{w}$, let $\ell_\gamma(\mathbf{w}, \mathbf{x}, y)$ denote the γ-loss attained on the example $(\mathbf{x}, y)$, defined as

$$\Big[\!\Big[\min_{J\,:\,V([n]\setminus J)\leq N} y \sum_{j\in J} w_j x_j \;<\; \frac{\gamma V(J)}{P} \Big]\!\Big] \;\;, \tag{10}$$

where $[\![\cdot]\!]$ again denotes the indicator function. Note that $\mathbb{E}[\ell_0(\mathbf{w}, \mathbf{x}, y)] = \mathcal{R}(\mathbf{w}, 0)$, where $\mathcal{R}$ is defined in Eq. (1).

Theorem 2. *Let S be a sample of size m drawn i.i.d from $\mathcal{D}$. For any $\delta > 0$, with probability at least $1 - \delta$, it holds for all $\mathbf{w} \in \mathbb{R}^n$ with $\|\mathbf{w}\|_\infty \leq C$ that the risk associated with $\mathbf{w}$ is at most*

$$\sup \left\{ \epsilon \ : \ \mathrm{KL}\left(\frac{1}{m} \sum_{i=1}^m \ell_\gamma(\mathbf{w}, \mathbf{x}_i, y_i) \ \middle\| \ \epsilon \right) \leq \frac{\beta(m,\delta,\gamma)}{m-1} \right\},$$

where $\beta(m, \delta, \gamma) = \ln(m/\delta) + \sum_{j=1}^n \ln(4PC/(\gamma v_j))$ and KL *is the Kullback-Leibler divergence. The above is upper-bounded by the empirical γ-loss (which equals $\frac{1}{m} \sum_{i=1}^m \ell_\gamma(\mathbf{w}, \mathbf{x}_i, y_i)$), plus the additional term*

$$\sqrt{\frac{2}{m} \sum_{i=1}^m \ell_\gamma(\mathbf{w}, \mathbf{x}_i, y_i) \frac{\beta(m,\delta,\gamma)}{m-1}} + \frac{2\beta(m, \delta, \gamma)}{m-1} \ .$$

Proof sketch. The proof follows along similar lines to the PAC-Bayesian bound for linear classifiers in (McAllester, 2003). First, define the axis-aligned box $B = \prod_{j=1}^n [w_j - \frac{\gamma v_j}{2P}, w_j + \frac{\gamma v_j}{2P}] \cap [-C, C]$. We use the margin concept to upper bound $\mathbb{E}_{(\mathbf{x},y)\sim\mathcal{D}}[\ell_0(\mathbf{w}, \mathbf{x}, y)]$ by the expected $\ell_{\gamma/2}$ loss over $\mathcal{D}$ of a classifier sampled uniformly from $B \cap [-C, C]^n$. We can upper bound this expected loss using the PAC-Bayesian theorem (McAllester, 2003), where the uniform distribution over $B \cap [-C, C]^n$ is the posterior classifier distribution, and the uniform distribution over $[-C, C]^n$ is the prior. The bound we get is defined in terms of the average empirical $\ell_{\gamma/2}$ loss of a random classifier from B, plus a complexity term dependent on the volume ratio between B and $[-C, C]^n$. Finally, this average loss can be upper bounded by the empirical ℓ_γ loss of $\mathbf{w}$ by repeating the technique of the first stage. The weaker bound stated in the theorem follows from a lower bound on the KL divergence, presented in (McAllester, 2003). □

It is interesting to note that L_∞ regularization emerges as the most natural one in this setting, since it induces the most convenient type of margin for relating the $\ell_0, \ell_{\gamma/2}, \ell_\gamma$ loss functions as described above. This lends theoretical support to our choice of the L_∞ norm in our algorithms.

2.4. Feature Corrupting Noise

We now shift our attention to the case where a subset of the features is corrupted with random noise, and show that the the same LP approach used to handle missing features can also deal with corrupted features if the margin parameter γ in Eq. (4) is sufficiently large. For simplicity, we shall assume that all features are supported on $[-1, 1]$ with zero mean. Unlike the feature deleting noise, we now assume that the each feature selected by the adversary is replaced with noise sampled from some distribution, also supported on $[-1, 1]$ and having zero mean. The following theorem relates the risk of a classifier in the above setting, to its expected γ-loss in the feature deletion setting, where the latter can be bounded with Thm. 2.

Theorem 3. *Let ϵ, C, and N be arbitrary positives, and let γ be at least $C\sqrt{N \ln(1/\epsilon)/2}$. Assume that we solve Eq. (4) with parameters γ, C, N and with $v_j = 1$ for all $j \in [n]$. Let $\mathbf{w}$ be the resulting linear classifier, and assume for simplicity that the bias term b is zero. Let f be a random vector-valued function on $\mathcal{X}$, such that for every $\mathbf{x} \in \mathcal{X}$, $f(\mathbf{x})$ is the instance $\mathbf{x}$ after the feature corruption scheme described above. Then, using ℓ_γ as defined in Eq. (10), for $(\mathbf{x}, y)$ drawn randomly from $\mathcal{D}$, we have:*

$$\Pr\left(y\langle \mathbf{w}, f(\mathbf{x})\rangle \leq 0\right) \ \leq \ \mathbb{E}\left[\ell_\gamma(\mathbf{w}, \mathbf{x}, y)\right] + \epsilon \ .$$

Proof. Let $(\mathbf{x}, y)$ be an example and let J denote the feature subset which remains uncorrupted by the adversary. Using Hoeffding's bound and our assumption on γ, we have that $\Pr\left(y \sum_{j\notin J} w_j f_j(\mathbf{x}) \leq -\gamma\right)$ is upper bounded by ϵ. Therefore, with probability at least $1 - \epsilon$ over the randomness of f, $y\langle \mathbf{w}, f(\mathbf{x})\rangle$ is equal to:

$$y \sum_{j\in J} w_j x_j + y \sum_{j\notin J} w_j f_j(\mathbf{x}) \ > \ y \sum_{j\in J} w_j x_j - \gamma \ . \quad (11)$$

Thus, with probability at least $1 - \epsilon$, $\Pr(y\langle \mathbf{w}, f(\mathbf{x})\rangle < 0)$ is upper bounded by $\mathbb{E}[\ell_\gamma(\mathbf{w}, \mathbf{x}, y)]$. Otherwise, with probability at most ϵ, $\Pr(y\langle \mathbf{w}, f(\mathbf{x})\rangle < 0) \leq 1$. □

We conclude with an interesting observation. In the feature corruption setting, making a correct prediction boils down to achieving a sufficiently large margin on the uncorrupted features. Let $r \in (0, 1)$ be a fixed ratio between N and n, and let n grow to infinity. Assuming a reasonable degree of feature redundancy, the term $y \sum_{j\in J} w_j x_j$ grows as $\Theta(n)$. On the other hand, Hoeffding's bound tells us that $y \sum_{j\notin J} w_j x_j$ grows only as $O(\sqrt{N})$. Therefore, for r arbitrarily close to 1 and a large enough n, the first sum in Eq. (11) dominates the second. Namely, by setting $\gamma = \Omega(\sqrt{N})$ in Eq. (4), our ability to withstand feature corruption matches our ability to withstand feature deletion.

3. Solving the Problem with the Perceptron

We now turn to our second learning algorithm, taking a different angle on the problem. We momentarily forget about the original statistical learning problem and instead define a related online prediction problem. In online learning there is no distinction between the training phase and the classification phase, so we cannot perfectly replicate the classification-time noise scenario discussed above. Instead, we assume that an adversary removes features from every instance that is presented to the algorithm. We address this online problem with a modified version of the

Perceptron algorithm (Rosenblatt, 1958) and use an online-to-batch conversion technique to convert the online algorithm back into a statistical learning algorithm. The detour through online learning gives us efficiency while the online-to-batch technique provides us with the statistical generalization properties we are interested in.

3.1. Perceptron with Projections onto the Cube

We start with a modified version of the well-known Perceptron algorithm (Rosenblatt, 1958), which observes a sequence of examples $\big((\mathbf{x}_i, y_i)\big)_{i=1}^m$, one example at a time, and incrementally builds a sequence $\big((\mathbf{w}_i, b_i)\big)_{i=1}^m$ of linear margin-based classifiers, while constraining them to a hyper-cube. Before processing example i, the algorithm has the vector $\mathbf{w}_i$ and the bias term b_i stored in its memory. An adversary takes the instance $\mathbf{x}_i$ and reveals only a subset J_i of its features to the algorithm, attempting to cause the online algorithm to make a prediction mistake. In choosing J_i, the adversary is restricted by the constraint $V([n] \setminus J) \leq N$. Next, the algorithm predicts the label associated with $\mathbf{x}_i$ to be

$$\text{sign}\left(b_i + \textstyle\sum_{j \in J_i} w_{i,j} x_{i,j}\right) \ .$$

After the prediction is made, the correct label y_i is revealed and the algorithms suffers a hinge-loss $\xi(\mathbf{w}, b, \mathbf{x}, y)$, defined as

$$\left[\max_{J\,:\,V([n]\setminus J)\leq N} \frac{\gamma V(J)}{P} \ - \ y\big(b + \textstyle\sum_{j\in J} w_j x_j\big)\right]_+ \ , \quad (12)$$

where $P = V([n]) - N$ and $[\alpha]_+$ denotes the hinge function, $\max\{\alpha, 0\}$. Note that $\xi(\mathbf{w}_i, b_i, \mathbf{x}_i, y_i)$ upper-bounds γ times the indicator of a prediction mistake on the current example, for any choice of J_i made by the adversary. We choose to denote the loss by ξ to emphasize the close relation between $\xi(\mathbf{w}_i, b_i, \mathbf{x}_i, y_i)$ and ξ_i in Eq. (3). Due to our choice of loss function, we can assume that the adversary chooses the subset J_i that inflicts the greatest loss.

The algorithm now uses the correct label y_i to construct the pair $(\mathbf{w}_{i+1}, b_{i+1})$, which is used to make the next prediction. If $\xi(\mathbf{w}, b, \mathbf{x}, y) = 0$, the algorithm defines $\mathbf{w}_{i+1} = \mathbf{w}_i$ and $b_{i+1} = b_i$. Otherwise, the algorithm defines $\mathbf{w}_{i+1}$ using the following coordinate-wise update

$$j \in [n] \quad w_{i+1,j} \ = \ \begin{cases} [w_{i,j} + y_i \tau x_{i,j}]_{\pm C} & \text{if } j \in J_i \\ w_{i,j} & \text{otherwise} \end{cases} \ ,$$

and $b_{i+1} = [b_i + y_i \tau]_{\pm C}$, where $\tau = \frac{\sqrt{n+1}C}{\sqrt{2m}}$ and $[\alpha]_{\pm C}$ abbreviates the function $\max\big\{\min\{\alpha, C\}, -C\big\}$. This update is nothing more than the standard Perceptron update with constant learning rate τ, with an added projection step onto the hyper-cube of radius C. The specific value of τ used above is the value that optimizes the cumulative loss bound below. As in the previous section, restricting the online classifier to the hyper-cube helps us control its complexity, while promoting dense classifiers. It also comes in handy in the next stage, when we convert the online algorithm into a statistical learning algorithm.

Using a rather straightforward adaptation of standard Perceptron loss bounds, to the case where the hypothesis is confined to the hyper-cube, leads us to the following theorem, which compares the cumulative loss suffered by the algorithm with the cumulative loss suffered by any fixed hypothesis in the hyper-cube of radius C.

Theorem 4. *Choose any $C > 0$ and let $\mathbf{w}^\star \in \mathbb{R}^n$ and $b^\star \in \mathbb{R}$ be such that $\|\mathbf{w}^\star\|_\infty \leq C$ and $|b^\star| \leq C$. Let $\big((\mathbf{x}_i, y_i)\big)_{i=1}^m$ be an arbitrary sequence of examples, with $\|\mathbf{x}_i\|_1 \leq 1$ for all i. Assume that this sequence is presented to our modified Perceptron, and let $\xi(\mathbf{w}_i, b_i, \mathbf{x}_i, y_i)$ be as defined in Eq. (12). Then it holds that $\frac{1}{\gamma m}\sum_{i=1}^m \xi(\mathbf{w}_i, b_i, \mathbf{x}_i, y_i)$ is upper-bounded by*

$$\frac{1}{\gamma m}\sum_{i=1}^m \xi(\mathbf{w}^\star, b^\star, \mathbf{x}_i, y_i) \ + \ \frac{C}{\gamma}\sqrt{\frac{2(n+1)}{m}} \ .$$

The next step is to convert our online algorithm into a statistical learning algorithm.

3.2. Converting Online to Batch

To obtain a statistical learning algorithm, with risk guarantees, we assume that the sequence of examples presented to the modified Perceptron algorithm is a training set sampled i.i.d. from the underlying distribution $\mathcal{D}$. We turn to the simple averaging technique presented in (Cesa-Bianchi et al., 2004) and define $\bar{\mathbf{w}} = \frac{1}{m}\sum_{i=1}^m \mathbf{w}_{i-1}$ and $\bar{b} = \frac{1}{m}\sum_{i=1}^m b_{i-1}$. $(\bar{\mathbf{w}}, \bar{b})$ is called the *average hypothesis*, and defines our robust classifier. We use the derivation in (Cesa-Bianchi et al., 2004) to prove that the average classifier provides an adequate solution to our original problem.

Note that the loss function we use, defined in Eq. (12), is bounded and convex in its first two arguments. This allows us to apply (Cesa-Bianchi et al., 2004, Corollary 2) to relate the risk of $(\bar{\mathbf{w}}, \bar{b})$ with the cumulative online loss suffered by the Perceptron. It also allows us to apply Hoeffding's bound to relate the expected loss of any fixed classifier $(\mathbf{w}^\star, b^\star)$ with its empirical loss on the training set. Combining both bounds results in the following corollary.

Corollary 1. *For any $\delta > 0$, with probability at least $1 - \delta$ over the random sampling of S, our algorithm constructs $(\bar{\mathbf{w}}, \bar{b})$ such that $\mathbb{E}_{(\mathbf{x},y)\sim\mathcal{D}}\left[\xi(\bar{\mathbf{w}}, \bar{b}, \mathbf{x}, y)\right]$ is at most*

$$\min_{(\mathbf{w},b)\in\mathcal{H}} \mathbb{E}\left[\xi(\mathbf{w}, b, \mathbf{x}, y)\right] \ + (3C + \phi)\sqrt{\frac{2(n + 1 + \ln(\frac{2}{\delta}))}{m}} \ ,$$

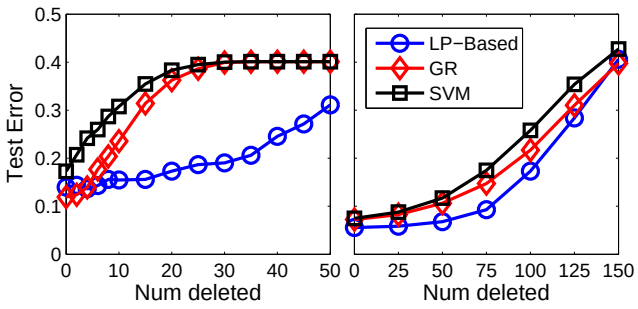

Figure 1. A comparison of our LP-based approach with the algorithm of (Globerson & Roweis, 2006) (GR) and with SVM on SPAM (left) and MNIST (right), with random noise.

where $\phi = \gamma \max_{J:V([n]\setminus J)\leq N} \big(V(J)/P\big)$*, and* $\mathcal{H}$ *is the set of all pairs* $(\mathbf{w}, b)$ *such that* $\|\mathbf{w}\|_\infty \leq C$ *and* $|b| \leq C$*.*

Using the fact that the hinge loss upper-bounds γ times the indicator function of a prediction mistake, regardless of the adversary's choice of the feature set, we have that the expected hinge loss upper-bounds $\gamma\mathcal{R}(\bar{\mathbf{w}}, \bar{b})$.

4. Experiments and Conclusions

We compare the performance of our two algorithms (LP-based and online-to-batch) with that of a linear L_2 SVM (Joachims, 1998) and with the results reported in (Globerson & Roweis, 2006). We used the GLPK package (`http://www.gnu.org/software/glpk`) to solve the LP formulation of our LP-based algorithm.

We begin with a highly illustrative sanity check. We generated a synthetic dataset of 1000 linearly separable instances in $\mathbb{R}^{20}$ and added label noise by flipping each label with probability 0.2. Then, we added two copies of the actual label as additional features to each instance, for a total of 22 features. We randomly split the data into equally sized training and test sets, and trained an SVM classifier on the training set. We set $v_j = 1$ for $j \in [20]$ and $v_{21} = v_{22} = 10$, expressing our prior knowledge that the last two features are more valuable. Using these feature values, we applied our technique with different values of the parameter N. We removed one or both of the high-value features from the test set and evaluated the classifiers. With only one feature removed both SVM and our approach attained a test error of zero. With two features removed, the test error of the SVM classifier jumped to 0.477 ± 0.004 (over 100 random repetitions of the experiment), indicating that it essentially put all of its weight on the two perfect features. With the noise parameter set to $N = 20$, our approach attained a test error of only 0.22 ± 0.002. This is only marginally above the best possible error rate for this setting.

Following the lead of (Globerson & Roweis, 2006), we conducted experiments using the SPAM and MNIST datasets. The SPAM dataset, taken from the UCI repository, is a collection of spam and non-spam e-mails. Spam can be detected by different word combinations, so we expect considerable feature redundancy in this dataset. The MNIST dataset is a collection of pixel-maps of handwritten digits. Again, following (Globerson & Roweis, 2006), we focused on the binary problem of distinguishing the digit 4 from the digit 7. Adjacent pixels often contain redundant information, making MNIST well-suited for our needs.

On each dataset, we performed 2 types of experiments. The first type follows exactly the protocol used in (Globerson & Roweis, 2006). Namely, the algorithm is trained with a small training set of 50 instances, and its performance is tested in the face of *random* feature-deleting noise, which uniformly deletes N non-zero features from each test instance, for various choices of N. Notice that this setting deviates from the adversarial setting considered so far, and the reason for conducting this experiment is to compare our results to those reported in (Globerson & Roweis, 2006). A validation set is used for parameter tuning. We did not test our online-to-batch algorithm within this setting, since it has little advantage with such a small training set. The results are presented in Fig. 1, and show test error as a function of the number of deleted features. Compared to its competitors, our algorithm has a clear and substantial advantage.

The second type of experiment simulates more closely the adversarial setting discussed throughout the paper. Using 10-fold cross-validation, we corrupted each test instance using a greedy adversary, which deletes the most valuable features of each instance until either the limit N is reached or all useful features are deleted. $1/9$ of the training set was used for parameter tuning. Due to computational considerations when running our LP-based algorithm, we performed a variant of bagging by randomly splitting the training set into chunks, training on each chunk individually, and finally averaging the resulting weight vectors. In contrast, our online-to-batch algorithm trained on the entire training set at once, and so did the SVM algorithm. We repeated this process for different values of N. For the SPAM dataset, we repeated this entire experiment twice, once with features values v_j set uniformly to 1, and once with v_j set using a mutual information heuristic. Formally, we set

$$v_j = \tfrac{1}{Z} \max_{c\in\mathbb{R}} I\big([\![x_j > c]\!]; y\big) \ ,$$

where Z is such that $\sum v_j = n$, and where $I([\![x_j > c]\!]; y)$ is the mutual information between the predicate $[\![x_j > c]\!]$ and the label y, over all examples in the training set. Intuitively, we are calculating the amount of information contained in each individual feature on the label, provided that

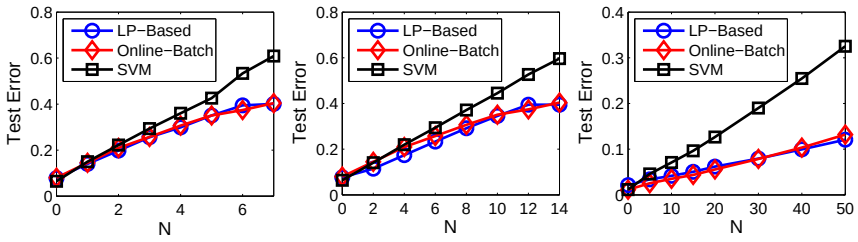

Figure 2. Experiments on SPAM with $\forall j \in J, v_j = 1$ (left) and with v_j set with a mutual information heuristic (center). Experiments on MNIST with v_j set with a mutual information heuristic (right).

we are looking only at linear threshold functions. When experimenting with the MNIST dataset, we only used the values of v_j set by our heuristic. This is a natural choice since the features of MNIST are of markedly different importance levels. For example, the corner pixels, which are always zero, are completely uninformative, while other pixels may be very informative. The results are presented in Fig. 2, and show test error as a function of N. Clearly, our algorithms have the advantage. SVM repeatedly puts all of its eggs in a small number of baskets, and is severely punished for this, while our technique anticipates the actions of the adversary and hedges its bets accordingly.

Moreover, the results in Fig. 2 demonstrate the tradeoffs between our LP-based and online-to-batch algorithms. Although we have handicapped the LP-based algorithm by chunking the training set, its performance is comparable and sometimes superior to that of the online-to-batch algorithm. With less or without chunking, we expect its performance to be even better.

We conclude that our proposed algorithms successfully withstand feature corruption at classification time, and considerably improve upon the current state of the art. On a more general note, this work has interesting connections to a recent trend in machine learning research, which is to develop sparse classifiers supported on a small subset of the features. In our setting, we are interested in the exact opposite, and the efficacy of using the L_∞ norm is clearly demonstrated here. The trade-off between robustness and sparsity provides fertile ground for future research.

Abstract

We propose a new rule induction algorithm for solving classification problems via probability estimation. The main advantage of decision rules is their simplicity and good interpretability. While the early approaches to rule induction were based on sequential covering, we follow an approach in which a single decision rule is treated as a base classifier in an ensemble. The ensemble is built by greedily minimizing the negative loglikelihood which results in estimating the class conditional probability distribution. The introduced approach is compared with other decision rule induction algorithms such as SLIPPER, LRI and RuleFit.

1. Introduction

Decision rule is a logical statement of the form: "if *condition* then *response*". It can be treated as a simple classifier that gives a constant response for the objects satisfying the condition part, and abstains from the response for all the other objects. Induction of decision rules has been widely considered in the early machine learning approaches (Michalski, 1983; Cohen, 1995; Fürnkranz, 1996), and rough set approaches to knowledge discovery (Stefanowski, 1998). The most popular algorithms were based on a sequential covering procedure (also known as separate-and-conquer approach). In this technique, a rule is learned which covers a part of the training examples, then examples are removed from the training set and the process is repeated until no examples remain.

Although it seems that decision (classification) trees are much more popular in data mining and machine learning applications, recently we are able to observe again a growing interest in decision rule models. As an example, let us mention such algorithms as RuleFit (Friedman & Popescu, 2005), SLIPPER (Cohen & Singer, 1999), Lightweight Rule Induction (LRI) (Weiss & Indurkhya, 2000). All these algorithms follow a specific iterative approach to decision rule generation by treating each decision rule as a subsidiary base classifier in the ensemble. This approach can be seen as a generalization of the sequential covering, because it approximates the solution of the prediction task by sequentially adding new rules to the ensemble without adjusting those that have already been added (RuleFit is an exception since it generates the trees first and then transforms them to rules). Each rule is fitted by concentrating on objects which were hardest to classify correctly by rules already present in the ensemble. All these algorithms can be explained within the framework of boosting (Freund & Schapire, 1997; Mason et al., 1999; Friedman et al., 2000) or forward stagewise additive modeling (FSAM) (Hastie et al., 2003), a greedy procedure for minimizing a loss function on the dataset.

The algorithm proposed in this paper, Maximum Likelihood Rule Ensembles (MLRules), benefits from the achievements in boosting machines (Freund & Schapire, 1997; Mason et al., 1999; Friedman et al., 2000; Friedman, 2001). Its main idea consists in rule induction by greedily minimizing the negative loglikelihood (also known as logit loss in binary classification case) to estimate the conditional class probability distribution. Minimization of such loss function with a

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

tree being a base classifier has already been used in LogitBoost (Friedman et al., 2000) and MART (Friedman, 2001), however, here we show a modified procedure, adapted to the case when the decision rule is a base classifier in the ensemble. In contrary to RuleFit (where trees are generated first), rules are generated directly; in contrary to SLIPPER and LRI, negative loglikelihood loss is used. Moreover, our approach is distinguished from other approaches to rule induction by the fact of estimating the class probability distribution instead of single classification and by using the same single measure (value of the negative loglikelihood) at all stages of the learning procedure: setting the best cuts (conditions), stopping the rule's growth and determining the response (weight) of the rule. We derive the algorithm for two optimization techniques, depending on whether we expand the loss function to the first order (fitting to the gradient) or to the second order (Newton steps). We report experiments showing the performance of MLRules and comparing them with the competitive rule ensemble methods.

The paper is organized as follows. In Section 2, the problems of classification is described. Section 3 presents a framework for learning rule ensembles. Section 4 is devoted to the problem of a single rule generation. In Section 5 we discuss the issue of convergence of the method, and we propose a modification to the main algorithm. Section 6 contains experimental results. The last section concludes the paper and outlines further research directions.

2. Problem Statement

In the classification problem, the aim is to predict the unknown class label $y \in \{1, \ldots, K\}$ of an object using known values of the attributes $\mathbf{x} = (x_1, x_2, \ldots, x_m)$. This is done by constructing a classification function $f(\mathbf{x})$ that predicts accurately the value of y. The accuracy of a single prediction is measured in terms of the loss function $L(y, f(\mathbf{x}))$, while the overall accuracy of the function $f(\mathbf{x})$ is measured by the expected loss (risk) over the data distribution $P(\mathbf{x}, y)$:

$$R(f) = \mathbb{E}[L(y, f(\mathbf{x}))].$$

Since $P(\mathbf{x}, y)$ is unknown, the risk-minimizing function (Bayes classifier), $f^* = \arg\min_f \mathbb{E}[L(y, f(\mathbf{x}))]$, is also unknown. The learning procedure uses only a set of training examples $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$ to construct f to be a good approximation of f^*. Usually, it is performed by minimization of the empirical risk:

$$R_{\text{emp}}(f) = \frac{1}{n} \sum_{i=1}^{n} L(y_i, f(\mathbf{x}_i)), \tag{1}$$

where function f is chosen from a restricted family of functions. The most commonly used loss function is 0-1 loss, $L_{0\text{-}1}(y, f(\mathbf{x})) = 1 - \delta_{y,f(\mathbf{x})}$, where $\delta_{ij} = 1$ if $i = j$, otherwise $\delta_{ij} = 0$. If the correct class is predicted, classification function is not penalized, otherwise the unit penalty is imposed. Bayes classifier has the following form:

$$f^*(\mathbf{x}) = \arg \min_{k \in \{1,\ldots,K\}} \Pr(y = k|\mathbf{x}). \tag{2}$$

The 0-1 loss has several drawbacks. Firstly, if we introduce unequal costs of misclassification, $f^*(\mathbf{x})$ does not longer have the form (2). Moreover, 0-1 loss is insensitive to the "confidence" of prediction: minimization of 0-1 loss results only in finding the most probable class, without estimating its probability. On the contrary, probability estimation provides us with the conditional class distribution $P(y|\mathbf{x})$, by which we can measure the prediction confidence. Moreover, all we need to obtain the Bayes classifier for *any* loss function is the conditional probability distribution. Here we consider the estimation of probabilities using the well-known maximum likelihood estimation (MLE) method. MLE can be stated as the empirical risk minimization by taking the negative logarithm of the conditional likelihood (negative log-likelihood) as the loss function:

$$\ell = \sum_{i=1}^{n} -\log P(y_i|\mathbf{x}_i). \tag{3}$$

We model probabilities $P(1|\mathbf{x}), \ldots, P(K|\mathbf{x})$ with a vector $\mathbf{f}(\mathbf{x}) = (f_1(\mathbf{x}), \ldots, f_K(\mathbf{x}))$ using the multinomial logistic transform:

$$P(y|\mathbf{x}) = \frac{e^{f_y(\mathbf{x})}}{\sum_{k=1}^{K} e^{f_k(\mathbf{x})}}. \tag{4}$$

Then (3) has the form:

$$\ell(\mathbf{f}) = \sum_{i=1}^{n} \log \left(\sum_{k=1}^{K} e^{f_k(\mathbf{x}_i)} \right) - f_{y_i}(\mathbf{x}_i). \tag{5}$$

This expression (with the exception that vector function $\mathbf{f}$ is used instead of scalar f) has the form of (1) if we identify $L(y_i, \mathbf{f}(\mathbf{x}_i)) = \log \left(\sum_{k=1}^{K} e^{f_k(\mathbf{x}_i)} \right) - f_{y_i}(\mathbf{x}_i)$. It is worth mentioning that the Bayes function $\mathbf{f}^*(\mathbf{x})$ is obtained by the inverse of (4).

3. Rules Ensembles

In this section, we describe the scheme of learning rule ensembles. Let X_j be the set of all possible values of attribute j. Condition part of the rule consists of

a conjunction of elementary expressions of the form $x_j \in S_j$, where x_j is the value of object $\mathbf{x}$ on attribute j and S_j is a subset of X_j, $j \in \{1, \ldots, m\}$. We assume that in the case of ordered value sets, S_j has the form of the interval $[s_j, \infty)$ or $(-\infty, s_j]$ for some $s_j \in X_j$, so that the elementary expressions take the form $x_j \geq s_j$ or $x_j \leq s_j$. For nominal attributes, we consider elementary expressions of the form $x_j = s_j$ or $x_j \neq s_j$. Let Φ be the set of elementary expressions constituting the condition part of the rule and let $\Phi(\mathbf{x})$ be an indicator function equal to 1 if $\mathbf{x}$ satisfies the condition part of the rule (all elementary expressions in the condition part), otherwise $\Phi(\mathbf{x}) = 0$. We say that a rule *covers* an object $\mathbf{x}$, if $\Phi(\mathbf{x}) = 1$. The response of the rule is a vector $\boldsymbol{\alpha} \in \mathbb{R}^K$ assigned to the region defined by Φ. Therefore, we define a decision rule as:

$$\mathbf{r}(\mathbf{x}) = \boldsymbol{\alpha}\Phi(\mathbf{x}). \tag{6}$$

Notice that the decision rule takes only two values, $\mathbf{r}(\mathbf{x}) \in \{\boldsymbol{\alpha}, \mathbf{0}\}$, depending whether $\mathbf{x}$ satisfies the condition part or not. In this paper, we assume the classification function is a linear combination of M rules:

$$\mathbf{f}(\mathbf{x}) = \sum_{m=1}^{M} \mathbf{r}_m(\mathbf{x}). \tag{7}$$

Using (4), we can obtain conditional probabilities from (7). Moreover, from (4) it follows that $P(y|\mathbf{x})$ is a monotone function of $f_y(\mathbf{x})$. Therefore, from (2) we have that object $\mathbf{x}$ is classified to the class with the highest $f_k(\mathbf{x})$. Thus, combination (7) has very simple interpretation as a voting procedure: rules vote for each class k, and object $\mathbf{x}$ is classified to the class with the highest vote.

The construction of an optimal rules ensemble minimizing the negative loglikelihood (empirical risk) is a hard optimization problem. That is why we follow here a forward stagewise strategy (Hastie et al., 2003), i.e. the rules are added one by one, greedily minimizing the loss function:

$$\mathbf{r}_m = \arg\min_{\mathbf{r}} \ell(\mathbf{f}_{m-1} + \mathbf{r}) = \arg\min_{\Phi, \boldsymbol{\alpha}} \ell(\mathbf{f}_{m-1} + \Phi\boldsymbol{\alpha}), \tag{8}$$

where $\mathbf{r}_m$ is a rule obtained in the m-th iteration and $\mathbf{f}_{m-1}$ is the rule ensemble after $m-1$ iterations. It has been shown (Hastie et al., 2003) that "shrinking" the base classifier while adding it to the ensemble improves the prediction accuracy. That is why we set:

$$\mathbf{f}_m(\mathbf{x}) = \mathbf{f}_{m-1}(\mathbf{x}) + \nu \cdot \mathbf{r}_m(\mathbf{x}),$$

where $\nu \in (0, 1]$ is the shrinkage parameter, which constitutes a trade-off between accuracy and interpretability. Higher values ($\nu \sim 1$) produce smaller ensembles, while low values ($\nu \sim 0.1$) produce larger but more accurate ones.

4. Generation of a Single Rule

In this section, we describe how the algorithm generates single rules. In order to obtain a rule, one has to solve (8). The optimization procedure is still computationally hard. Therefore, we restrict analysis to the rules voting for only one class, so that the response of the rule has the form $\boldsymbol{\alpha} = \alpha\mathbf{v}$, where $\mathbf{v}$ is a vector with only one non-zero coordinate $v_k = 1$, for some $k = 1, \ldots, K$, and α is a positive real value.

We propose two heuristic procedures for solving (8). The first, called gradient method (Mason et al., 1999), approximates $\ell(\mathbf{f} + \alpha\mathbf{v}\Phi)$ up to the first order with respect to α:

$$\ell(\mathbf{f} + \alpha\mathbf{v}\Phi) \simeq \ell(\mathbf{f}) + \alpha\ell'(\mathbf{f}, \mathbf{v}\Phi), \tag{9}$$

where

$$\ell'(\mathbf{f}, \mathbf{v}\Phi) = \left.\frac{\partial \ell(\mathbf{f} + \alpha\mathbf{v}\Phi)}{\partial \alpha}\right|_{\alpha=0}. \tag{10}$$

Since the first term in (9) is constant, minimization of the loss for *any* positive α is equivalent to minimization of the second term. Thus, if we define:

$$\mathcal{L}_m(\Phi) = \min_{\mathbf{v}} -\ell'(\mathbf{f}, \mathbf{v}\Phi) \tag{11}$$

(we remind, that there are only K possible vectors $\mathbf{v}$, so the arg min operation can be done by simply checking all K possibilities), then Φ_m can be obtained by minimizing $\mathcal{L}_m(\Phi)$.

The second heuristic, Newton method, approximates $\ell(\mathbf{f} + \alpha\mathbf{v}\Phi)$ up to the second order:

$$\ell(\mathbf{f} + \alpha\mathbf{v}\Phi) \simeq \ell(\mathbf{f}) + \alpha\ell'(\mathbf{f}, \mathbf{v}\Phi) + \frac{\alpha^2}{2}\ell''(\mathbf{f}, \mathbf{v}\Phi), \tag{12}$$

where $\ell'(\mathbf{f}, \mathbf{v}\Phi)$ is defined as before, and:

$$\ell''(\mathbf{f}, \mathbf{v}\Phi) = \left.\frac{\partial^2 \ell(\mathbf{f} + \alpha\mathbf{v}\Phi)}{\partial \alpha^2}\right|_{\alpha=0}. \tag{13}$$

Due to convexity of the loglikelihood, expression (12) is minimized by the Newton step:

$$\alpha = -\frac{\ell'(\mathbf{f}, \mathbf{v}\Phi)}{\ell''(\mathbf{f}, \mathbf{v}\Phi)}. \tag{14}$$

By substituting (14) into (12), and taking the square root, we get:

$$\mathcal{L}_m(\Phi) = \min_{\mathbf{v}} -\frac{\ell'(\mathbf{f}, \mathbf{v}\Phi)}{\sqrt{\ell''(\mathbf{f}, \mathbf{v}\Phi)}}, \tag{15}$$

and we can obtain Φ_m by minimizing $\mathcal{L}_m(\Phi)$.

Algorithm 1 MLRules

input: set of n training examples $\{(y_i, \mathbf{x}_i)\}_1^n$,
M – number of decision rules.
output: rule ensemble $\{r_m(\mathbf{x})\}_1^M$.

$\mathbf{f}_0 := \boldsymbol{\alpha}_0$.
for $m = 1$ **to** M **do**
$\Phi_m(\mathbf{x}) = \arg\min_\Phi \mathcal{L}_m(\Phi)$
$\boldsymbol{\alpha}_m = -\ell'(\mathbf{f}, \mathbf{v}\Phi)/\ell''(\mathbf{f}, \mathbf{v}\Phi)$
$\mathbf{r}_m(\mathbf{x}) = \boldsymbol{\alpha}_m \Phi_m(\mathbf{x})$
$\mathbf{f}_m(\mathbf{x}) = \mathbf{f}_{m-1}(\mathbf{x}) + \nu \mathbf{r}_m(\mathbf{x})$
end for

Expressions $\ell'(\mathbf{f}, \mathbf{v}\Phi)$ and $\ell''(\mathbf{f}, \mathbf{v})$ have a very simple form. Let $\mathbf{v}$ be such that $v_k = 1$. Then:

$$\ell'(\mathbf{f}, \mathbf{v}\Phi) = \sum_{\Phi(\mathbf{x}_i)=1} p_{ik} - \delta_{k,y_i}, \tag{16}$$

$$\ell''(\mathbf{f}, \mathbf{v}\Phi) = \sum_{\Phi(\mathbf{x}_i)=1} p_{ik}(1 - p_{ik}), \tag{17}$$

where $p_{ik} = P(k|\mathbf{x}_i)$ and $\delta_{i,j} = 1$ iff $i = j$. To calculate $\mathcal{L}_m(\Phi)$, these expressions must be obtained for each k.

What we still need for finding Φ_m using both gradient and Newton techniques, is a fast procedure for minimizing $\mathcal{L}_m(\Phi)$, regardless whether it is defined by (11) or (15). We propose the following simple iterative procedure: at the beginning, Φ_m is empty (no elementary expressions are specified) and we set $\mathcal{L}_m(\Phi) = 0$. In each step, an elementary expression $x_j \in S_j$ is added to Φ_m that minimizes $\mathcal{L}_m(\Phi)$ (if it exists). Such expression is searched by sequentially testing the elementary expressions, attribute by attribute. For ordered attributes, each expression of the form $x_j \geq s_j$ or $x_j \leq s_j$ is tested, for every $s_j \in X_j$; for nominal attributes, we test each expression of the form $x_j = s_j$ or $x_j \neq s_j$, for every $s_j \in X_j$. Adding new expressions is repeated until $\mathcal{L}_m(\Phi)$ cannot be decreased. We also simultaneously obtain $\mathbf{v}_m$, i.e. the value of $\mathbf{v}$ for which the minimum is reached in (11) or (15). Notice that since $\mathcal{L}_m(\Phi) = 0$ at the beginning, $\mathcal{L}_m(\Phi)$ must be strictly negative at the end, otherwise no rule will be generated. The procedure for finding optimal Φ is very fast and proved to be efficient in computational experiments. The ordered attributes can be sorted once before generating any rule. This procedure resembles the way the decision trees are generated. Here, we look, however, for only one path from the root to the leaf. Moreover, let us notice that a minimal value of $\mathcal{L}_m(\Phi)$ is a natural stop criterion in building a single rule and we do not use any other measures (e.g. impurity measures) for choosing the optimal cuts.

Having found Φ_m, we can obtain α_m by solving the following convex line-search problem:

$$\alpha_m = \arg\min_\alpha \ell(\mathbf{f} + \alpha \mathbf{v}_m \Phi_m). \tag{18}$$

To speed up the computations, we follow, however, simpler procedure and obtain α_m by the Newton step (14). The whole procedure for constructing the rule ensemble is presented as Algorithm 1. We call this procedure MLRules. Note that we start with $\mathbf{f}(\mathbf{x})$ equal to $\boldsymbol{\alpha_0}$, which is a "default rule" with fixed $\Phi(\mathbf{x}) \equiv 1$, while $\mathbf{v}_0$ and α_0 are obtained as usual. Since the response always indicates the majority class, such a rule serves as a default classification when no other rule covers a given object.

In our implementation of the algorithm, we employed the resampling technique (Friedman & Popescu, 2003), which is known to improve both accuracy and computational complexity. To obtain less correlated rules, we search for Φ_m, using (11) or (15), on a random subsample (drawn without replacement) of the training set of size $\eta < n$. Then, however, the response α_m is obtained using *all* of the training objects (including those objects, which have not been used to obtain Φ_m). This usually decreases $|\alpha_m|$, so it plays the role of a regularization method, and avoids overfitting the rule to the training set.

5. Extensions

In this section, we shortly discuss the problem of convergence and propose two simple extensions of the main algorithm.

5.1. Convergence

The procedure of obtaining α_m with the Newton step does not always decrease the empirical risk and does not guarantee the convergence of the algorithm. However, using a simple backtracking line-search is sufficient for convergence: we start with α_m obtained by the Newton step. If $\ell(\mathbf{f} + \alpha \mathbf{v}\Phi) < \ell(\mathbf{f})$, the procedure stops; otherwise repeat $\alpha_m := \alpha_m/2$ until the above condition is satisfied. This procedure ends after a finite number of steps, since from the definition of $\mathcal{L}_m$, either (11) or (15), it follows that $\mathcal{L}_m = 0$ if and only if $\ell'(\mathbf{f}, \mathbf{v}\Phi) = 0$, so if a rule is generated, $\mathcal{L}_m < 0$ and $\mathbf{v}\Phi$ is a descent direction. Therefore, ℓ is decreased in each iteration. Since ℓ is bounded from below, the procedure converges, i.e.: $\lim_{m\to\infty} \ell(\mathbf{f}_m) = \ell^\infty$. In the implementation of the algorithm we do not use such a procedure since the algorithm is stopped after M rounds anyway.

This raises the question, whether ℓ^∞ is the solution with the minimum achievable value of negative log-

likelihood in the class of rule ensembles $\mathcal{F}$, i.e. if ℓ^∞ is equal to $\ell^* = \inf_{\mathbf{f}\in\mathcal{F}} \ell(\mathbf{f})$? The answer is negative because a greedy procedure is used to find the condition part of rule Φ. Then, even if a "descent direction" rule exists, the procedure may fail to find it (although the resampling strategy improves the procedure by randomly perturbing the training set in each iteration, which helps to avoid "local minima"). Nevertheless, this questions seems not to be of practical importance here, since we fix the maximal number of rules M. This is due to the empirical evidences showing that ensemble methods sometimes overfit on real-life data when the size of the ensemble is too large. In the next subsection, we describe another stopping condition, independent of the parameter M.

5.2. Avoiding overfitting

A decision rule has the form of m-dimensional rectangle. It can be shown, that the class of m-dimensional rectangles has Vapnik-Chervonenkis (VC) dimension equal to $2m$ and the VC dimension does not depend on the number of cuts. This is contrary to the tree classifier, for which the VC dimension grows to infinity with increasing number of cuts (nodes). Therefore, in case of tree ensembles, one usually specifies some constraints on tree complexity, e.g. maximal number of nodes, while in case of a rule ensemble no such constraints are necessary.

The theoretical results (Schapire et al., 1998) suggest that an ensemble with a simple base classifier (with low VC dimension) and high prediction confidence (margin) on the dataset generalizes well, regardless of the size of the ensemble. Nevertheless, we conducted the computational experiments which show that the performance of rule ensemble can deteriorate as the number of rules grows, especially for the problems with high noise level. Similar phenomenon has been observed for other boosting algorithms, in particular for AdaBoost (Mason et al., 1999; Friedman et al., 2000; Dietterich, 2000). Therefore, we propose a procedure for stopping the ensemble growth, based on the simple "holdout set" analysis.

Each rule is induced from the subsample of size $\eta < n$ without replacement. Thus, there are $n - \eta$ objects which do not take part in the induction procedure and can be used as a holdout set to estimate the quality of the induced rule. Since each rule votes for a single class, we calculate a simple 0-1 error (accuracy) of such a rule on the covered objects from the holdout set. A rule is *acceptable* if the holdout error is better (lower) than random guessing. Then, the stopping condition has the following form: in any p subsequent iterations at least q rules are not acceptable. Such "averaging" over the iterations removes variations and allows us to observe the longer-term behavior of rule acceptability. We set $p = 10$ and $q = 8$, and those values were obtained by noticing, that when the null hypothesis states that rules are not worse than random guessing, at least 8 unacceptable rules must be obtained in 10 trials to reject the null hypothesis in the binomial test with confidence level 0.05. Another possibility for stopping the ensemble growth is running the internal cross validation, but such procedure has not been used in the experiment due to computational complexity.

5.3. Ordinal classification

It is often the case that a meaningful order relation between class labels exists. For example, in recommender systems, users are often asked to evaluate items on five value ("stars") scale. Such problems are often referred to as ordinal classification problems. Here we show how the order relation can be taken into account in MLRules. Without loss of generality, we assume that the order between classes is concordant with the order between class labels coded as natural numbers $Y = \{1, \ldots, K\}$.

To capture the ordinal properties of Y, we only take into account rules voting for "at least" and "at most" class unions, where by "at least" class union we mean set $\{k, \ldots, K\}$ for some k, while by "at most" class union we mean $\{1, \ldots, k\}$. Such rules can be incorporated by considering the vectors $\mathbf{v}$ in the response of the rule to be of the form: $\mathbf{v} = \{-1, \ldots, -1, 1, \ldots, 1\}$ (vote for "at least" union) or $\mathbf{v} = \{1, \ldots, 1, -1, \ldots, -1\}$ (vote for "at most" union), so that the rule increases the probability of a class union, and not of a single class.

The whole algorithm remains the same, apart from the formulas (16) and (17), which now takes the form:

$$\ell'(\mathbf{f}, \mathbf{v}\Phi) = \sum_{\Phi(\mathbf{x}_i)=1} \sum_{k=1}^{K} v_k (p_{ik} - \delta_{k,y_i}), \tag{19}$$

$$\ell''(\mathbf{f}, \mathbf{v}\Phi) = \sum_{\Phi(\mathbf{x}_i)=1} \sum_{1=t}^{K} v_k p_{ik} \left(1 - \sum_{k=1}^{K} v_k p_{ik}\right). \tag{20}$$

The experimental verification of the usefulness of such rule representation is postponed for future research due to the lack of space.

6. Experimental Results

In this section, we show the results of the computational experiments on real datasets. First, we examine

the behavior of the ensemble as the number of rules increases. Then, we compare our algorithm with existing approaches to rule induction.

6.1. Error curves

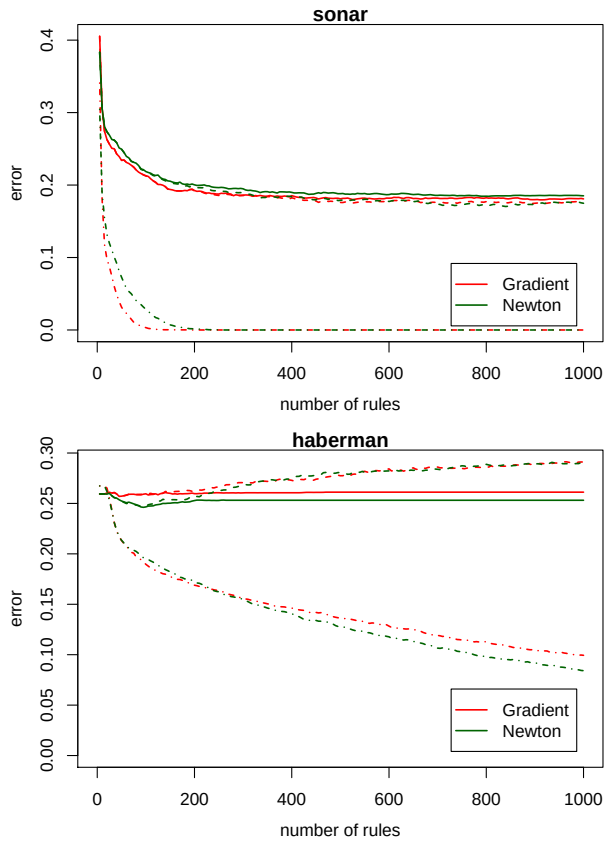

Figure 1. Train and test errors as functions of the ensemble size, obtained by splitting the data into train (66%) and test (33%) sets and averaging over 50 random splits. The lower lines (dashed-dotted) correspond to the train error, upper solid lines – to the test error with stopping condition described in Section 5.2, upper dashed line – test error when the stopping condition was not applied. Parameters of the MLRules are: $\nu = 0.1, \eta = 0.5n$

In Figure 6.1, we present the train and test error as a function of the ensemble size M for two real datasets, taken from the UCI Repository (Asuncion & Newman, 2007). On the *sonar* dataset, both ensembles (gradient and Newton) do not overfit and the test error decreases even if the number of rules reaches 1000; this is a rather typical situation. An atypical one can be found on the second dataset (*haberman*), where from some point, test error starts to increase. However, then a stopping condition described in Section 5.2 is satisfied which prevents rule ensemble from overfitting.

6.2. Comparison with other rule ensemble algorithms

To check the performance of MLRules on the real datasets, we compare them with three existing rule induction algorithms. SLIPPER (Cohen & Singer, 1999) was proposed within the AdaBoost reweighting scheme and uses an induction procedure which involves pruning. LRI (Weiss & Indurkhya, 2000) generates rules in the form of a DNF-formula and uses a specific reweighting scheme based on the cumulative errors. RuleFit (Friedman & Popescu, 2005) is based on FSAM framework (Hastie et al., 2003), but it uses the regression trees as base classifiers and then transforms them to rules. All three approaches are thus based on some boosting/reweighting strategy. According to our knowledge, RuleFit has not been compared with SLIPPER and LRI yet.

We used 35 files taken from UCI Repository (Asuncion & Newman, 2007), among which 20 files are binary classification tasks and 15 are multi-class tasks. We omit characteristics of the datasets due to lack of space. We tested four classifiers on each dataset (MLRules with gradient and Newton steps, LRI and SLIPPER) and RuleFit on binary datasets only (RuleFit does not handle multi-class case). We selected the following parameters for each method:

- SLIPPER: we set maximum number of iteration to 500, rest of parameters were set to default (we kept the internal cross validation, used to choose the optimal number of rules).
- LRI: According to (Weiss & Indurkhya, 2000), we set the rule length to 5 and froze feature after 50 rounds; we also chose 200 rules per class and 2 disjuncts since some previous tests showed that those values work well in practice.
- RuleFit: According to the experiment in (Friedman & Popescu, 2005), we chose mixed rule-linear mode, set average tree size to 4, increased the number of trees to 500, and chose subsample size η as $\min\{0.5n, 100 + 6\sqrt{n}\}$.
- MLRules: We set $\eta = 0.5n, \nu = 0.1, M = 500$, but for the tree biggest datasets (*letter*, *optdigits*, *pendigits*) we increased M to 2000 (to compare, LRI had 26×200 rules for *letter*). Those parameters have not been optimized on the UCI data. We used artificial data to this end and due to the space limit we omit the characteristic of the data generating model.

Each test was performed using 10-fold cross validation

Table 1. Test errors and ranks (in parenthesis). MLRules.G and MLRules.N are MLRules with gradient and Newton method, respectively. Average ranks in the last row correspond to comparing LRI and MLRules on all 35 files.

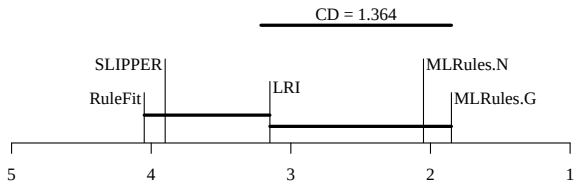

Figure 2. Critical difference diagram

(with exactly the same train/test splits for each classifier) and average 0-1 loss on the test set was calculated. The results are shown in Table 6.2.

We first restrict the analysis to binary-class problems only. To compare multiple classifiers on the multiple datasets, we follow Demšar (2006), and make the Friedman test, which uses ranks of each algorithm to check whether all the algorithms perform equally well (null hypothesis). Friedman statistics gives 33.28 which exceeds the critical value 9.488 (for confidence level 0.05), so we can reject the null hypothesis and state that classifiers are not equally good. Next, we proceed to a post-hoc analysis and calculate the *critical difference* (CD) according to the Nemeneyi statistics. We obtain $CD = 1.364$ which means that algorithms with difference in average ranks more than 1.364 are significantly different. In Figure 6.2 average ranks were marked on a line, and groups of classifiers that are not significantly different were connected. This shows that both MLRules algorithms are not sig-

nificantly different to LRI, however they outperform both SLIPPER and RuleFit. On the other hand, none of three well-known rule ensemble algorithms (LRI, SLIPPER, RuleFit) is significantly better to any other.

The situation remains roughly the same if we compare the algorithms using all 35 datasets. We exclude RuleFit (it does not work with multi-class problems) and SLIPPER (its results are very poor, the worst almost every time[1]). Thus, we end up with 3 algorithms. Friedman statistics gives 3.53 which does not exceed the critical value 5.991, so that the null hypothesis cannot be rejected. Note that the difference in ranks decreased, mainly because LRI performs excellent on the largest datasets (letters and digits recognition).

It is interesting to check how much of the improvement in accuracy of MLRules comes from shrinkage, resampling and regularizing the rule response, because those techniques can also be simply incorporated to SLIPPER and LRI. We plan to investigate this issue in our future research.

7. Conclusions and Future Research

We proposed a new rule induction algorithm for solving classification problems, called MLRules, based on the maximum likelihood estimation method and using boosting strategy in rule induction. In contrary to previously considered algorithms, it estimates the conditional class probability distribution and therefore can work with any cost matrix for classification. We considered two optimization techniques, based on gradient and Newton steps, and introduced a stopping condition to avoid overfitting. The performance of MLRules was verified on a large collection of datasets, both binary- and multi-class. Our algorithm is competitive or outperforms the best existing approaches to rule induction.

We also suggested the way in which MLRules can capture the order between classes and therefore can solve the ordinal classification problems. We plan to verify this issue experimentally in the future.

Abstract

We address the problem of learning decision functions from training data in which some attribute values are unobserved. This problem can arise, for instance, when training data is aggregated from multiple sources, and some sources record only a subset of attributes. We derive a generic joint optimization problem in which the distribution governing the missing values is a free parameter. We show that the optimal solution concentrates the density mass on finitely many imputations, and provide a corresponding algorithm for learning from incomplete data. We report on empirical results on benchmark data, and on the email spam application that motivates our work.

1. Introduction

In many applications, one has to deal with training data with incompletely observed attributes. For instance, training data may be aggregated from different sources. If not all sources are capable of providing the same set of input attributes, the combined training sample contains incompletely observed data. This situation occurs in email spam detection, where it is helpful to augment the content of an email with real-time information about the sending server, such as its blacklist status. This information is available for all training emails that arrive at a mail server under one's own control, and it is also available at application time. But if one wants to utilize training emails from public archives, this information is missing.

We adress a learning setting in which values are *missing at random:* here, the presence or absence of values does not convey information about the class labels. If this condition is not met, it is informative to consider the presence or absence of values as additional input to the decision function. Techniques for learning from incomplete data typically involve a distributional model that imputes missing values, and the desired final predictive model. Prior work on learning from incomplete data is manifold in the literature, and may be grouped by the way the distributional model is used.

The first group models the distribution of missing values in a first step, and learns the decision function based on the distributional model in a second step. Shivaswamy et al. (2006) formulate a loss function that takes a fixed proportion of the probability mass of each instance into account, with respect to the estimated distribution of missing values. They derive second order cone programs which renders the method applicable only to very small problems. Other examples include Williams and Carin (2005), Williams et al. (2005), and Smola et al. (2005).

The second group estimates the parameters of a distributional model and the final predictive model jointly. As an example, recently Liao et al. (2007) propose an EM-algorithm for jointly estimating the imputation model and a logistic regression classifier with linear kernel, assuming the data arises from a mixture of multivariate Gaussians.

The third group makes no model assumption about the missing values, but learns the decision function based on the visible input alone. For example, Chechik et al. (2007) derive a geometrically motivated approach. For each example, the margin is re-scaled according to the visible attributes. This procedure specifically aims at learning from data with values that are *structurally missing*—as opposed to *missing at random*. Chechik et al. (2007) find empirically that the procedure is not adequate when values are missing at random.

Jointly learning a distributional model and a kernel predictive model relates to the problem of learning a

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

kernel function from a prescribed set of parameterized kernels. This problen drew a lot of attention recently; see, for example, Argyriou et al. (2005) and Micchelli and Pontil (2007).

Estimating the distributional model first and training the predictive model in a second step leaves the user free to choose any learning algorithm for this second step. However, a harder problem has to be solved than would be necessary. If one is only interested in a decision function that minimizes the desired loss, knowing the values or distribution of the missing attributes in the training set is not actually required. Furthermore, errors made in the imputation step and errors made in estimating the parameters of the predictive model can add up in a sequential procedure.

Consequently, we investigate learning the decision function and the distribution of imputations dependently. Unlike prior work on this topic, we develop a solution for a very general class of optimization criteria. Our solution covers a wide range of loss functions for classification and regression problems. It comes with all the usual benefits of kernel methods. We derive an optimization problem in which the distribution governing the missing values is a free parameter. The optimization problem searches for a decision function and a distribution governing the missing values which together minimize a regularized empirical risk.

No fixed parametric form of the distributional model is assumed. A regularizer that can be motivated by a distributional assumption may *bias* the distributional model *towards* a prior belief. However, the regularizer may be overruled by the data, and the resulting distributional model may be different from any parametric form. We are able to prove that there exists an optimal solution based on a distribution that is supported by finitely many imputations. This justifies a greedy algorithm for finding a solution. We derive manifestations of the general learning method and study them empirically.

The paper is structured as follows. After introducing the problem setting in Section 2, we derive an optimization problem in Section 3. Section 4 proves that there is an optimal solution that concentrates the density mass on finitely many imputations and presents an algorithm. Example instantiations of the general solution are presented in Section 5. We empirically evaluate the method in Section 6. Section 7 concludes.

2. Problem Setting

We address the problem of learning a decision function f from a training sample in which some attribute values are unobserved.

Let $\mathbf{X}$ be a matrix of n training instances $\mathbf{x}_i$ and let $\mathbf{y}$ be the vector of corresponding target values y_i. Instances and target values are drawn *iid* from an unknown distribution $p(\mathbf{x}, y)$ with $\mathbf{x}_i \in \mathbb{R}^d$ and $y_i \in \mathcal{Y}$, where $\mathcal{Y}$ denotes the set of possible target values. Matrix $\mathbf{Z}$ indicates which features are observed. A value of $z_{il} = 1$ indicates that x_{il}, the l-th feature of the i-th example, is observed. Values are *missing at random:* y_i is conditionally independent of $\mathbf{z}_i$ given $\mathbf{x}_i$.

The goal is to learn a function $f : \mathbf{x} \mapsto y$ that predicts target values for *completely observed* examples. The decision function should incur only a minimal true risk $R(f) = \int L(y, f(\mathbf{x}))p(\mathbf{x}, y)d\mathbf{x}dy$, where L is a loss function for the task at hand.

As a means to minimizing the true risk, we seek a function f in the *reproducing kernel Hilbert space* $\mathcal{H}_k$ induced by a kernel k that minimizes a regularized empirical risk functional $R(f) = \sum_{i=1}^{n} l(y_i, f(\mathbf{x}_i)) + \eta\|f\|_k^2$. We demand k to be a Mercer kernel. Loss function l approximates the true loss L. The *representer theorem* allows us to write the minimizer as a sum over functions in $\mathcal{H}_k$ centered at training instances: $f(\mathbf{x}) = \sum_{j=1}^{n} c_j k(\mathbf{x}_j, \mathbf{x})$.

The learning problem from completely observed data would amount to solving Optimization Problem 1.

Optimization Problem 1 (Primal learning problem, observed data). *Over* $\mathbf{c}$*, minimize*

$$R(\mathbf{c}, k) = \sum_{i=1}^{n} l\Big(y_i, \sum_{j=1}^{n} c_j k(\mathbf{x}_j, \mathbf{x}_i)\Big) + \eta \sum_{i,j=1}^{n} c_i c_j k(\mathbf{x}_j, \mathbf{x}_i)$$

We require that the loss function be defined in such a way that Optimization Problem 1 can be written in the dual form of Optimization Problem 2. A wide range of loss functions satisfies this demand; we will later see that this includes hinge loss and squared loss.

Optimization Problem 2 (Dual of learning problem). *Given* $a < 0$*, over* $\mathbf{c}$*, maximize*

$$a \langle \mathbf{c}, \mathbf{K}\mathbf{c} \rangle - R^*(\mathbf{c})$$

subject to the constraints

$$\forall_{i=1}^{m_1^*} g_i^*(\mathbf{c}) \leq 0, \qquad \forall_{j=1}^{m_2^*} h_j^*(\mathbf{c}) = 0. \tag{1}$$

$R^*(\mathbf{c})$ denotes a differentiable convex function of the dual variables $\mathbf{c}$ which we demand to be independent of the kernel matrix $\mathbf{K}$. The inequality constraints g_i^* are differentiable convex and the equality constraints h_j^* differentiable affine. We like to note that the requirement of independence between R^* and $\mathbf{K}$ is not

very restrictive in practice, as we will see in chapter 5. Furthermore, we demand strong duality to hold between Optimization problems 1 and 2.

3. Learning from Incomplete Data in One Step

If any instance $\mathbf{x}_i$ has unobserved features, then $k(\mathbf{x}_i, \mathbf{x})$ and, consequently, the decision function f are not properly defined. In order to learn from incomplete data, we will marginalize the decision function and risk functional by the observable attributes and integrate over all unobserved quantities. To this end, we define $\boldsymbol{\omega} \in \Omega_{\mathbf{X}}^{\mathbf{Z}} \subset \mathbb{R}^{n \times d}$ as a matrix of imputations constrained by $\omega_{il} = x_{il}$ if $z_{il} = 1$. We demand $\Omega_{\mathbf{X}}^{\mathbf{Z}}$ to be compact for the rest of this paper. Let $\boldsymbol{\omega}_i$ denote the i-th row of $\boldsymbol{\omega}$. Then we can define a family of kernels $K(\boldsymbol{\omega})(\mathbf{x}_j, \mathbf{x}_i) = k(\boldsymbol{\omega}_j, \boldsymbol{\omega}_i)$. Any probability measure $p(\boldsymbol{\omega})$ on imputations induces a marginalization of the kernel by the observable variables. Equation 2 integrates over all imputations of unobserved values; it can be evaluated based on the observed values.

$$K(p)(\mathbf{x}_j, \mathbf{x}_i) = \int_{\boldsymbol{\omega} \in \Omega_{\mathbf{X}}^{\mathbf{Z}}} k(\boldsymbol{\omega}_j, \boldsymbol{\omega}_i) dp(\boldsymbol{\omega}) \tag{2}$$

Any probability measure $p(\boldsymbol{\omega})$ constitutes an optimization criterion $R(\mathbf{c}, K(p))$. In the absence of knowledge about the true distribution of missing values, $p(\boldsymbol{\omega})$ becomes a free parameter. Note that $p(\boldsymbol{\omega})$ is a continuous probability measure that is not constrained to any particular parametric form; the space of parameters is therefore of infinite dimensionality.

It is natural to add a regularizer $Q(p)$ that reflects prior belief on the distribution of imputations $p(\boldsymbol{\omega})$ to the optimization criterion, in addition to the empirical risk and regularizer on the predictive model. The regularizer is assumed to be continuous in p. The regularizer does not *constrain* $p(\boldsymbol{\omega})$ to any specific class of distribution, but it reflects that some distributions are believed to be more likely. Without a regularizer, the criterion can often be minimized by imputations which move instances with missing values far away from the separator, thereby removing their influence on the outcome of the learning process. This leads to Optimization Problem 3.

Optimization Problem 3 (Learning problem with infinite imputations). *Given n training examples with incomplete feature values, $\gamma > 0$, kernel function k, over all $\mathbf{c}$ and p, minimize*

$$\tilde{R}_{k,\gamma}(\mathbf{c}, p) \quad = \quad R(\mathbf{c}, K(p)) + \gamma Q(p) \tag{3}$$

subject to the constraints

$$\forall \boldsymbol{\omega} : \; p(\boldsymbol{\omega}) \geq 0, \qquad \int_{\boldsymbol{\omega} \in \Omega_{\mathbf{X}}^{\mathbf{Z}}} p(\boldsymbol{\omega}) d\boldsymbol{\omega} = 1.$$

Each solution to Optimization Problem 3 integrates over *infinitely* many different imputations. The search space contains all continuous probability measures on imputations, the search is guided by the regularizer Q. The regularization parameter γ determines the influence of the regularization on the resulting distribution. For $\gamma \to \infty$ the solution of the optimization reduces to the solution obtained by first estimating the distribution of missing attribute values that minimizes the regularizer. For $\gamma \to 0$ the solution is constituted by the distribution minimizing the risk functional R.

4. Solving the Optimization Problem

In this section, we devise a method for efficiently finding a solution to Optimization Problem 3. Firstly, we show that there exists an optimal solution $\hat{\mathbf{c}}, \hat{p}$ with $\hat{p}$ supported on at most $n+2$ imputations $\boldsymbol{\omega} \in \Omega_{\mathbf{X}}^{\mathbf{Z}}$. Secondly, we present an algorithm that iteratively finds the optimal imputations and parameters minimizing the regularized empirical risk.

4.1. Optimal Solution with Finite Combination

In addition to the parameters $\mathbf{c}$ of the predictive models, continuous probability measure $p(\boldsymbol{\omega})$ contributes an infinite set of parameters to Optimization Problem 3. The implementation of imputations as parameters of a kernel family allows us to show that there exists an optimal probability measure $\hat{p}$ for Equation 3 such that $\hat{p}$ consists of finitely many different imputations.

Theorem 1. *Optimization Problem 3 has an optimal solution $\hat{\mathbf{c}}, \hat{p}$ in which $\hat{p}$ is supported by at most $n+2$ imputations $\boldsymbol{\omega} \in \Omega_{\mathbf{X}}^{\mathbf{Z}}$.*

Proof. The compactness of $\Omega_{\mathbf{X}}^{\mathbf{Z}}$ and the continuity of $\mathbf{K}$ immediately imply that *there exists some* solution to Optimization Problem 3. It remains to be shown that at least one of the solutions is supported by at most $n+2$ imputations. Let $\bar{\mathbf{c}}, \bar{p}$ be *any* solution and let all requirements of the previous section hold. The idea of this proof is to construct a correspondence between distributions over imputations and vectors in $\mathbb{R}^{n+1}$, where a finite support set is known to exist. Define $\mathbf{S}(\boldsymbol{\omega}) = \mathbf{K}(\boldsymbol{\omega})\bar{c} \in \mathbb{R}^n$ and $D = \{(\mathbf{S}(\boldsymbol{\omega})^\top, Q(\boldsymbol{\omega}))^\top : \boldsymbol{\omega} \in \Omega_{\mathbf{X}}^{\mathbf{Z}}\} \subset \mathbb{R}^{n+1}$. Since $\Omega_{\mathbf{X}}^{\mathbf{Z}}$ is compact and $K(\cdot)$ and $Q(\cdot)$ are continuous by definition, D is compact as well. We define a measure over D as $\mu(A \times B) = \bar{p}(\{\boldsymbol{\omega} : \mathbf{S}(\boldsymbol{\omega}) \in A \wedge Q(\boldsymbol{\omega}) \in B\})$.

Then, by Carathéodory's convex hull theorem, there exists a set of k vectors $\{(\mathbf{s}_1^\top, q_1)^\top, \ldots, (\mathbf{s}_k^\top, q_k)^\top\} \subseteq D$ with $k \leq n+2$ and nonnegative constants ν_i with

$\sum_{i=1}^{k} \nu_i = 1$, such that

$$\int_D (\mathbf{s}^\top, q)^\top d\mu((\mathbf{s}^\top, q)^\top) = \sum_{i=1}^{k} (\mathbf{s}_i^\top, q_i)^\top \nu_i.$$

For each i, select any $\boldsymbol{\omega}_i$ such that $(\mathbf{S}(\boldsymbol{\omega}_i)^\top, Q(\boldsymbol{\omega}_i)) = (\mathbf{s}_i^\top, q_i)$. We construct $\hat{p}$ by setting $\hat{p}(\boldsymbol{\omega}) = \sum_{i=1}^{k} \nu_i \delta_{\boldsymbol{\omega}_i}$, where $\delta_{\boldsymbol{\omega}_i}$ denotes the Dirac measure at $\boldsymbol{\omega}_i$. The optimal $\hat{\mathbf{c}}$ results as $\arg\min_{\mathbf{c}} R(\mathbf{c}, K(\hat{p}))$. We have

$$\begin{aligned} \int_D \mathbf{s} d\mu((\mathbf{s}^\top, q)^\top) &= \sum_{i=1}^{k} \mathbf{s}_i \nu_i, \quad \text{and} \\ \int_D q d\mu((\mathbf{s}^\top, q)^\top) &= \sum_{i=1}^{k} q_i \nu_i. \end{aligned}$$

Then

$$\begin{aligned} \mathbf{K}(\bar{p})\bar{\mathbf{c}} &= \left(\int_{\Omega_{\mathbf{X}}^{\mathbf{Z}}} \mathbf{K}(\boldsymbol{\omega}) d\bar{p}(\boldsymbol{\omega}) \right) \bar{\mathbf{c}} = \int_{\Omega_{\mathbf{X}}^{\mathbf{Z}}} \mathbf{S}(\boldsymbol{\omega}) d\bar{p}(\boldsymbol{\omega}) \\ &= \int_D \mathbf{S}(\boldsymbol{\omega}) d\mu \left((\mathbf{S}(\boldsymbol{\omega})^\top, Q(\boldsymbol{\omega}))^\top \right) \\ &= \sum_{i=1}^{k} \mathbf{s}_i \nu_i = \int_{\Omega_{\mathbf{X}}^{\mathbf{Z}}} \mathbf{S}(\boldsymbol{\omega}) d\hat{p}(\boldsymbol{\omega}) \\ &= \int_{\Omega_{\mathbf{X}}^{\mathbf{Z}}} \mathbf{K}(\boldsymbol{\omega}) d\hat{p}(\boldsymbol{\omega}) \bar{\mathbf{c}} = \mathbf{K}(\hat{p})\bar{\mathbf{c}}. \end{aligned}$$

Likewise,

$$\begin{aligned} Q(\bar{p}) &= \int_D Q(\boldsymbol{\omega}) \, d\mu \left((\mathbf{S}(\boldsymbol{\omega})^\top, Q(\boldsymbol{\omega}))^\top \right) \\ &= \sum_{i=1}^{k} q_i \nu_i = Q(\hat{p}). \end{aligned}$$

Since $Q(p)$ does not depend on $\mathbf{c}$, $\bar{\mathbf{c}} = \arg\min_{\mathbf{c}} R(\mathbf{c}, \mathbf{K}(\bar{p}))$, and by strong duality, $\bar{\mathbf{c}} = \arg\max_{\mathbf{c}} a \langle \mathbf{c}, \mathbf{K}(\bar{p})\mathbf{c} \rangle - R^*(\mathbf{c})$. This implies that the Karush-Kuhn-Tucker conditions hold for $\bar{\mathbf{c}}$, namely there exist constants $\kappa_i \geq 0$ and λ_j such that

$$a\mathbf{K}(\bar{p})\bar{\mathbf{c}} - \nabla R^*(\bar{\mathbf{c}}) + \sum_i \kappa_i \nabla g_i^*(\bar{\mathbf{c}}) + \sum_j \lambda_j \nabla h_j^*(\bar{\mathbf{c}}) = 0$$

$$\forall_i \;\; g_i^*(\bar{\mathbf{c}}) \leq 0, \quad \forall_j \;\; h_i^*(\bar{\mathbf{c}}) = 0, \quad \forall_i \;\; \kappa_i g_i^*(\bar{\mathbf{c}}) = 0$$

It is easy to see that therefore $\bar{\mathbf{c}}$ is also a maximizer of $a \langle \mathbf{c}, \mathbf{K}(\hat{p})\mathbf{c} \rangle - R^*(\mathbf{c})$, because $\mathbf{K}(\bar{p})\bar{\mathbf{c}} = \mathbf{K}(\hat{p})\bar{\mathbf{c}}$ and the Karush-Kuhn-Tucker conditions still hold. Their sufficiency follows from the fact that $\mathbf{K}(p)$ is positive semi-definite for any p, and the convexity and affinity premises. Thus,

$$\begin{aligned} & R(\bar{\mathbf{c}}, K(\bar{p})) + \gamma Q(\bar{p}) \\ &= \left[\min_{\mathbf{c}} R(\mathbf{c}, K(\bar{p})) \right] + \gamma Q(\bar{p}) \\ &= \left[\max_{\mathbf{c}} a \langle \mathbf{c}, \mathbf{K}(\bar{p})\mathbf{c} \rangle - R^*(\mathbf{c}) \right] + \gamma Q(\bar{p}) \\ &= [a \langle \bar{\mathbf{c}}, \mathbf{K}(\bar{p})\bar{\mathbf{c}} \rangle - R^*(\bar{\mathbf{c}})] + \gamma Q(\bar{p}) \\ &= [a \langle \bar{\mathbf{c}}, \mathbf{K}(\hat{p})\bar{\mathbf{c}} \rangle - R^*(\bar{\mathbf{c}})] + \gamma Q(\hat{p}) \\ &= \left[\max_{\mathbf{c}} a \langle \mathbf{c}, \mathbf{K}(\hat{p})\mathbf{c} \rangle - R^*(\mathbf{c}) \right] + \gamma Q(\hat{p}) \\ &= \left[\min_{\mathbf{c}} R(\mathbf{c}, K(\hat{p})) \right] + \gamma Q(\hat{p}) \\ &= R(\hat{\mathbf{c}}, K(\hat{p})) + \gamma Q(\hat{p}). \end{aligned}$$

We have now established that there exists a solution with at most $n + 2$ imputations. □

4.2. Iterative Optimization Algorithm

This result justifies the following greedy algorithm to find an optimal solution to Optimization Problem 3. The algorithm works by iteratively optimizing Problem 1 (or, equivalently, 2), and updating the distribution over the missing attribute values. Let $p_{\bar{\boldsymbol{\omega}}}$ denote the distribution $p(\boldsymbol{\omega}) = \delta_{\bar{\boldsymbol{\omega}}}$. Algorithm 1 shows the steps.

Algorithm 1 Compute optimal distribution of imputations on $\Omega_{\mathbf{X}}^{\mathbf{Z}}$

Initialization: Choose $p^{(1)} = p_{\boldsymbol{\omega}^{(1)}}$; e.g., $\boldsymbol{\omega}_{il}^{(1)} = 0$ for all $z_{il} \neq 1$
for $t = 1 \ldots$ **do**
1. $\hat{\mathbf{c}} \leftarrow \arg\min_{\mathbf{c}} R(\mathbf{c}, K(p^{(t)}))$
2. Find $\boldsymbol{\omega}^{(t+1)} \in \Omega_{\mathbf{X}}^{\mathbf{Z}}$: $\tilde{R}_{k,\gamma}(\hat{\mathbf{c}}, p_{\boldsymbol{\omega}^{(t+1)}}) < \tilde{R}_{k,\gamma}(\hat{\mathbf{c}}, p^{(t)})$. If no such $\boldsymbol{\omega}^{(t+1)}$ exists, terminate.
3. $\beta_t \leftarrow \arg\min_{\beta \in (0,1]} \left[\min_{\mathbf{c}} \tilde{R}_{k,\gamma}(\mathbf{c}, \beta p_{\boldsymbol{\omega}^{(t+1)}} + (1-\beta)p^{(t)}) \right]$
4. $p^{(t+1)} \leftarrow \beta_t p_{\boldsymbol{\omega}^{(t+1)}} + (1-\beta_t)p^{(t)}$
5. $\forall j < t : \; \beta_j \leftarrow \beta_j(1-\beta_t)$
end for

Step 1 consists of minimizing the regularized empirical risk functional R, given the current distribution. In step 2 a new imputation is constructed which improves on the current objective value. Since in general $\tilde{R}_{k,\gamma}(\mathbf{c}, p_{\boldsymbol{\omega}})$ is not convex in $\boldsymbol{\omega}$, one cannot find the *optimal* $\boldsymbol{\omega}$ efficiently. But the algorithm only requires to find *any* better $\boldsymbol{\omega}$. Thus it is reasonable to perform gradient ascent on $\boldsymbol{\omega}$, with random restarts in case the found local optimum does not satisfy the inequality of step 2. In step 3 and 4 the optimal distribution consisting of the weighted sum of currently used Dirac impulses $\sum_{i=1}^{t} \beta_i \delta_{\boldsymbol{\omega}_i}$ and the new imputation $\delta_{\boldsymbol{\omega}^{(t+1)}}$ is computed. This step is convex in β if

$\tilde{R}_{k,\gamma}(\mathbf{c}, \beta p_{\boldsymbol{\omega}^{(t+1)}} + (1-\beta)p^{(t)})$ is linear in β. By looking at Optimization Problem 2, we see that this is the case for R. Thus the convexity depends on the choice for Q (see Sect. 5.2). Step 5 updates the weights of the previous imputations.

The algorithm finds t imputations $\boldsymbol{\omega}^{(j)}$ and their weights β_j, as well as the optimal example coefficients $\mathbf{c}$. We can construct the classification function f as

$$f(\mathbf{x}) \quad = \quad \sum_{j=1}^{t} \sum_{i=1}^{n} \beta_j \mathbf{c}_i k(\boldsymbol{\omega}_i^{(j)}, \mathbf{x}). \tag{4}$$

Note that the value $n+2$ is an upper bound for the number of basic kernels which constitute the optimal solution. The algorithm is not guaranteed to terminate after $n+2$ iterations, because the calculated imputations are not necessarily optimal. In practice, however, the number of iterations is usually much lower. In our experiments, the objective value of the optimization problem converges in less than 50 iterations.

5. Example Learners

In this chapter we present manifestations of the generic method, which we call *weighted infinite imputations*, for learning from incomplete data that we use in the experimental evaluation.

Recall from Section 3 the goal to learn a decision function f from incomplete data that minimizes the expected risk $R(f) = \int L(y, f(\mathbf{x}))p(\mathbf{x}, y)d\mathbf{x}dy$. In classification problems the natural loss function L becomes the *zero-one loss*, whereas in regression problems the loss depends on the specific application; common choices are the *squared error* or the ϵ-*insensitive* loss. The considerations in the previous chapters show that, in order to learn regression or classification functions from training instances with missing attribute values, we only have to specify the dual formulation of the preferred learning algorithm on complete data and a regularizer on the distribution of imputations p.

5.1. Two Standard Learning Algorithms

For binary classification problems, we choose to approximate the zero-one by the *hinge* loss and perform *support vector machine* learning. The dual formulation of the SVM is given by $R^{SVM}(\mathbf{c}, k) = \sum_{i=1}^{n} \frac{c_i}{y_i} - \frac{1}{2}\sum_{i,j=1}^{n} c_i c_j k(\mathbf{x}_j, \mathbf{x}_i)$ subject to the constraints $0 \leq \frac{c_i}{y_i} \leq \frac{1}{\eta}$ and $\sum_{i=1}^{n} c_i = 0$. We see that the demands of Optimization Problem 2 are met and a finite solution can be found. Taking the SVM formulation as the dual Optimization Problem 2 gives us the means – in conjunction with an appropriate regularizer Q – to learn a classification function f from incomplete data.

For regression problems, the loss depends on the task at hand, as noted above. We focus on penalizing the *squared error*, though we like to mention that the approach works for other losses likewise. One widely used learning algorithm for solving the problem is *kernel ridge regression*. Again, we can learn the regression function f from incomplete data by using the same principles as described above. Kernel ridge regression minimizes the regularized empirical risk $\sum_{i=1}^{n}(y_i - f(\mathbf{x}_i))^2 + \eta\|f\|^2$. The dual formulation $R^{KRR}(\mathbf{c}, k) = \sum_{i=1}^{n} c_i y_i - \frac{1}{4}\sum_{i=1}^{n} c_i^2 + \frac{1}{4\eta}\sum_{i,j=1}^{n} c_i c_j k(x_i, x_j)$ again meets the demands of the dual optimization problem 2. Substituting its primal formulation for R in step 1 of Algorithm 1 and in Eqn. 3 solves the problem of learning the regression function from incomplete data after specifying a regularizer Q.

5.2. Regularizing towards Prior Belief in Feature Space

A regularizer on the distribution of missing values can guide the search towards distributions $\hat{\boldsymbol{\omega}}$ that we believe to be likely. We introduce a regularization term which penalizes imputations that are different from our prior belief $\hat{\boldsymbol{\omega}}$. We choose to penalize the sum of squared distances between instances $\mathbf{x}_i$ and $\hat{\boldsymbol{\omega}}_i$ in *feature space* $\mathcal{H}_k$ induced by kernel k. We define the squared distance regularization term Q^{sq} as

$$\begin{aligned} Q^{sq}(k, \hat{\boldsymbol{\omega}}) \quad &= \quad \sum_{i=1}^{n} \|\phi_k(\mathbf{x}_i) - \phi_k(\hat{\boldsymbol{\omega}}_i)\|_2^2 \\ &= \quad \sum_{i=1}^{n} k(\mathbf{x}_i, \mathbf{x}_i) - 2k(\mathbf{x}_i, \hat{\boldsymbol{\omega}}_i) + k(\hat{\boldsymbol{\omega}}_i, \hat{\boldsymbol{\omega}}_i). \end{aligned}$$

Note that when using Q^{sq}, step 3 of Algorithm 1 becomes a convex minimization procedure.

5.3. Imputing the Mean in Feature Space

In principle any imputation we believe is useful for learning a good classifier can be used as $\hat{\boldsymbol{\omega}}$. Several models of the data can be assumed to compute corresponding optimal imputations. We like to mention one interesting model, namely the class-based mean imputation in the *feature space* $\mathcal{H}_k$ induced by kernel k. This model imputes missing values such that the sum of squared distances between completed instances to the class-dependent mean in feature space is minimal over all possible imputations. $\hat{\boldsymbol{\omega}} = \arg\min_{\boldsymbol{\omega}} \sum_{i=1}^{n} \|\phi_k(\boldsymbol{\omega}_i) - \frac{1}{n_{y_i}}\sum_{j:y_j=y_i} \phi_k(\boldsymbol{\omega}_j)\|_2^2$, where n_y denotes the number of instances with label y. Simple algebraic manipulations show that this is equivalent to

minimizing the sum of squared distances between all instances $\sum_{v\in\{-1,1\}} \frac{1}{n_v} \sum_{i,j:y_i=y_j=v} \|\phi_k(\boldsymbol{\omega}_i) - \phi_k(\boldsymbol{\omega}_j)\|_2^2 = \sum_{v\in\{-1,1\}} \frac{1}{n_v} \sum_{i,j:y_i=y_j=v} \big[k(\boldsymbol{\omega}_i,\boldsymbol{\omega}_i) - 2k(\boldsymbol{\omega}_i,\boldsymbol{\omega}_j) + k(\boldsymbol{\omega}_j,\boldsymbol{\omega}_j)\big]$

Definition 1 (Mean in Feature Space). *The class-based* mean in feature space *imputation method imputes missing values $\hat{\boldsymbol{\omega}}$ which optimize*

$$\hat{\boldsymbol{\omega}} = \arg\min_{\boldsymbol{\omega}} \sum_{v\in\{-1,+1\}} \frac{1}{n_v} \sum_{i,j:y_i=y_j=v} \big[k(\boldsymbol{\omega}_i,\boldsymbol{\omega}_i) - 2k(\boldsymbol{\omega}_i,\boldsymbol{\omega}_j) + k(\boldsymbol{\omega}_j,\boldsymbol{\omega}_j)\big]$$

Note that this model reduces to the standard mean in input space when using the linear kernel.

6. Empirical Evaluation

We evaluate the performance of our generic approach *weighted infinite imputations* for two example realizations. We test for classification performance on the email spam data set which motivates our investigation. Furthermore, we test on seven additional binary classification problems and three regression problems.

6.1. Classification

We choose to learn the decision function for the binary classification task by substituting the risk functional of the *support vector machine*, $-R^{SVM}$, as presented in section 5.1 for R and the squared distance regularizer Q^{sq} (Section 5.2) for Q in Optimization Problem 3.

For the motivating problem setting, we assemble a data set of 2509 spam and non-spam emails, which are preprocessed by a linear text classifier which is currently in use at a large webspace hosting company. This classifier discriminates reasonably well between spam and non-spam, but there is still a small fraction of misclassified emails. The classifier has been trained on about 1 million emails from a variety of sources, including spam-traps as well as emails from the hosting company itself, recognizing more than 10 million distinct text features. On this scale, training a support vector machine with Gaussian kernel is impractical, therefore we employ a two-step procedure. We discard the contents of the emails and retain only their spam score from the text classifier and their size in bytes as content features in the second-step classifier. At the time of collection of the emails, we record auxiliary real-time information about the sending servers. This includes the number of valid and invalid receiver addresses of all emails seen from the server so far, and the mean and standard deviation of the sizes and spam scores of all emails from the server. Such information is not available for emails from external sources, but will be available when classifying unseen emails. We randomly draw 1259 emails, both spam and non-spam, with server information, whereas half of those were drawn from a set of misclassified spam-emails. We augment this set with 1250 emails drawn randomly from a source without server information for which only 2 of the 8 attributes are observed.

To evaluate the common odd versus even digits discrimination, random subsets of 1000 training examples from the USPS handwritten digit recognition set are used. We test on the remaining 6291 examples. Additionally, we test on KDD Cup 2004 Physics (1000 train, 5179 test, 78 attributes) data set and on the 4-view land mine detection data (500, 213, 41) as used by Williams and Carin (2005). In the latter, instances consist of 4 views on the data, each from a separate sensor. Consequently, we randomly select complete views as missing. From the UCI machine learning repository we take the Breast (277 instances, 9 features), Diabetes (768, 8), German (1000, 20), and Waveform (5000, 21) data sets. Selection criteria for this subset of the repository were minimum requirements on sample size and number of attributes.

On each data set we test the performance of *weighted infinite imputation* using four different regularization imputations $\hat{\boldsymbol{\omega}}$ for the regularizer $Q^{sq}(K(p),\hat{\boldsymbol{\omega}})$. These imputations are computed by *mean imputation in input space* (**MeanInput**) and *mean imputation in feature space* (**MeanFeat**) as by Definition 1. Additionally we use the *EM* algorithm to compute the attributes imputed by the maximum likelihood parameters of an assumed multivariate Gaussian distribution with no restrictions on the covariate matrix (**Gauss**), and a Gaussian Mixture Model with 10 Gauss centers and spherical covariances (**GMM**).

Four learning procedures based on single imputations serve as reference methods: the **MeanInput**, **MeanFeat**, **Gauss**, and **GMM** reference methods first determine a single imputation, and then invoke the learning algorithm.

All experiments use a spheric Gaussian kernel. Its variance parameter σ as well as the SVM-parameter η are adjusted using the regular SVM with a training and test split on fully observed data. All experiments on the same data set use this resulting parameter setting. Results are averaged over 100 runs were in each run training and test split as well as missing attributes are chosen randomly. If not stated otherwise, 85% of attributes are marked missing on all data sets. In order to evaluate our method on the email data set, we perform 20-fold cross-validation. Since the emails with

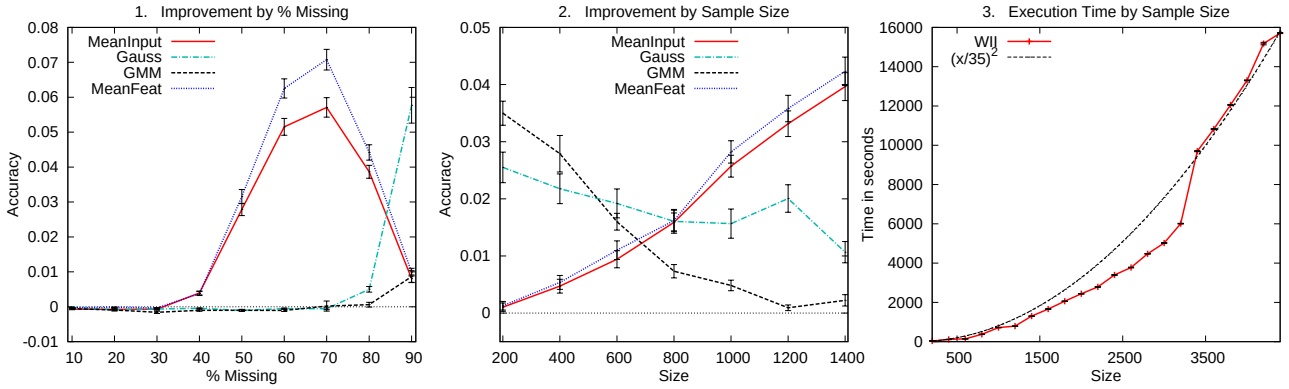

Figure 1. Detailed results on USPS classification task.

missing attributes cannot be used as test examples, the test sets are only taken from the fully observed part of the data set.

Table 6.1 shows accuracies and standard errors for the *weighted infinite imputations* (WII) method with squared distance regularization compared to all single imputations $\hat{\boldsymbol{\omega}}$ on each data set. Regularization parameter γ is automatically chosen for each run based on the performance on a separate tuning set. Baselines are obtained by first imputing $\hat{\boldsymbol{\omega}}$ and learning the classifier in a second step. The *weighted infinite imputations* method outperforms the single imputation in virtually all settings. We test for significant improvements with a paired t-test on the 5% significance level. Significant improvements are marked with a "∗" in the table.

We explore the dependence of classification performance on training sample size and the percentage of missing attribute values in more detail. The first graph in Figure 1 shows improvements in classification accuracy of our method over the single imputations depending on the percentage of missing values. Graph 2 shows classification accuracy improvements depending on the size of the labeled training set. Both experiments are performed on USPS data set and we again adjust γ separately for each run based on the performance on the tuning set. We note that similar results are obtained for the other classification problems. The *weighted infinite imputation* method can improve classification accuracy even when only 30% of the attribute values are missing. It shows, though, that it works best if at least 60% are missing, depending on $\hat{\boldsymbol{\omega}}$. On the other hand, we see that it works for all training set sizes, again depending on $\hat{\boldsymbol{\omega}}$. Similar results are obtained for the other data sets.

Table 2. Mean squared error results and standard errors for regression data sets. Smaller mean squared errors are written in bold face, "∗" denotes significant improvement.

	WII	$\mathbf{306.257 \pm 12.500}$ ∗	$\mathbf{204.180 \pm 5.058}$ ∗	$\mathbf{305.651 \pm 13.627}$ ∗	$\mathbf{247.988 \pm 8.010}$ ∗

To evaluate the convergence of our method, we measure classification accuracy after each iteration of the learning algorithm. It shows that classification accuracy does not change significantly after about 5 iterations for a typical γ, in this case $\gamma = 10^5$ for the USPS data set. On average the algorithm terminates after about 30-40 iterations. The computational demands of the *weighted infinite imputation* method are approximately quadratic in the training set size for the classification task, as can be seen in Graph 3 of Figure 1. This result depends on the specific risk functional R and its optimization implementation. Nevertheless, it shows that risk functionals which are solvable in quadratic time do not change their computational complexity class when learned with incomplete data.

6.2. Regression

We evaluate the *weighted infinite imputations* method on regression problems using the squared error as loss function. Consequently, risk functional R^{KRR} (Sect. 5.1) is used as R and again the squared distance regularizer Q^{sq} for Q in Optimization Problem 3. From UCI we take the Housing data (506, 14), and from the Weka homepage cpu_act (1500, 21) and ailerons (2000, 40). Ridge parameter η and RBF-kernel parameter σ were again chosen such that they lead to best results on the completely observed data. Regularization parameter γ was chosen based on the performance on a tuning set consisting of 150 examples. Results are shown in Table 2. We can see that our method outperforms the results obtained with the single imputations significantly for all settings.

7. Conclusion

We devised an optimization problem for learning decision functions from incomplete data, where the distribution p of the missing attribute values is a free parameter. The investigated method makes only minor assumptions on the distribution by the means of a regularizer on p that can be chosen freely. By simultaneously optimizing the function and the distribution of imputations, their dependency is taken into account properly. We presented a proof that the optimal solution for the joint learning problem concentrates the density mass of the distribution on finitely many imputations. This justifies the presented iterative algorithm that finds a solution. We showed that instantiations of the general learning method consistently outperform single imputations.

Abstract

Rich representations in reinforcement learning have been studied for the purpose of enabling generalization and making learning feasible in large state spaces. We introduce Object-Oriented MDPs (OO-MDPs), a representation based on objects and their interactions, which is a natural way of modeling environments and offers important generalization opportunities. We introduce a learning algorithm for deterministic OO-MDPs and prove a polynomial bound on its sample complexity. We illustrate the performance gains of our representation and algorithm in the well-known Taxi domain, plus a real-life videogame.

1. Introduction

In the standard Markov Decision Process (MDP) formalization of the *reinforcement-learning* (RL) problem (Sutton & Barto, 1998), a decision maker interacts with an environment consisting of finite state and action spaces. Algorithms for RL in MDP environments suffer from what is known as the *curse of dimensionality*: an exponential explosion in the total number of states as a function of the number of *state variables*. Learning in environments with extremely large state spaces is challenging if not infeasible without some form of generalization. Exploiting the underlying structure of a problem can enable generalization and has long been recognized as important in representing sequential decision tasks (Boutilier et al., 1999).

In this paper, we propose an extension to the standard MDP formalism, which we call *Object-Oriented MDPs (OO-MDPs)*, and present an efficient learning algorithm for deterministic OO-MDPs. We claim that this object-based approach is a natural way of viewing and describing many real-life domains that enables multiple opportunities for generalization. There are many ways of incorporating objects into models for learning and decision making—this paper explores one particular approach as a first attempt to understand the issues that arise.

Our representation has multiple connections with other formalisms proposed in the Relational Reinforcement Learning literature (van Otterlo, 2005), but emphasizes simplicity and tractability over expressive power. Our representation starts from attributes that can be directly perceived by the agent, rather than predicates or propositions introduced by the designer (although we allow the encoding of prior knowledge in propositional form). A similar formalism, *relational MDPs (RMDPs)*, was introduced by Guestrin et al. (2003) in the context of planning, and is based on the same insight. While our formalism has similarities to *RMDPs*, we introduce a number of changes, mainly in the way transition dynamics are described, to enable efficient learning and generalization.

To present and test our approach, we first provide benchmark experiments in the well-known Taxi domain (Dietterich, 2000). We further demonstrate its applicability by designing an agent that can solve an interesting problem in the real-life videogame *Pitfall*[1].

2. Notation

We use a standard Markov Decision Process (MDP) notation throughout this paper (Puterman, 1994). A finite MDP M is a five tuple $\langle \mathcal{S}, \mathsf{A}, T, \mathcal{R}, \gamma \rangle$. We use $T(s'|s,a)$ to denote the transition probability of state s' given state–action pair (s,a) and $R(s,a)$ to denote the expected reward value. A *deterministic MDP* is one in which there is a single next state s' for every given state s and action a; that is, $\forall s \in \mathcal{S}, a \in \mathsf{A}, \exists s' \in \mathcal{S} : T(s'|s,a) = 1$.

3. Object-oriented Representation

We will use the Taxi domain, defined by Dietterich (2000), as an example to introduce our formalism. Taxi is a grid-

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

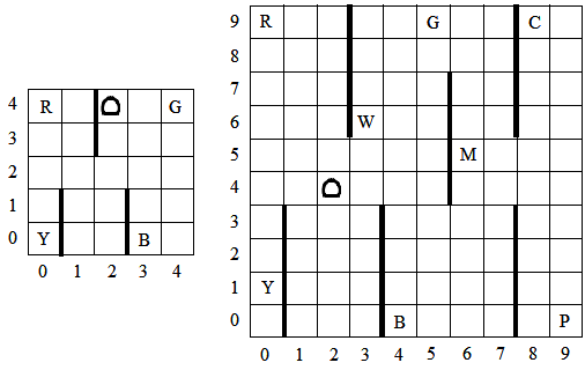

Figure 1. The taxi domain. (a) Original 5×5 Taxi problem. (b) Extended 10×10 version, with a different wall distribution and 8 possible passenger locations and destinations.

world domain (see Figure 1.a), where a *taxi* has the task of picking up a *passenger* in one of a pre-designated set of locations (identified in the figure by the letters *Y, G, R, B*) and dropping it off at a goal *destination*, also one of the pre-designed locations. The set of actions for the taxi are *North*, *South*, *East*, *West*, *PICKUP* and *DROPOFF*. Walls in the grid limit the taxi's movements.

A common factored-state representation for the Taxi problem uses Dynamic Bayesian Networks (DBNs) to indicate how state variables influence each other. For example, the location of the *taxi* after a *North* action only depends on its current location and is independent of the *passenger* or *destination* variables.

We depart from this representation and introduce one based on objects and their interactions. Many elements in our representation are similar to those of *relational MDPs* (Guestrin et al., 2003) with significant differences in the way we represent transition dynamics. Similar to *RMDPs*, we define a set of *classes* $\mathcal{C} = \{C_1, \ldots, C_c\}$. Each class includes a set of *attributes* $Att(C) = \{C.a_1, \ldots, C.a_a\}$, and each attribute has a *domain* $Dom(C.a)$. A particular environment will consist of a set of *objects* $O = \{o_1, \ldots, o_o\}$, where each object is an instance of one class: $o \in C_i$. The state of an object o.*state* is a value assignment to all its attributes. The state of the underlying MDP is the union of the states of all its objects: $s = \bigcup_{i=1}^{o} o_i.state$.

An OO-MDP representation of Taxi has four object classes: *Taxi*, *Passenger*, *Destination* and *Wall*. *Taxi*, *Passenger* and *Destination* have attributes x and y, which define their location in the grid. *Passenger* also has a Boolean attribute *in-taxi*, which specifies whether the passenger is inside the taxi. *Walls* have an attribute that indicates their position in the grid. The Taxi domain, in its 5×5 version shown in Figure 1.a, has one object of each class *Taxi*, *Passenger*, and *Destination*, and multiple (26) objects of class *Wall*. This list of objects points out a significant feature of the OO-MDP representation. Whereas in the classical MDP model, the effect of encountering walls is felt as a property of specific locations in the grid, the OO-MDP view is that wall interactions are the same regardless of their location. As such, agents' experience can transfer gracefully throughout the state space.

When two objects interact in some way, they define a *relation* between them. A combination of the relation established, plus the internal states of the two objects, determines an *effect*—a change in value of one or multiple attributes in either or both interacting objects. This behavior is defined at the class level, meaning that different objects that are instances of the same class behave in the same way when interacting with other objects. Formally, a relation $r : C_i \times C_j \rightarrow$ *Boolean* is a function, defined at the class level, over the combined attributes of objects of classes C_i and C_j. Its value gets defined when instantiated by two objects $o_1 \in C_i$ and $o_2 \in C_j$. For our Taxi representation, we will define 5 relations: $touch_N(o_1, o_2)$, $touch_S(o_1, o_2)$, $touch_E(o_1, o_2)$, $touch_W(o_1, o_2)$ and $on(o_1, o_2)$, which define whether an object $o_2 \in C_j$ is exactly one cell North, South, East or West of an object $o_1 \in C_i$, or if both objects are overlapping (same x, y coordinates). Different domains require different relations.

When the object $taxi_i \in$ *Taxi* is on the northern edge of the grid and tries to perform a *North* action, it hits some object $wall_j \in$ *Wall* and the observed behavior is that it doesn't move. We say that a $touch_N(taxi_i, wall_j)$ relation has been established and the effect of an action *North* under that condition is *no-change*. On the other hand, if $\neg touch_N(taxi_i, wall_j)$ is true and the taxi performs the action *North*, the effect will be $taxi_i.y \leftarrow taxi_i.y + 1$. As stated before, these behaviors are defined at the class level, so we can refer in general to the relation $touch_N(Taxi, Wall)$ as producing the same kind of effects on any instance of $taxi_i \in$ *Taxi* and $wall_j \in$ *Wall*.

We define some properties of these transition dynamics more formally in the next section.

3.1. Transition Dynamics

Every state s induces a certain value assignment to all attributes of all objects—and therefore all relations—in the domain. Transitions are determined by interactions between objects. Every pair of objects $o_1 \in C_i$ and $o_2 \in C_j$, their internal states $o_1.state$ and $o_2.state$, an action a, and the set of relations $r(o_1, o_2)$ that are true—or false—at the current state, determine an effect—a change of value in some of the objects' attributes.

Definition 1 *An* effect *is a single operation over a single attribute att in the OO-MDP. We will group effects into* types, *based on the kind of operation they perform. Ex-*

amples of types are arithmetic *(increment att by* 1*, subtract* 2 *from att), and* constant assignment *(set att to* 0*).*

Definition 2 *A* term t *is any Boolean function. In our OO-MDP representation, we will consider terms representing either a relation between two objects, a certain possible value of an attribute of any of the objects or, more generally, any Boolean function defined over the state space that encodes prior knowledge. All transition dynamics in an OO-MDP are determined by the different possible settings of a special set of terms called* T*.*

Definition 3 *A* condition *is a set* T_c *of terms and negations of terms from* T *that* must *be true in order to produce a particular effect* e *under a given action* a*.*

We can summarize an OO-MDP transition cycle as follows:

1: **while** agent is acting **do**
2: Agent observes current state s and returns action a.
3: From state s, the environment extracts all relations that currently hold between objects and observes the value of all attributes of all objects, assigning a True/False value to all terms in T.
4: For each (if any) fulfilled condition in T_c, there's an effect that will occur, determining a set of effects to be applied to s.
5: If no conditions were fulfilled, no change takes place to s.
6: Otherwise, the environment uses the set of effects to compute s'. New state $s \leftarrow s'$.
7: The environment chooses a reward r from $R(s, a)$.
8: Agent is told r.
9: **end while**

4. *DOORMAX*: Learning and Solving Deterministic OO-MDPs

We introduce Deterministic Object-Oriented Rmax (*DOORMAX*), an algorithm for learning and solving deterministic OO-MDPs. *DOORMAX* is correct and, as we will show, provably efficient under the following assumptions.

Assumption 1 *For each action and each attribute, only effects of one type can occur.*

Assumption 2 *For every action* a*, attribute att and effect type* t*, there is a set* $\mathcal{CE}$ *of* condition–effect *pairs that determine changes to att given* a*. No effect can appear twice on this list, and there are at most* k *different pairs—*$|\mathcal{CE}| \leq k$*. Plus, no conditions* T_i *and* T_j *in the set* $\mathcal{CE}$ *contain each other:* $\neg(T_i \subset T_j \vee T_j \subset T_i)$*. The number of terms or negations of terms in any condition is bounded by a known constant* M*.*

Assumption 3 *Effects are* invertible*, that is, given states* s *and* s'*, for each attribute att and each effect type we can determine a unique effect that would transform att from its value in* s *to its value in* s'*.*

4.1. Definitions and Data Structures

We introduce some definitions, notation, and data structures that will be used to describe *DOORMAX*:

- T is the union of all terms t that will be involved in the conditions that determine the transition dynamics of the environment described by the OO-MDP, plus their negations $\neg t$, with $|T| = 2n$.
- For every state $s \in S$, the function *cond*(s) returns the subset of terms in T that are true in s.
- A condition $T_c \subseteq T$ is represented by a string c_S of length n, where $c_S^i = 1$ if $t_i \in T_c$, $c_S^i = 0$ if $\neg t_i \in T_c$ and $c_S^i =$ * if $t_i \notin T_c \wedge \neg t_i \notin T_c$.
- Given two conditions represented as strings c_1 and c_2, we define the commutative operator $\oplus : c \times c \rightarrow c$ as follows:

c_1	c_2	$c_1 \oplus c_2$
0	0	0
1	1	1
0	1	*
0|1	*	*

- A condition c_1 *matches* another condition c_2, noted $c_1 \models c_2$, if $\forall 1 \leq i \leq n : c_1^i = * \vee c_1^i = c_2^i$.
- For any states s and s' and attribute *att*, the function *eff*$_{att}(s, s')$ returns one effect of each type that would transform attribute *att* in s into its value in s'.
- A *prediction* p is a pair $(p.model, p.\text{effect})$, where $p.model$ is a condition that represents the set of terms that need to be true for $p.$effect to occur.
- For each action a, each attribute *att* and each effect type *type*, a set of predictions *pred*$(a, att, type)$ is maintained. We refer to the set of *models* in a set of predictions as *pred*$(a, att, type).models$.
- If an action a produces no effect from a given state s ($s' = s$), we call the induced condition *cond*(s) a *failure condition*. We define F_a to be a set of failure conditions for action a.
- Two effects are *incompatible* if, for any initial value of an attribute, applying these two effects would yield two different final values.

4.2. OO-MDP Representation of Taxi

To facilitate understanding of the notation and data structures, we present a full example of our representation in the Taxi domain.

The set of terms T, which determines the transition dynamics of the OO-MDP, includes the four $touch_{N/S/E/W}$ relations between the taxi and the walls; the relevant relations between the taxi and the passenger and destination; the attribute value *passenger.in-taxi* $= T$; and all their negations:

$$\{\ touch_{N/S/E/W}(taxi, wall),\quad on(taxi, passenger),\quad \neg touch_{N/S/E/W}(taxi, wall),\quad \neg on(taxi, passenger),\quad on(taxi, destination),\quad \neg on(taxi, destination),\quad passenger.in\text{-}taxi = T,\quad passenger.in\text{-}taxi = F\ \}$$

Consider the state s where the taxi is in position $(2, 4)$ (as in Figure 1.a), the passenger is inside the taxi, and the destination is G. For this state, the function *cond*(s) returns:

$$\{\ touch_N(taxi, wall),\quad \neg touch_S(taxi, wall),\quad \neg touch_E(taxi, wall),\quad touch_W(taxi, wall),\quad \neg on(taxi, passenger),\quad \neg on(taxi, destination),\quad passenger.in\text{-}taxi = T\ \}.$$

The corresponding 7-character string representation for this condition is 1001001, following the prior order for the terms.

Let's now assume that the agent tries to perform the action *East*, which takes it to state s' where the taxi is in location $(3, 4)$. The corresponding *cond*(s') is similar, except that now the taxi is not touching a wall to its West ($\neg touch_W(taxi, wall)$). The corresponding string representation of the new condition is: 1000001. The observed effect is that the taxi moved to location $(3, 4)$. In our representation, two effect types are allowed: arithmetic and constant assignment. Therefore, the function $eff_{taxi.x}(s, s')$ will return two values: increment(1) and set-to(3).

Now, the agent takes another *East* action, and gets to state s'', where location is $(4, 4)$, it's touching a wall to the East and standing on the destination. *cond*(s'') can now be represented as 1010011. The two observed effects to $taxi.x$ are increment(1) and set-to(4). Note that the transition model for an OO-MDP need not predict the changes to the conditions, only to the attributes. The condition values are then derived separately using the knowledge of the relevant relations and their definitions.

Finally, we'll consider separately the actions that produce no effect. Let's assume the agent also attempted an action *North* from each of the previous states, which resulted in it hitting a wall and staying in the same state. We treat these cases differently: The corresponding conditions 1001001, 1000001 and 1010011 will be identified as failure conditions for action *North* and incorporated into the set F_{North}. Whenever we observe a new condition c_i such that any existing condition in F_{North} matches it, we predict that performing a *North* action will have no effect.

4.3. Learning Algorithm

The *DOORMAX* algorithm (Algorithm 1) follows the general structure of most RL algorithms in the Rmax family, which work as follows. Using examples of transitions (s, a, s'), a learning algorithm constructs the transition model T. The learning algorithm must satisfy the KWIK (knows what it knows) conditions (Li et al., 2008), which say: (1) all predictions must be accurate (assuming a valid hypothesis class), and (2) however, the learning algorithm may also return $\perp$, which indicates that it cannot yet predict the output for this input. The sample complexity or KWIK bound of a learning algorithm is the maximum number of times it returns $\perp$. In the Rmax setting, any transition that cannot yet be predicted is assumed to lead to a fictious $s_{\max}$ state from which maximum reward can be obtained.

Algorithm 1 *DOORMAX*: `main()` method

```
// Set up data structures:
for all actions a ∈ A do
    F_a ← ∅
    for all attributes att ∈ ⋃_{c∈C} Att(c) do
        for all effect types type do
            pred(a, att, type) ← ∅
            Add pred(a, att, type) to set of active predictions P
        end for
    end for
end for
while ¬(Termination criterion) do
    Observe current state s.
    Choose action a according to exploration policy, based on prediction for T(s'|s, a) returned by predictTransition(s, a).
    Observe new state s'.
    Update learned model using method addExperience(s, a, s', k).
end while
```

The two main routines of the algorithm are `predictTransition` (Algorithm 2), which predicts the next state given a current state and action based on the current model, and `addExperience` (Algorithm 3), which learns a model of the OO-MDP. If `predictTransition` is not able to predict a next state with accuracy, it returns $s_{\max}$.

To help understand these routines, we present a couple of intuitions, based on the Taxi examples presented in the previous section. Notice that if we applied the $\oplus$ operator to

cond(s) and *cond*(s'), the two conditions from which an *East* action produced an increment(1) effect, we would obtain: $1001001 \oplus 1000001 = 100$*$001$. The resulting condition indicates that the term $\textit{touch}_W(\textit{wall}, \textit{taxi})$ is irrelevant with respect to action *East* and effect increment(1). If we also compare the two pairs of effects obtained, we observe that we consistently observed increment(1), whereas set-to(3) and set-to(4) are incompatible effects. These observations constitute the central ideas for the learning algorithm.

Algorithm 2 `predictTransition(s,a)` method

Inputs: state s and action a.
Output: a predicted state $s' \in S \cup \{s_{\max}\}$.
if $\exists c \in F_a$ s.t. $c \models$ *cond*(s) **then**
  // The current condition is a known failure condition.
  Return s
else
  for all attributes *att* $\in \bigcup_{c \in C}$ *Att*(c) **do**
    $E \leftarrow \emptyset$
    for all effect types *type* **do**
      if $\exists p \in$ *pred*$(a, \textit{att}, \textit{type})$ s.t. $p.\textit{model} \models \textit{cond}(s)_S$ **then**
        Add p.effect to E
      end if
    end for
    if $E = \emptyset \vee \exists e_i, e_j \in E$ s.t. e_i and e_j are incompatible **then**
      Return $s_{\max}$
    else
      // Set E contains all the individual operations that need to be applied to attributes in s in order to convert it to s'.
      $s' \leftarrow$ apply E to s
      Return s'
    end if
  end for
end if

5. Analysis

Under the current assumptions, the effects of a given action on a given attribute assuming effects of a given type can be learned with a worst-case bound of $O(n^M)$, where $n = |T|$ is the number of terms and M is the maximum number of terms involved in any of the conditions. This worst-case bound can be guaranteed by a variant of *SLF-Rmax*, an algorithm introduced by Strehl et al. (2007).

The uniqness assumption, Assumption 2, is not needed for *SLF-Rmax* to achieve this worst-case bound. However, *DOORMAX*, by taking advantage of this assumption, is able to learn faster in many domains. Some empirical evidence to support this claim appears in Section 6.

If we assume M is a constant, SLF-Rmax can be used to provide guaranteed efficient results. However, for many domains DOORMAX will result much more efficient in practice. We conjecture that the two approaches can be run in parallel, to achieve the best of both.

Intuitively, the good empirical results of DOORMAX lie in the way condition-effects are learned each time they are observed. The worst-case occurs when the agent observes an exponential amount of failures before observing instances of the set of effects it needs to learn.

We now show that the problem of learning the transition dynamics of an OO-MDP has polynomial sample complexity in the KWIK setting, when by sample we only refer to the cases where an effect is observed (as opposed to failure samples where $s' = s$).

We split the proof in two parts. First, we show that learning the right (condition, effect) pairs for a single action and attribute is KWIK-learnable, and then we show that learning the right effect type for each action–attribute, given all the possible effect types, is also KWIK learnable.

Theorem 1 *The transition model for a given action a, attribute att and effect type type in a deterministic OO-MDP is KWIK-learnable with a bound of $O(nk+k+1)$, where n is the number of terms in a condition and k is the maximum number of effects per action–attribute.*

Proof:

Given state s and action a, the predictor for effect type *type* will return $\perp$ if *cond*(s) is not a known failure condition and there is no condition in *pred*$(a, \textit{att}, \textit{type})$ that matches *cond*(s). In that case, it gets to observe s' and updates its model with *cond*(s) and the observed effect e. We show that the number of times the model can be updated until it always has a correct prediction is $O(nk + k + 1)$:

- if the effect e has never been observed before for this particular action, attribute and effect type, it gets added to *pred*$(a, \textit{att}, \textit{type})$. This outcome happens at most k times, which is the maximum number of different effects allowed per action-attribute-type combination.
- if the effect e has never been observed, but $|\textit{pred}(a, \textit{att}, \textit{type})| = k$, the algorithm concludes that the current effect type is not the correct one for this action–attribute, and it removes all predictions of this type from its set $\mathcal{P}$. This event can only happen once.
- if the effect e is such that there already exists a prediction for it, $\perp$ is only returned if the existing condition

in the model does not match *cond*(s). This case can only happen if a term in the model is a 0 or 1 and the observation is the opposite. Once it happens, that term becomes a *, so there will never be another mismatch for that term, as * matches either 0 or 1. In the worst case, with every $\perp$ returned, one term at a time gets converted into *. These updates can only happen n times for each effect in *pred*$(a, att, type)$, for a total of nk times.

Therefore, there can be at most $nk + k + 1$ updates to the model for a particular action a, attribute *att* and effect type *type* before *pred*$(a, att, type)$ either has a correct prediction or gets eliminated. □

Corollary 1 *The transition model for a given action and attribute in a deterministic OO-MDPs is KWIK-learnable with a bound of $O(h(nk + k + 1) + (h - 1))$, where n is the number of terms in a condition, k is the max number of effects per action–attribute, and h is the number of effect types.*

Proof: Whenever *DOORMAX* needs to predict s' given state s and action a, it will consult its current predictions for each attribute and effect type. It will return $\perp$ if:

- for any of the h effect types $type_i$, *pred*$(a, att, type_i)$ returns $\perp$. As shown in Theorem 1, *pred*$(a, att, type_i)$ can only return $\perp$ up to $nk + k + 1$ times. Therefore, this case can only happen $h(nk + k + 1)$ times.
- for some attribute *att*, there are two effect types $type_1$ and $type_2$ such that *pred*$(a, att, type_1) \neq$ *pred*$(a, att, type_2)$. When this happens, we get to observe the actual effect e, which will necessarily mismatch one of the predictions. The model will therefore be updated by removing either *pred*$(a, att, type_1)$ or *pred*$(a, att, type_2)$ from its set of predictions. This case can only occur $h - 1$ times for a given action and attribute.

We have shown that, in total, *DOORMAX* will only predict $\perp$ $O(h(nk + k + 1) + (h - 1))$ times before having an accurate model of the transition dynamics for an action and attribute in the OO-MDP. □

6. Experiments

First, we use the Taxi domain to demonstrate how *DOORMAX* makes use of the OO-MDP representation to outperform *Factored-Rmax*, an algorithm based on a factored-state MDP representation. Second, we show how *DOORMAX* and *Factored-Rmax* scale when the size of the state space increases, by comparing them on the 10×10 version of Taxi. Finally, we demonstrate how *DOORMAX* can be

Algorithm 3 `addExperience(s,a,s',k)` method

Inputs: an observation $< s, a, s' >$; k, the maximum number of different effects possible for any action, attribute and effect type.
if $s = s'$ **then**
  // Found a failure condition for action a, update F_a
  Remove all $c \in F_a$ s.t. *cond*$(s) \models c$.
  $F_a \leftarrow F_a \cup \{$*cond*$(s)\}$

        end if
      end if
    end for
  end for
end if

applied to succesfuly model and solve a real-life problem, the *Pitfall* videogame.

6.1. Taxi

The first experiments we present are based on the Taxi domain previously introduced. We run experiments on two versions: the original 5×5-grid version presented by Dietterich (2000), which consists of 500 states, and an extended 10×10-grid version with 8 passenger locations and destinations, with 7200 states (see Figure 1). The purpose of the extended version is to demonstrate how *DOORMAX* scales by properly generalizing its knowledge about conditions and effects when more objects of the same known classes are introduced.

We compare *DOORMAX* against *Factored-Rmax*, an algorithm from the Rmax family that uses a factored-state MDP and models transitions using a DBN provided as input. Both algorithms are model based and use Rmax-style exploration, so we hope to be able to truly compare the underlying representations.

The representation used for *DOORMAX* was described in the previous sections. In the case of *Factored-Rmax*, we provide a DBN with some derived features that make learning faster. The state variables used are the *Taxi* x and y locations, plus two Boolean features: *in-taxi*, representing whether the *passenger* is in the *taxi*, and *at-destination*, representing whether the *taxi* is standing at the *passenger*'s *destination*.

The experiments for both algorithms and both versions of the Taxi problem were repeated 100 times, and the results averaged. For each experiment, we run a series of episodes, each starting from a random start state. We evaluate the agent's learned policy after each episode on a set of six "probe" combinations of $\langle$taxi (x,y) location, passenger location, passenger destination$\rangle$. The probe states used were: $\{(2,2), Y, R\}$, $\{(2,2), Y, G\}$, $\{(2,2), Y, B\}$, $\{(2,2), R, B\}$, $\{(0,4), Y, R\}$, $\{(0,3), B, G\}$. We report the number of steps taken before learning an optimal policy for these six start states.

The results are shown in the following table, with the last column showing the ratio between the results for the 10×10 version vs the 5×5 one:

	Taxi 5×5	Taxi 10×10	Ratio
Number of states	500	7200	14.40
Factored Rmax			
# steps	1676	19866	11.85
Time per step	43.59ms	306.71ms	7.03
OO-Rmax			
# steps	529	821	**1.55**
Time per step	13.88ms	293.72ms	21.16

We can see how *DOORMAX* not only learns with significantly less sample complexity, but also how well it scales to the larger problem. After increasing the number of states by more than 14 times, *DOORMAX* only requires 1.55 times the experience.

The main difference between *DOORMAX* and *Factored-Rmax* is their internal representation, and the kind of generalization it enables. After just a few examples in which $\neg$*touch*$_N$(*taxi*, *wall*) is true, *DOORMAX* learns that the action *North* has the effect of incrementing *taxi*.y by 1, whereas under *touch*$_N$(*taxi*, *wall*) it fails. This knowledge, as well as its equivalent for *touch*$_{S/E/W}$, is generalized to all 25 (or 100) different locations. *Factored-Rmax* only knows that variable *taxi*.y' in state s' depends on its value in state s, but still needs to learn the transition dynamics for each possible value of *taxi*.y (5 or 10 different values). In the case of actions *East* and *West*, it's even worse, as walls make *taxi*.x' depend on both *taxi*.x and *taxi*.y, which are 25 (or 100) different values.

As *DOORMAX* is based on interactions between objects, it learns that the relation between taxi and wall is independent of the wall location. Each new wall is therefore the same as any known wall, rather than a new exception in the movement rules, the kind *Factored-Rmax* needs to learn.

6.2. Pitfall

Pitfall is a video game released in 1982 by Activision for the Atari game console. The goal is to have the main character (*Man*) traverse a series of screens while collecting as many points as possible while avoiding obstacles (such as holes, pits, logs, crocodiles and walls) and under the time constraint of 20 minutes. All transitions in Pitfall are deterministic. Our goal in this experiment was to have the *Man* cross the first screen from the left to the right with as few actions as possible. Figure 2 ilustrates this first screen.

Our experiments were run using a modified Atari emulator that ran the actual game and detected objects from the displayed image. We used a simple heuristic that identified objects by color clusters and sent joystick commands to the emulator to influence the play. For each frame of the game, a list of object locations was sent to an external learning module that analyzed the state of the game and returned an action to be executed before the emulator continued on to the next frame. If we consider that we start from screen pixels, the flat state representation for Pitfall is enormous: $16^{640x420}$. By breaking it down into basic objects, through an object recognition mechanism, the state space is in the order of the number of objects to the number of possible locations of each object: $6^{640x420}$. OO-MDPs allow for a very succint representation of the problem, that can be learned with only a few experience samples.

Figure 2. Initial screen of Pitfall.

The first screen contains six object types: *Man*, *Hole*, *Ladder*, *Log*, *Wall* and *Tree*. Objects have the attributes x, y, $width$ and $height$, which define their location on the screen and dimension. The *Man* also has a Boolean attribute of $direction$ that specifies which way he is facing. We extended the $touch_X$ relation from Taxi to describe diagonal relations between objects, including: $touch_{NE}(o_i, o_j)$, $touch_{NW}(o_i, o_j)$, $touch_{SW}(o_i, o_j)$ and $touch_{SE}(o_i, o_j)$. These relations were needed to properly capture the effects of moving on and off of ladders.

In our implementation of *DOORMAX*, we defined seven actions: *WalkRight*, *WalkLeft*, *JumpLeft*, *JumpRight*, *Up*, *Down* and *JumpUp*. For each of these actions, however, the emulator has to actually execute a set sequence of smaller frame-specific actions. For example, *WalkLeft* requires four frames: one to tell Pitfall to move the *Man* to the left, and three frames where no action is taken to allow for the animation of the *Man* to complete. Effects are represented as arithmetic increments or decrements to the attributes x, y, $width$, $height$, plus a constant assignment of either R or L to the attribute $direction$.

The starting state of Pitfall is fixed, and given that all transitions are deterministic, only one run of *DOORMAX* was necessary to learn the dynamics of the environment. *DOORMAX* learns an optimal policy after 494 actions, or 4810 game frames, exploring the area beneath the ground as well as the objects en route to the goal. Once the transition dynamics are learned, restarting the game results in the *Man* exiting the first screen through the right, after jumping the hole and the log, in 94 actions (905 real game frames), which is what the optimal policy requires.

A few examples of the (condition, effect) pairs learned by *DOORMAX* are shown below:

Action	Condition	Effects
WalkRight	direction $= L$	{direction $= R$, $\Delta x = +8$}
WalkRight	$touch_E(Man, Wall)$	no-effect
JumpRight	direction $= R$	$\Delta x = +214$
Up	$on(Man, Ladder)$	$\Delta y = +8$

7. Conclusions and Future Work

We introduced OO-MDPs, an object-oriented representation for reinforcement-learning problems that provides a natural way of modeling a broad set of domains, while enabling generalization. We presented *DOORMAX*, a learning algorithm for deterministic OO-MDPs that not only outperforms state-of-the-art algorithms for factored-state representations, but also scales very nicely with respect to the size of the state space, as long as transition dynamics between objects do not change. We presented bounds for learning transition dynamics of determinstic OO-MDPs in the KWIK framework.

One limitation of our work is that we do not yet have a provably efficient algorithm for stochastic domains, which is part of our future work. While OO-MDPs can model stochastic transitions, a more complex learning algorithm would be needed to learn transitions effectively in the face of noise.

The second component of our future research is the extension of the object-oriented model to be able to handle inheritance. We hope to be able to exploit knowledge about objects being part of a common super-class to learn their behaviors faster. Ideally, algorithms could also learn the object definitions and classes automatically, as well.

Optimizing Estimated Loss Reduction for Active Sampling in Rank Learning

Pinar Donmez PINARD@CS.CMU.EDU
Jaime G. Carbonell JGC@CS.CMU.EDU
Language Technologies Institute, Carnegie Mellon University, 5000 Forbes Ave., Pittsburgh, PA 15213 USA

Abstract

Learning to rank is becoming an increasingly popular research area in machine learning. The ranking problem aims to induce an ordering or preference relations among a set of instances in the input space. However, collecting labeled data is growing into a burden in many rank applications since labeling requires eliciting the relative ordering over the set of alternatives. In this paper, we propose a novel active learning framework for SVM-based and boosting-based rank learning. Our approach suggests sampling based on maximizing the estimated loss differential over unlabeled data. Experimental results on two benchmark corpora show that the proposed model substantially reduces the labeling effort, and achieves superior performance rapidly with as much as 30% relative improvement over the margin-based sampling baseline.

1. Introduction

Learning to rank has recently drawn broad attention among machine learning researchers (Joachims, 2002; Freund et al., 2003; Cao et al., 2006). The objective of rank learning is to induce a mapping (ranking function) from a predefined set of instances to a set of partial (or total) orders. For instance, in recommendation systems each customer is represented with a set of features ranging from the income level to age and her preference order over a set of products (e.g. movies in Netflix). The ranking task is to learn a mapping from the feature space to a set of permutations of the products. The applications include document retrieval, collaborative filtering, product rating, and so on. In this paper, we are interested in IR applications, and focus on document retrieval. A number of queries are provided such that each query is associated with an ordering of documents indicating the relevance of each document to the given query. Like many other ranking applications, this requires a human expert to carefully examine the documents in order to assign relevance-based permutations. It is often unrealistic to spend extensive human effort and money for labeling in ranking. Thus, it is crucial to design methods that will considerably reduce the labeling effort without significantly sacrificing ranking accuracy.

The active learning paradigm addresses this type of problem. The central idea is to start with only a small amount of labeled examples and sequentially select new examples to be labeled by an oracle. The selected examples are then added to the training set. It is clear that labeling data in ranking requires a complete (or partial) ordering of data whereas in classification labeling considers only absolute class assignments. The target domain of a set of permutations is more complex than that of absolute classes. Hence, it is even more crucial to select the most informative examples to be labeled in order to learn a ranking model using fewer labeled examples.

In this paper, we propose a novel active sampling framework for SVM rank learning (Joachims, 2002), or RankSVM in short, and RankBoost (Freund et al., 2003). The proposed method considers the capacity of an unlabeled example to update the current model if rank-labeled and added to the training set. We show that this capacity can be defined as a function that estimates the error of a ranker introduced by the addition of a new example. The capacity function takes different forms in RankSVM and RankBoost due to different formulations of the ranking function. For example in the case of RankSVM, the ranking function is defined via a normal vector which is a weighted sum of the support vectors whereas the ranking func-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

tion is a weighted sum of weak learners in RankBoost. However, in both cases, the proposed strategy selects the samples which are estimated to produce a faster convergence from the current predicted ranking to the true ranking. Our empirical evaluations on two benchmark corpora from topic distillation tasks in TREC competitions show a significant advantage favoring our method against the margin-based sampling heuristic of (Brinker, 2004; Yu, 2005) and a random sampling baseline.

The rest of the paper is organized as follows: Section 2 provides a brief literature review to the related work. Section 3 motivates the choice of the proposed active learning framework and introduces two novel methods for active learning in the RankSVM and RankBoost settings. In Section 4, we report the experimental results and demonstrate the effectiveness of our methods on benchmark datasets. Finally, we offer our conclusions and next steps in Section 5.

2. Related Work

A number of strategies have been proposed for active learning in the classification framework. Some of those center around the version space (Mitchell, 1982) reduction principle (Tong & Koller, 2000): selecting unlabeled instances that limit the volume of the version space the most, or equivalently selecting the ones with the smallest margin. Some of the others adopt the idea of reducing the generalization error (Roy & McCallum, 2001; Xu et al., 2003; Nguyen & Smeulders, 2004; Donmez et al., 2007): the selection of the unlabeled data that has the highest affect on the test error, i.e. points in the maximally uncertain and highly dense regions of the underlying data distribution (Xu et al., 2003; Nguyen & Smeulders, 2004; Donmez et al., 2007).

Unfortunately, it is not straightforward to extend these theoretical principles to ranking problems. The generalization power of ranking functions is measured by different evaluation metrics than the ones used for classification. Moreover, the classical performance metrics for ranking, such as MAP (Mean Average Precision), precision at the k^{th} rank cut-off, NDCG (Normalized Discounted Cumulative Gain), etc., are harder to directly optimize than the classical loss functions for classification, i.e. log loss, 0/1 loss, squared loss, etc.

Recently, there have been attempts to address the challenges in active sampling for rank learning. Brinker (2004) uses a notion of the margin as an approximation to reducing the volume of the version space. The margin in the ranking scenario is defined as the minimum difference of scores between two instances assuming the ranking solution is a real-valued scoring function. Yu (2005) adopted the same notion of margin for SVM rank learning and proposed a batch mode for instance selection that minimizes the sum of the rank score differences of all data pairs within a set of samples. Yu (2005) proposed an efficient implementation which considers only the rank-adjacent pairs and showed that this strategy is optimal in terms of selecting the most ambiguous set of samples with respect to the ranking function. The major drawback of this margin-based sampling method of (Brinker, 2004; Yu, 2005) is that a scoring function for ranking may assign very similar scores to instances with the same rank label since the ranking function does not distinguish between the relative order of two relevant or two non-relevant examples. However, such instances do not carry any additional information for the rank learner to distinguish between the relevant and the non-relevant data.

Another recent development in active rank learning is the divergence-based sampling method of (Amini et al., 2006). The proposed method selects the samples at which two different ranking functions maximally disagree. One of the two functions is the current ranking function trained on the labeled data, and the other is a randomized function obtained by cross validation. The divergence-based strategy is effective only when provided with a sufficiently large initial labeled set, which is impractical for many real-world ranking applications, such as document retrieval.

3. Active Sampling in Rank Learning

3.1. Motivation

This section presents a novel method for active learning using RankSVM and RankBoost. Roy and McCallum (2001) argue that an optimal active learner is the one that asks for the labels of the examples that, once incorporated into training, would result in the lowest expected error on the test set. The expected error on the test set can be estimated using the posterior distribution $\hat{P}_D(y \mid x)$ of class labels estimated from the training set using some loss function L

$$E_{\hat{P}_D} = \int_x L(P(y \mid x), \hat{P}_D(y \mid x))P(x) \qquad (1)$$

Their aim is then to select the point x^* such that when added to the training set with a chosen label y^*, the classifier trained on the new set $\{D + (x^*, y^*)\}$ would have less error than any other candidate x.

$$\forall(x, y) E_{\hat{P}_{D+(x^*,y^*)}} \leq E_{\hat{P}_{D+(x,y)}} \qquad (2)$$

Since the true label y^* is unknown, the expectation calculation is carried out by calculating the estimated error for each possible label $y \in Y$, and then taking the average weighted by the current learner's posterior $\hat{P}_D(y \mid x)$. The naive implementation of this method would be quite inefficient and almost intractable on large datasets. Roy and McCallum (2001) address this problem using fast updates for a Naive Bayes classifier. Although efficient re-training procedures are available for some learners such as SVMs (Cauwenberghs & Poggio, 2000), it would still be infeasible for ranking tasks, especially considering the interactive nature of ranking systems. In this paper, we propose a method to estimate how likely the addition of a new example will result in the lowest expected error on the test set *without any re-training on the enlarged training set*. Our method is based on the likelihood of an example to change the current hypothesis significantly. There are a number of reasons why we believe this is a reasonable indicator for estimating that error:

- Adding a new data point to the labeled set can only change the error on the test set if it changes the current learner.
- The more significant that change, the greater chance to learn the true hypothesis faster.
- We note that a big change in the current hypothesis might not always lead to better generalization. However, as more data is sampled and the hypothesis gets closer to the truth, it is less likely that a single outlier could hurt the performance noticeably.

In the following sections, we briefly review the RankSVM and the RankBoost algorithms and propose a novel active learning method for each.

3.2. Preliminaries

Assume the data is represented as a set of feature vectors $\vec{x} \in \mathbb{R}^d$ and corresponding labels (ranks) $y \in Y = \{r_1, r_2, ..., r_n\}$ where n denotes the number of ranks. We assume binary relevance in this paper, though our framework can be generalized to multi-level ranking scenarios as long as the rank learner works on pairwise preference relationships, which is the case for the majority of rank learning algorithms. Features are numerical values for attributes in the data. Assume further that there exists a preference relationship between data vectors such that $y_i \succ y_j$ denotes $\vec{x}_i$ is ranked higher than $\vec{x}_j$. A perfect ranking function $f \in F$ preserves the order relationships between instances:

$$\vec{x}_i \succ \vec{x}_j \Leftrightarrow f(\vec{x}_i) > f(\vec{x}_j)$$

Suppose we are given a set of instances $D = \{(\vec{x}_i, y_i) : (\vec{x}_i, y_i) \in X \times Y\}_{i=1}^m$. The objective for rank learning is to learn a mapping $f : X \times Y \mapsto \mathbb{R}$ that minimizes a given loss function on the training data.

3.3. SVM Rank Learning

Assume $f \in F$ is a linear function, i.e. $f(\vec{x}) = \langle \vec{w}, \vec{x} \rangle$, that satisfies

$$\vec{x}_i \succ \vec{x}_j \Leftrightarrow \langle \vec{w}, \vec{x}_i \rangle > \langle \vec{w}, \vec{x}_j \rangle$$

The SVM model targeting this problem can be formulated as a Quadratic Optimization problem:

$$\min_{\vec{w}} \frac{1}{2}\|\vec{w}\|^2 + C \sum \xi_{ij} \tag{3}$$
$$\text{subject to } \langle \vec{w}, \vec{x}_i \rangle \geq \langle \vec{w}, \vec{x}_j \rangle + 1 - \xi_{ij} \ , \ \xi_{ij} \geq 0 \ \forall i, j$$

The above optimization can be equivalently written by re-arranging the constraints and substituting the trade-off parameter C for $\lambda = \frac{1}{2C}$ as follows:

$$\min_{\vec{w}} \sum_{k=1}^{K} \left[1 - z_k \left\langle \vec{w}, \vec{x}_k^1 - \vec{x}_k^2 \right\rangle\right]_+ + \lambda \|\vec{w}\|^2 \tag{4}$$

where $[\ldots]_+$ indicates the standard hinge loss. $\vec{x}^1 - \vec{x}^2$ is a pairwise difference vector whose label z is positive, i.e., $z = +1$ if $\vec{x}^1 \succ \vec{x}^2$ and $z = -1$ otherwise. K is the total number of such pairs in the training set. Finally, a ranked list is obtained by sorting the instances according to the output of the ranking function in descending order.

3.4. Active Sampling for RankSVM

Let us consider a candidate example $\vec{x} \in U$, where U is the set of unlabeled examples. Assume $\vec{x}$ is incorporated into the labeled set with a rank label $y \in Y$. We denote the total loss on the instance pairs that include $\vec{x}$ by a function of $\vec{x}$ and $\vec{w}$, i.e. $D(\vec{x}, \vec{w}) = \sum_{j=1}^{J_y} \left[1 - z_j \langle \vec{w}, \vec{x}_j - \vec{x} \rangle\right]_+$ where J_y is the number of examples in the training set with a different label than the label y of $\vec{x}$. For instance, J_y is the number of negative(non-relevant) examples in the training set if y is assumed to be positive(relevant), and vice versa. The objective function to be minimized by RankSVM then becomes:

$$\min_{\vec{w}} \left\{ \lambda \|\vec{w}\|^2 + \sum_{k=1}^{K} \left[1 - z_k \left\langle \vec{w}, \vec{x}_k^1 - \vec{x}_k^2 \right\rangle\right]_+ + D(\vec{x}, \vec{w}) \right\} \tag{5}$$

Assume $\vec{w}^*$ is the solution to the optimization in Equation 4, and it is unique. Burges and Crisp (2000) show

the necessary and sufficient conditions for the uniqueness of the SVM solution. There are only rare cases where uniqueness does not hold, thus it is a rather safe assumption to make. Since we do not actually rerun the optimization problem on the enlarged data, we restrict ourselves to the current solution(hypothesis) $\vec{w}^*$. Instead of re-optimizing, we estimate the effect of adding each candidate instance on the training loss using the current solution to tell how much incorporating x into the labeled set is likely to change the current hypothesis. First, let us consider two cases.

1. Assume $\vec{w}^* = \text{argmin}_{\vec{w}}\, D(\vec{w}, \vec{x})$
   Then, $\vec{w}^*$ is also the solution to the optimization problem in Equation 5, combining the assumption with $\vec{w}^*$ being the solution to Equation 4. That means, adding $\vec{x}$ to the training set would not change the current hypothesis. From an active learning point of view, this example is useless since the learning algorithm is indifferent to its inclusion.

2. Assume $\vec{w}^* \neq \text{argmin}_{\vec{w}}\, D(\vec{w}, \vec{x})$
   This is the situation where the current solution could be different if that example $\vec{x}$ were incorporated into training. The magnitude of the difference depends on the magnitude of the deviation of $D(\vec{w}^*, \vec{x})$ from its optimal value, $min_{\vec{w}} D(\vec{w}, \vec{x})$.

We now study the second case in more detail. Let $\hat{\vec{w}}$ be the weight vector that minimizes $D(\vec{w}, \vec{x})$, i.e. $\hat{\vec{w}} = \text{argmin}_{\vec{w}}\, D(\vec{w}, \vec{x})$. Then, as the difference $\|\vec{w}^* - \hat{\vec{w}}\|$ increases it becomes less likely that $\vec{w}^*$ is optimal for Equation 5. In other words, the current solution $\vec{w}^*$ is in most need of updating in order to compensate for the loss on the new pairs. Let us write $\hat{\vec{w}}$ in terms of $\vec{w}^*$ as follows:

$$\hat{\vec{w}} = \vec{w}^* - \Delta w$$

Minimizing $D(\vec{w}, \vec{x})$ requires working with the hinge loss, the direct optimization of which is difficult due to the discontinuity of the derivative. However, it can still be solved using a gradient-descent-type algorithm[1]. Recall the objective function to be minimized:

$$\min_{\vec{w}} D(\vec{w}, \vec{x}) = \min_{\vec{w}} \sum_{j=1}^{J_y} \left[1 - z_j \left\langle \vec{w}, \vec{x}_j - \vec{x} \right\rangle\right]_+ \qquad (6)$$

The derivative of the above equation with respect to $\vec{w}$ at a single point $\vec{x}_j$, $\Delta\vec{w}_j$, is:

$$\Delta\vec{w}_j = \begin{cases} 0 & \text{if } z_j \left\langle \vec{w}, \vec{x}_j - \vec{x} \right\rangle \geq 1 \\ -z_j(\vec{x}_j - \vec{x}) & \text{if } z_j \left\langle \vec{w}, \vec{x}_j - \vec{x} \right\rangle < 1 \end{cases} \qquad (7)$$

[1]For a detailed discussion on solving SVM rank learning using gradient descent, see (Cao et al., 2006).

Algorithm 1 RankBoost

Input: initial data distribution D_1 over $X \times X$
for $t = 1$ **to** T **do**
  Train a weak learner on D_t
  Obtain the weak ranking $h_t : X \mapsto \mathbb{R}$
  Choose a weight $\alpha_t \in \mathbb{R}$ for h_t
  $D_{t+1}(\vec{x}^1, \vec{x}^2) = \frac{D_t(\vec{x}^1, \vec{x}^2) exp(-\alpha_t(h_t(\vec{x}^1) - h_t(\vec{x}^2)))}{Z_t}$
end for

We substitute $\vec{w}$ in Equation 7 for the current weight vector $\vec{w}^*$ to estimate how the solution of Equation 6 deviates from it, i.e. $\|\vec{w}^* - \hat{\vec{w}}\| = \|\Delta\vec{w}\|$. We can now write the magnitude of the total derivative as a function of $\vec{x}$ and the rank label y as follows:

$$\begin{aligned} g(\vec{x}, y) &= \|\Delta\vec{w}\| = \sum_j \|\Delta\vec{w}_j\| \qquad (8) \\ &= \sum_{j=1}^{J_y} \begin{cases} 0 & \text{if } z_j \left\langle \vec{w}^*, \vec{x}_j - \vec{x} \right\rangle \geq 1 \\ \| - z_j(\vec{x}_j - \vec{x})\| & \text{if } z_j \left\langle \vec{w}^*, \vec{x}_j - \vec{x} \right\rangle < 1 \end{cases} \end{aligned}$$

$g(\vec{x}, y)$ estimates how likely the current hypothesis is to be updated to minimize the loss introduced as a result of the addition of the example $\vec{x}$ with the rank label y. Thus, we use this function to estimate the ability of each unlabeled candidate example to change the current learner if incorporated into training. Since the true labels of the candidate examples are unknown, we use the current learner to estimate the true label probabilities. Then, we can take the expectation of $g(\vec{x}, y)$ by taking the weighted sum over the current posterior $\hat{P}(y \mid \vec{x})$ for all $y \in Y$. Among all the unlabeled examples, we choose the one with the highest value for that expectation:

$$\begin{aligned} \vec{x}^* &= \underset{\vec{x} \in U}{\text{argmax}} \sum_{y \in Y} \hat{P}(y \mid \vec{x}) g(\vec{x}, y) \\ &= \underset{\vec{x} \in U}{\text{argmax}} \Big\{ \hat{P}(y = 1 \mid \vec{x}) g(\vec{x}, y = 1) + \qquad (9) \\ &\qquad \hat{P}(y = -1 \mid \vec{x}) g(\vec{x}, y = -1) \Big\} \end{aligned}$$

3.5. RankBoost Learning

RankBoost is a boosting algorithm designed for ranking problems. Like all algorithms in boosting family, RankBoost learns a weak learner on each round, and maintains a distribution D_t over the ranked pairs, $X \times X$, to emphasize the pairs whose relative order is the hardest to learn. An outline of the algorithm is given as Algorithm 1. Z_t is a normalization constant, and the final ranking is a weighted sum of the weak rankings $H(\vec{x}) = \sum_{t=1}^{T} \alpha_t h_t(\vec{x})$. For more details and theoretical discussion see (Freund et al., 2003).

3.6. Active Sampling for RankBoost

This section introduces a similar method for active sampling for the RankBoost algorithm (Freund et al., 2003). Consider a candidate point $\vec{x} \in U$ and assume it is merged into the training set with rank label $y \in Y$. Unlike RankSVM, RankBoost algorithm does not directly operate with an optimization function. But the ranking loss with respect to the distribution at time t can be written as:

$$\sum_{\vec{x}^1,\vec{x}^2} D_t(\vec{x}^1,\vec{x}^2) I(H(\vec{x}^2) \geq H(\vec{x}^1)) \tag{10}$$

where I is defined to be 1 if the predicate holds and 0 otherwise. Hence, this is a sum over misranked pairs, assuming $\vec{x}^1 \succ \vec{x}^2$. The distribution at time $T+1$ can be written as:

$$D_{T+1}(\vec{x}^1,\vec{x}^2) = D_1(\vec{x}^1,\vec{x}^2) \frac{exp(H(\vec{x}^2) - H(\vec{x}^1))}{\prod_t Z_t} \tag{11}$$

The initial distribution term D_1 can be dropped without loss of generality, assuming it is uniform (which is reasonable given the fact that we do not have prior information about the data). Similarly to RankSVM, we would like to estimate how much the current ranking function would change if the point $\vec{x}$ were in the training set. We estimate this deviation by the difference in the ranking loss after enlarging the current labeled set with each example $\vec{x} \in U$. The ranking loss on the enlarged set with respect to the distribution D_{T+1} is:

$$\sum_{\vec{x}^1,\vec{x}^2} \frac{exp(H(\vec{x}^2) - H(\vec{x}^1))}{\prod_t Z_t} I(H(\vec{x}^2) \geq H(\vec{x}^1)) + \sum_{\vec{x}^j,\vec{x}} \frac{exp(H(\vec{x}^j) - H(\vec{x}))}{\prod_t Z_t} I(H(\vec{x}^j) \geq H(\vec{x})) \tag{12}$$

Note that the rank label y of $\vec{x}$ is assumed to be positive (relevant) with $\vec{x} \succ \vec{x}_j$ in this case. We have a similar calculation for the case where y is assumed to be negative (non-relevant). We adopt the distribution D_{T+1} because 1) it can easily be written in terms of the final ranking function, 2) it contains information about which pairs remain the hardest to determine after the iterative weight updates. Then, the difference in the ranking loss between the current and the augmented set simply becomes:

$$\Delta L(\vec{x}, y=1) = \sum_{\vec{x}^j,\vec{x}} \frac{exp(H(\vec{x}^j) - H(\vec{x}))}{\prod_t Z_t} I(H(\vec{x}^j) \geq H(\vec{x})) \tag{13}$$

This difference indicates how much the current ranking function needs to be modified to compensate for the loss incurred by including this example. Note that $I(x \geq 0) \leq e^x$ for $\forall x \in \mathbb{R}$ (Freund et al., 2003). Therefore, the upper bound on ΔL can be written as:

$$\Delta L(\vec{x}, y=1) \leq \sum_{\vec{x}^j,\vec{x}} \frac{exp(2(H(\vec{x}^j) - H(\vec{x})))}{\prod_t Z_t} \tag{14}$$

$\Delta L(\vec{x}, y=-1)$ can be similarly bounded, e.g. $\Delta L(\vec{x}, y=-1) \leq \sum_{\vec{x},\vec{x}^m} \frac{exp(2(H(\vec{x}) - H(\vec{x}^m)))}{\prod_t Z_t}$. Now, the loss difference can be estimated by taking the expectation over the possible rank labels of $\vec{x}$ with respect to the current ranker's posterior, $\hat{P}(y \mid \vec{x})$:

$$E_{\hat{P}}(\Delta L(\vec{x})) = \hat{P}(y=1 \mid \vec{x}) \Delta L(\vec{x}, y=1) + \hat{P}(y=-1 \mid \vec{x}) \Delta L(\vec{x}, y=-1) \tag{15}$$

Note the similarity with Equation 9 in the SVM case. Finally, we select the instance $\vec{x}$ that has the highest expected loss differential, e.g. $\vec{x}^* = \text{argmax}_{\vec{x}} E_{\hat{P}}(\Delta L(\vec{x}))$. For notational clarity, we take the maximum over the upper bound in Equation 14 as follows:

$$\vec{x}^* = \underset{\vec{x} \in U}{\text{argmax}} \Big\{ \hat{P}(y=1 \mid \vec{x}) \Big(\sum_{\vec{x}^j,\vec{x}} exp(2(H(\vec{x}^j) - H(\vec{x}))) \Big) + \hat{P}(y=-1 \mid \vec{x}) \Big(\sum_{\vec{x},\vec{x}^m} exp(2(H(\vec{x}) - H(\vec{x}^m))) \Big) \Big\} \tag{16}$$

For simplicity, we leave out the normalization constant $\prod_t Z_t$ since we are interested in the relative expectation rather than the absolute expectation.

3.7. Final Selection

The sample selection in both RankSVM and RankBoost requires estimating a posterior label distribution. We adopt a sigmoid function to estimate that posterior in the SVM case, as suggested by (Platt, 1999):

$$\hat{P}(y \mid \vec{x}) = \frac{1}{1 + exp(-y * f(\vec{x}) + C)}$$

where $f(\vec{x})$ is the real-valued score of the ranking algorithm, and C is a constant for calibrating the estimate. C is tuned on a separate corpus not used for evaluation in this paper. The final ranking in RankBoost is a sum of weak learners with the corresponding weights. When the weights are too small (or too large), the posterior gets close to the extreme (either 0 or 1) regardless of the example. Hence, we normalize the RankBoost output dividing by the maximum possible

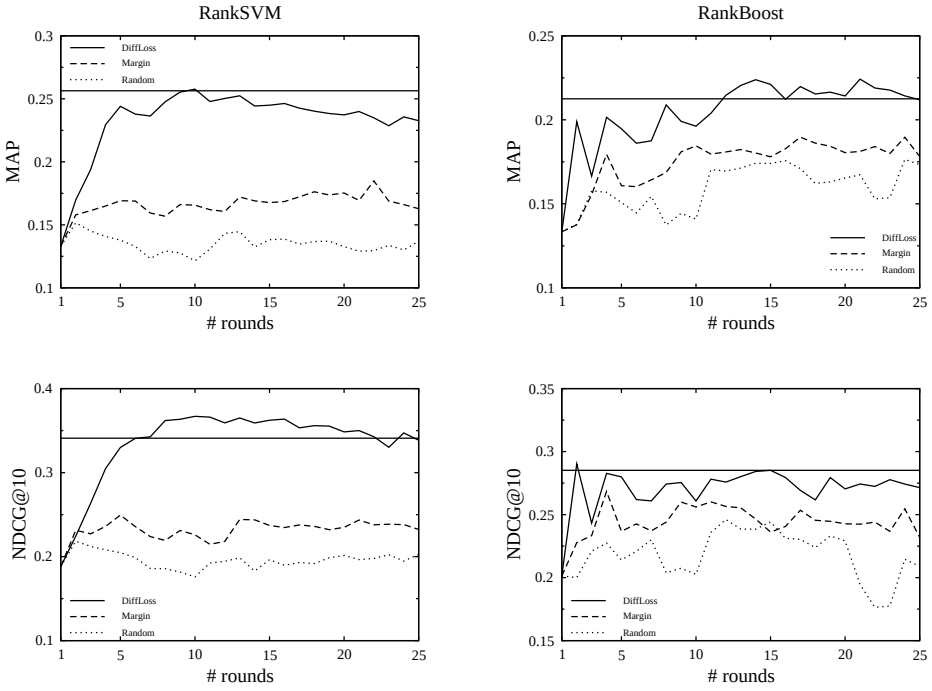

Figure 1. Comparison of different active learners on TREC 2003. The horizontal line indicates the performance when the entire training data is used. Only $\sim 15\%$ of the training data is actively labeled in total by each method.

rank score without changing the rank order:

$$\hat{P}(y \mid \vec{x}) = \frac{1}{1 + exp(-y * \frac{H(\vec{x})}{\sum_{t=1}^{T} \alpha_t} + C)}$$

Note $max_{\vec{x}} H(\vec{x}) = max_{\vec{x}} \sum_{t=1}^{T} \alpha_t h_t(\vec{x}) = \sum_{t=1}^{T} \alpha_t$ since the weak learner $h_t(\vec{x})$ in RankBoost is a {0,1}-valued function defined on the ordering information provided by the corresponding feature (Freund et al., 2003).

4. Evaluation

4.1. Data and Settings

We used two datasets in the experiments: TREC 2003 and 2004 topic distillation tasks in LETOR (Liu et al., 2007). The topic distillation task in TREC is very similar to web search where a page is considered relevant to a query if it is an entry page of some web site relevant to the query. The relevance judgments on the web pages with respect to the queries are binary. There are 44 features, e.g. content and hyperlink features, each of which is extracted from each document-query pair and normalized into $[0, 1]$. There are 50 and 75 queries with 1% and 0.6% relevant documents in TREC03 and TREC04, respectively. The total number of documents per query is ~ 1000 for both datasets. We used the standard train/test splits over 5 folds in LETOR. For each fold, we randomly picked 16 documents including exactly one relevant document per query for initial labeling. The remaining training data is considered as the unlabeled set. We compared our method with the margin-based sampling of (Brinker, 2004; Yu, 2005) and random sampling baselines. Each method selects 5 documents per query for labeling at each round, e.g. our method selects the top 5 documents according to the criteria in Equation 9 and 16. Then, the ranking function is re-trained, and evaluated on the test set. This process is repeated for 25 iterations which corresponds to labeling only $\sim 15\%$ of the entire training data. The reported results are averaged over 5 folds.

We adopted two standard, widely used performance metrics for evaluation, namely the Mean Average Precision (MAP) and the Normalized Discounted Cumulative Gain (NDCG) (Järvelin & Kekäläinen, 2002). For a single query, average precision is defined as the average of the precision as computed at each rank for all relevant documents: $AP = \frac{\sum_{n=1}^{N}(P(r)*rel(r))}{\#\text{ relevant documents for this query}}$ where r is the rank, N is the number of documents retrieved, $rel()$ is a binary function on the relevance of a given rank, and $P(r) = \frac{\#\text{ relevant docs in top r results}}{r}$ is the precision at

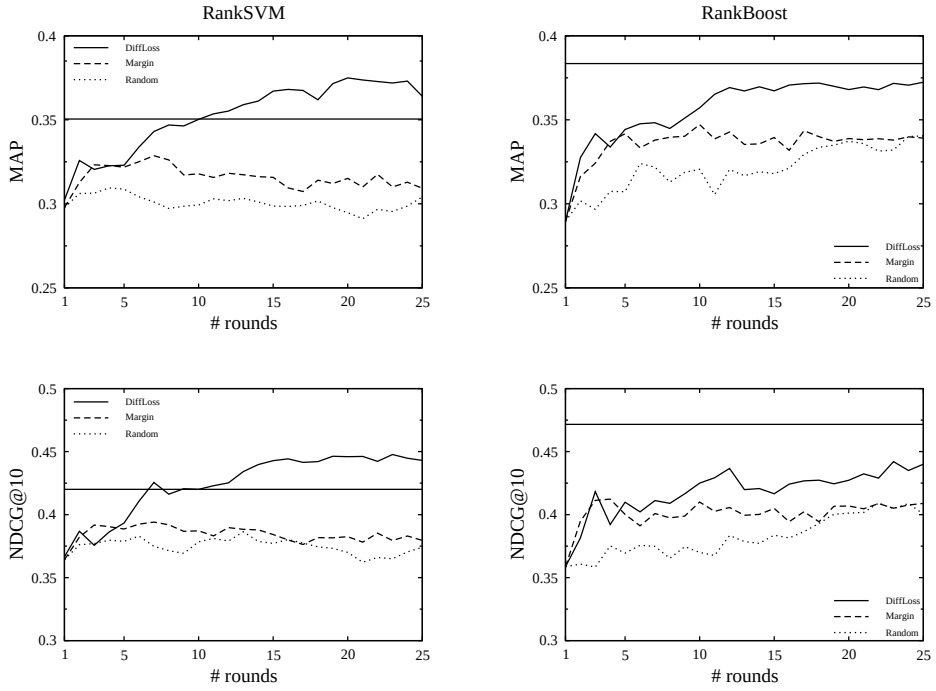

Figure 2. Comparison of different active learners on TREC 2004. The horizontal line indicates the performance when the entire training data is used. Only $\sim 15\%$ of the training data is actively labeled in total by each method.

the rank cut-off r. MAP is obtained by averaging the AP values for all queries. NDCG is cumulative and discounted since the overall utility of a list is measured by the sum of the gain of each relevant document, but the gain is discounted as a function of rank position. The NDCG value of a rank list at position n is given as follows: $NDCG@n = Z_n \sum_{j=1}^{n} \frac{2^{r(j)}-1}{log(1+j)}$ where $r(j)$ is the rank of the j^{th} document in the list, and Z_n is the normalization constant so that a perfect ranking yields an NDCG score of 1.

4.2. Results

Figure 1 and 2 plot the performance of the proposed method (denoted by *DiffLoss*), and as comparative baselines, the margin-based sampling and random sampling strategies on TREC 2003 and 2004 datasets. DiffLoss has a clear advantage over margin-based and random sampling in all cases with respect to different evaluation metrics. The differences over the entire operating range are also statistically significant ($p < 0.0001$) according to a two-sided paired t-test at 95% confidence level. DiffLoss especially achieves 30% relative improvement over the margin-based sampling for RankSVM on TREC 2003 dataset.

The horizontal line in each figure indicates the performance if all the training data was used, which we call the "optimal" performance. The performance of DiffLoss for RankBoost is comparable to the "optimal" on TREC 2003 and 2004 datasets. In case of RankSVM, DiffLoss is close to the "optimal" on TREC 2003, and outperforms it on TREC 2004 dataset. More precisely, DiffLoss using RankSVM reaches the optimal performance (even surpassing it on TREC 2004) after 10 rounds of labeling on average (labeling 5 documents per query at each round). DiffLoss using RankBoost, on the other hand, reaches 95% and 90% of the optimal performance on MAP and NDCG@10, respectively on TREC 2004 dataset after 10 rounds. This suggests that carefully chosen samples might lead to a higher level of accuracy than blindly using large amounts of training data. This is an important development over traditional supervised rank learning since it not only reduces the expensive labeling effort, but also may lead to greater generalization power. As follow-up work, we intend to explore methods that will automatically tell the sampling algorithm when to stop so that maximum gain with minimum cost is obtained, as well as exploring the underlying criteria for measuring the quality of actively selected examples.

We conducted another set of experiments to test the hypothesis that selecting a diverse set of samples might

lead to better results. We adopted the maximal marginal relevance principle of (Carbonell & Goldstein, 1998), originally proposed for text summarization. The idea is to select samples for labeling such that they have both the maximum potential to change the current ranking function and are maximally dissimilar to each other. See (Carbonell & Goldstein, 1998) for more details. However, incorporating this diversity principle into our selection criteria only slightly improved our results at the very beginning of the learning curve, but the improvement vanished afterwards. Thus, we do not report these results here in this paper.

5. Conclusion

We proposed two novel active sampling methods based on SVM rank learning and RankBoost. Our framework relies on the estimated risk of the ranking function on the labeled set after adding a new instance with all possible labels. The samples with the largest expected risk(loss) differential are selected to maximize the degree of learning at the fastest rate. Empirical results on two standard test collections indicate that our method significantly reduces the required number of labeled examples to learn an accurate ranking function. Possible extensions of this work include a study of the risk minimization in terms of direct optimization of ranking performance metrics, such as MAP, NDCG, precision@k, etc. and self-regulating algorithms that can decide when to terminate.

Abstract

Partially Observable Markov Decision Processes (POMDPs) have succeeded in planning domains that require balancing actions that increase an agent's knowledge and actions that increase an agent's reward. Unfortunately, most POMDPs are defined with a large number of parameters which are difficult to specify only from domain knowledge. In this paper, we present an approximation approach that allows us to treat the POMDP model parameters as additional hidden state in a "model-uncertainty" POMDP. Coupled with model-directed queries, our planner actively learns good policies. We demonstrate our approach on several POMDP problems.

1. Introduction

Partially Observable Markov Decision Processes (POMDPs) have succeeded in many planning domains because they can reason in the face of uncertainty, optimally trading between actions that gather information and actions that achieve a desired goal. This ability has made POMDPs attractive in real-world problems such as dialog management (Roy et al., 2000), but such problems often require a large number of parameters that are difficult to specify from domain knowledge alone. Recent advances can solve POMDPs with tens of thousands of states (Shani et al., 2007), but learning in POMDPs remains limited to small problems (Jaulmes et al., 2005).

Traditional reinforcement learning approaches (Watkins, 1989; Strehl et al., 2006; Even-Dar et al., 2005) to learning in MDP or POMDP domains require a reinforcement signal to be provided after each of the agent's actions. If learning must occur through interaction with a human expert, the feedback requirement may be undesirable. The traditional approach also does not guarantee the agent's performance during training. We identify and address three limitations in the traditional approach in this work:

1. Gathering sufficient training data for supervised learning may be prohibitively expensive.
2. Most approaches require the agent to experience a large penalty (i.e., make critical mistakes) to discover the consequences of a poor decision.
3. Accurate numerical reward feedback is especially hard to obtain from people, and inverse reinforcement learning (identifying the reward model without explicit reinforcement) poses its own challenges (Ng & Russell, 2000).

Our objective is to propose a framework for simultaneous learning and planning in POMDPs that overcomes the limitations above, allowing us to build agents that behave effectively in domains with model uncertainty.

We now discuss how our approach will address each of these three issues. To address the issue of long training periods, we adopt a Bayesian reinforcement learning approach and express model-uncertainty as additional hidden state. Bayesian methods (Dearden et al., 1999; Strens, 2000; Poupart et al., 2006; Jaulmes et al., 2005) have received recent attention in reinforcement learning because they allow experts to incorporate domain knowledge into priors over models. Thus, the system begins the learning process as a robust, functional (if conservative) agent while learning to adapt online to novel situations. The domain knowledge specified as a prior can also provide the agent with a basic understanding of potential pitfalls. Our work builds on previous Bayesian reinforcement learning approaches in that we provide both practical approximation schemes as well as guarantees on correctness and convergence.

To ensure robustness toward catastrophic mistakes, we develop an active learning scheme that determines when additional training is needed (typically active learning involves

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

asking for a few labels from unlabeled data; in this work, the 'label' corresponds to asking for the optimal action at a particular point in time). If the agent deems that model uncertainty may cause it to take undue risks, it queries an expert regarding what action it should perform. These queries both limit the amount of training required and allow the agent to infer the potential consequences of an action without executing it. Depending on the domain, we can imagine that different forms of information are most readily available. For example, in a navigation task, it may be straight-forward to query a state oracle (i.e., a GPS system) for a location. Similarly, rewards may be easy to measure based on quantities such as energy usage or time to goal. However, in other domains—particularly when working with human-robot interaction and dialog management systems—policy information may be more accurate; a human user may know what he wishes the agent to do, but may be unable to provide the agent with an accurate state representation (which is often complex, for optimization purposes). In these domains, asking for policy information, instead of a traditional reward signal, also side-steps the issue of getting explicit reward feedback from a human user, which can also be inaccurate (Millet, 1998). In this work, we deal exclusively with policy-based queries.

We are still left with the inverse reinforcement learning problem, as the user's response regarding correct actions provides only implicit information about the underlying reward. To date, Bayesian reinforcement learning has succeeded in learning observation and transition distributions (Jaulmes et al., 2005; Poupart et al., 2006), where updates have closed forms (such as updating Dirichlet counts); previous inverse reinforcement learning work (Ng & Russell, 2000) does not extend to the partially observable case. To overcome this issue, we use a non-parametric approach to model distributions over POMDPs; we demonstrate our approach on several standard problems.

We describe two practical contributions. First, we propose an approximation based on minimizing the immediate Bayes risk for choosing actions when transition, observation, and reward models are uncertain. The Bayes risk criterion avoids the computational intractability of solving large, continuous-valued POMDPs; we show it performs well in a variety of problems. Second, to gather information about the model without assuming state observability, we introduce the notion of *meta-queries*. These meta-queries accelerate learning and help the agent to infer the consequences of a potential pitfall without experiencing its effects. They are a powerful way of gaining information, but they make the strong assumption that they will be answered. Fortunately, a number of decision-making problems exist where this assumption is reasonable, particularly in collaborative human-machine tasks (e.g. automated dialogue systems and shared robot control scenarios).

2. The POMDP Model

A POMDP consists of the n-tuple $\{S,A,O,T,\Omega,R,\gamma\}$. S, A, and O are sets of states, actions, and observations. The transition function $T(s'|s,a)$ is a distribution over the states the agent may transition to after taking action a from state s. The observation function $\Omega(o|s,a)$ is a distribution over observations o that may occur in state s after taking action a. The reward function $R(s,a)$ specifies the immediate reward for each state-action pair. The factor $\gamma \in [0,1)$ weighs the importance of current and future rewards.

In the POMDP model, the agent must choose actions based on past observations; the true state is hidden. The belief, a probability distribution over states, is a sufficient statistic for a history of actions and observations. The belief at time $t+1$ can be computed from the previous belief, b_t, the last action a, and observation o, by applying Bayes rule:

$$b_{t+1}^{a,o}(s) = \Omega(o|s,a) \sum_{s' \in S} T(s|s',a) b_t(s') / Pr(o|b,a), \quad (1)$$

where $Pr(o|b,a) = \sum_{s' \in S} \Omega(o|s',a) \sum_{s \in S} T(s'|s,a) b_t(s)$. If the goal is to maximize the expected discounted reward, then the optimal policy is given by:

$$V_t(b) = \max_{a \in A} Q_t(b,a), \quad (2)$$

$$Q_t(b,a) = R(b,a) + \gamma \sum_{o \in O} Pr(o|b,a) V_t(b^{a,o}), \quad (3)$$

where the value function $V(b)$ is the expected discounted reward that an agent will receive if its current belief is b and $Q(b,a)$ is the value of taking action a in belief b. The exact solution to equation 3 is only tractable for tiny problems, so we use a point-based approximation (Pineau et al., 2003).

3. Modeling POMDP Uncertainty

We assume that the sets S, A, and O are known. The POMDP learning problem is to determine the parameters of T, Ω, and R that describe the dynamics and objective of the problem domain. A Bayesian approach is attractive in many real-world settings because we may have strong notions regarding certain parameters, but the value of those parameters may be difficult to specify exactly. We place a prior over the model parameters to express our domain knowledge, and improve upon this prior with experience.

If the state, action, and observation sets are discrete, T and Ω are collections of multinomial distributions. As conjugate priors, Dirichlet distributions are a natural choice of prior for T and Ω. We use a uniform prior over expert-specified ranges for the reward function R. Together these priors specify a distribution over POMDP models. To build a POMDP that incorporates the model parameters into the hidden state, we consider the joint state space $S' = S \times M$, where M is the space of models as described by all valid values for the model parameters. Although S' is continuous and high dimensional, the transition model for M is simple (assuming the true model is static).

The formulation above makes the agent aware of the uncertainty in the model parameters, and by trying various actions, it will be able to reduce uncertainty both in its state and in the parameters. However, the model information provided by the standard actions may be weak, and we would like the agent to be able to explicitly reduce model uncertainty in a safe manner. To allow for active learning, we augment the action space A of our original POMDP with a set of meta-queries $\{q_m\}$. The meta-queries consult an oracle (e.g., a domain expert) for the optimal action at a particular time step. We assume that the expert has access to the history of actions and observations (as does the agent), as well as the true POMDP model, and thus can advise the agent on the optimal action at any particular time. The agent begins by confirming the action it thinks is best:

"I think a_i is the best action. Should I do a_i?"

If the oracle answers to the negative, the agent follows with what it thinks is next best:

"Then I think a_j is best. Is that correct?"

until it receives an affirmative response. The ordered list of actions helps give the expert a sense of the agent's uncertainty; if the agent is uncertain, the expert might advise it to gather information rather than risk an incorrect decision.[1]

Meta-queries may be applied in situations where an expert is available to guide the agent. Unlike the oracle of Jaulmes et al. (2005), the meta-queries ask for policy information, not state information, which can be important if optimization procedures make the state-space unintuitive to the user (e.g., Williams and Young (2005)). In human-robot interaction, it may also simply be more natural to ask "I think you want me to go to the coffee machine. Should I go there?" which may be more natural than "Please enter your most recent statement" or "Please enter our position coordinates."

We can think of these meta-queries simply as additional actions and simply attempt to solve the model-uncertainty POMDP with this augmented action space. However, such an approach quickly becomes intractable. Therefore, we will treat the meta-query as a special action to be taken if the other actions are too risky. We take the cost ξ of querying the user to be a fixed parameter of the problem.

4. Solution Techniques

Table 1 summarizes our two-part approach to solving the model-uncertainty POMDP. First, given a history of actions and observations, the agent must select the next action. Second, the agent must update its distribution over the model parameters given additional interactions with the environment. In the most general case, both steps are intractable via standard POMDP solution techniques.[2]

[1] Our simulations used a shortened meta-query for speed.

[2] Analytic updates are possible if the distributions take certain forms (Poupart & Vlassis, 2008), but even here pruning is needed to keep the solutions to a tractable size.

Table 1. POMDP active learning approach.

ACTIVE LEARNING WITH BAYES RISK

- Sample POMDPs from a prior distribution.
- Complete a task choosing actions based on Bayes risk:
  - Use the POMDP samples to compute the action with minimal Bayes risk (Section 4.1).
  - If the risk is larger than a given ξ, perform a meta-query (Section 4.1).
  - Update each POMDP sample's belief based on the observation received (Section 4.2).
- Once a task is completed, update prior (Section 4.2):
  - Use a kernel incorporating action-observation history to propagate POMDP samples.
  - Weight POMDPs based on meta-query history.

Performance and termination bounds are in 4.3 and 4.4.

4.1. Bayes-Risk Action Selection

Let the loss $L_m(a, a^*; b)$ of taking action a in model m be $Q^*_m(b, a) - Q^*_m(b, a^*)$, where a^* is the optimal action in belief b according to model m. Given a belief $p_M(m)$ over models, the expected loss $E_M[L]$ is the Bayes risk:

$$BR(a) = \int_M (Q^*_m(b_m, a) - Q^*_m(b_m, a^*_m))p_M(m), \quad (4)$$

where M is the space of models, b_m is the current belief according to model m, and a^*_m is the optimal action for the current belief b_m according to model m. Let $a' = \arg\max_{a \in A} BR(a)$ be the action with the least risk. In the passive learning scenario, our agent just performs a'.

If the risk of the least-risky action a' is large, the agent may still incur significant losses. We would like our agent to be sensitive to the absolute magnitude of the risks that it takes. In the active learning scenario, the agent performs a meta-query if $BR(a')$ is less than $-\xi$, that is, if the least expected loss is more than the cost of the meta-query. The series of meta-queries will lead us to choose the correct action and thus incur no risk.

Intuitively, our criterion selects the least risky action now and hopes that the uncertainty over models will be resolved at the next time step. We can rearrange equation 4 to get:

$$BR(a) = \int_M Q(b_m, a)p_M(m) - \int_M Q(b_m, a^*_m)p_M(m). \quad (5)$$

The second term is independent of the action choice; to maximize $BR(a)$, one may simply maximize the first term:

$$V_{BR} = \max \int_M Q(b_m, a)p_M(m). \quad (6)$$

The Bayes risk criterion is similar to the Q_{MDP} heuristic (Littman et al., 1995), which uses the approximation $V(b) = \max \sum_s Q(s, a)b(s)$ to plan in known POMDPs.

In our case, the belief over states $b(s)$ is replaced by a belief over models $p_M(m)$ and the action-value function over states $Q(s,a)$ is replaced by an action-value function over beliefs $Q(b_m,a)$. In the Q_{MDP} heuristic, the agent assumes that the uncertainty over states will be resolved after the next time step. Our Bayes-risk criterion may be viewed as similarly assuming that the next action will resolve the uncertainty over models.

Though similar, the Bayes risk action selection criterion differs from Q_{MDP} in two important ways. First, our actions come from POMDP solutions and thus do fully consider the uncertainty in the POMDP state. Unlike Q_{MDP}, we do not act on the assumption that our state uncertainty will be resolved after taking the next action; our approximation supposes that only the model uncertainty will be resolved. Thus, if the model stochasticity is an important factor, our approach will take actions to reduce state uncertainty. This observation is true regardless of whether the agent is passive (does not ask meta-queries) or active.

In the active learning setting, the second difference is the meta-query. Without the meta-query, while the agent may take actions to resolve state uncertainty, it will never take actions to reduce model uncertainty. However, meta-queries ensure that the agent rarely (with probability δ) takes a less than ξ-optimal action in expectation. Thus the meta-queries make the learning process robust from the start and allow the agent to resolve model uncertainty.

Approximation and bounds: The integral in equation 4 is computationally intractable, so we approximate it with a sum over a sample of POMDPs from the space of models:

$$BR(a) \approx \sum_i (Q(b_i,a) - Q(b_i,a_i^*))p_M(m_i) \qquad (7)$$

There are two main sources of approximation that can lead to error in our computation of the Bayes risk:

- Error due to the Monte Carlo approximation of the integral in equation 4: Note that the maximum value of the $Q(b_i,a) - Q(b_i,a_i^*)$ is trivially upper bounded by $\frac{R_{\max} - \min(R_{\min},\xi)}{1-\gamma}$ and lower bounded by zero. Applying the Hoeffding bound with sampling error ϵ_s and confidence δ, we will require n_m samples:[3]

$$n_m = \frac{(R_{\max} - \min(R_{\min},\xi))^2}{2(1-\gamma)^2\epsilon_s^2} \log \frac{1}{\delta} \qquad (8)$$

- Error due to the point-based approximation of $Q(b_i,a)$: The difference $Q(b_i,a) - Q(b_i,a_i^*)$ may have an error of up to $\epsilon_{PB} = \frac{2(R_{\max} - R_{\min})\delta_B}{(1-\gamma)^2}$, where δ_B is the sampling density of the belief points. This result is directly from the error bound due to Pineau et al. (2003).

[3] An error of ϵ with confidence δ means $Pr[x - \hat{x} > \epsilon] < \delta$.

To obtain a confidence δ when calculating if the Bayes risk is greater than $-\xi$, we combine these bounds, setting $\epsilon_s = \xi - \epsilon_{PB}$, and computing the appropriate number of samples n from equation 8. We note however that the Hoeffding bounds used to derive this approximation are quite loose; for example in the shuttle POMDP problem, we used 200 samples, whereas equation 8 suggested over 3000 samples may have been necessary even with a perfect POMDP solver.

4.2. Updating the Model Distribution

As described in Section 3, we initially placed Dirichlet priors over the transition and observation parameters and uniform priors over the reward parameters. As our agent interacts with the environment, it receives two sources of information to update its prior: a history h of actions and observations and a set of meta-queries (and responses) Q. Given h and Q, the posterior $p_{M|h,Q}$ over models is:

$$p_{M|h,Q}(m|h,Q) \propto p(Q|m)p(h|m)p_M(m), \qquad (9)$$

where Q and h are conditionally independent given m because they are both computed from the model parameters. The history h is the sequence of actions and observations since p_M was last updated. The set Q is the set of *all* meta-queries asked (and the expert's responses). Each source poses a different challenge when updating the posterior.

If the agent were to have access to the hidden underlying state, then it would be straightforward to compute $p_{M|h}(m|h) \propto p(h|m)p_M(m)$; we simply need to add counts to the appropriate Dirichlet distributions. However, when the state sequence is unknown, the problem becomes more difficult; the agent must use its belief over the state sequence to update the posterior. Thus, it is best to perform the update when it is most likely to be accurate. For example, in a robot maze scenario, if the robot is lost, then estimating its position may be inaccurate. However, once the robot reaches the end of the maze, it knows both its start and end position, providing more information to recover its path. We focus on episodic tasks in this work and update the belief over models at the completion of a task.

The meta-query information poses a different challenge: the questions provide information about the policy, but our priors are over the model parameters. The meta-queries truncate the original Dirichlet as models inconsistent with meta-query responses have zero likelihood. We approximate the posterior with a particle filter.

4.2.1. During a task: Updating particle weights

Recall that sequential Monte Carlo techniques let us represent a distribution at time t using a set of samples from time $t-1$ using the following procedure (Moral et al., 2002):

$$m_t \sim K(m_{t-1}, m_t), \qquad (10)$$

$$w_t = w_{t-1} \frac{p_{M,t}(m_t)}{p_{M,t-1}(m_{t-1})K(m_{t-1},m_t)}, \qquad (11)$$

where $K(m, m')$ is an arbitrary transition kernel and p_M is the probability of the model m under the true posterior.

Sampling a new model requires solving a POMDP, which is computationally expensive and thus may be undesirable while an agent is in the process of completing a task. Thus, we do not change our set of samples during a task (that is, $K(m, m') = \delta_m(m')$ where $\delta()$ is the Dirac delta function). We begin at time $t-1$ with a set of models m_i and weights w_i that represent our current belief over models. If a meta-query occurs at time t, then $p_{M,t}(m) \propto p(Q_t|m)p_{M,t-1}(m)$, and the weight update reduces to

$$w_t = w_{t-1}p(Q_t|m). \tag{12}$$

In theory, the $p(Q|m)$ should be a delta function: either the model m produces a policy that is consistent with the meta-query ($p(Q|m) = 1$), or it does not ($p(Q|m) = 0$). In practice, approximation techniques used to compute the model's policy are imperfect (and expert advice can be incorrect) so we do not want to penalize a model that occasionally acts incorrectly. We model the probability of seeing k incorrect responses in n trials as a binomial variable with parameter p_e, where p_e is the probability a model fails a meta-query due to the approximate solver. This value is hard to characterize, of course, and is problem-specific; we used $p_e = 0.3$ in our tests.

4.2.2. Between tasks: Resampling Particles.

Over time, samples taken from the original prior may no longer represent the posterior well. Moreover, if only a few high weight samples remain, the Bayes risk may appear smaller than it really is because most of the samples are in the wrong part of the space. We also need to update the models based on the history information, which we have ignored so far. We do both these steps at the end of a task.

Action-Observation Histories: Dirichlet Update. We first discuss how to update the posterior $p(m|h)$ in closed form. Recall that updating the Dirichlet counts given actions and observations requires knowing the underlying state history, and our agent only has access to history of actions and observations. We therefore update our parameters using an online extension of the standard EM algorithm (Sato, 1999). In the E-step, we estimate a distribution over state sequences in the episode. In the M-step, we use this distribution to update counts on our Dirichlet priors. Online EM guarantees convergence to a local optimum.

For the E-step, we first estimate the true state history. Two sources of uncertainty are present: model stochasticity and unknown model parameters. To compute the expectation with respect to model stochasticity, we use the standard forward-backward algorithm to obtain a distribution over states for each sample. Next, we combine the distributions for each sample based on the sample's weight. For example, suppose a sampled model assigns a probability $p_i(s)$ to being in state s. Then the expected probability $\hat{p}(s)$ of being in state s is $\hat{p}(s) = \sum_i^n w_i p_i(s)$. The samples represent our distribution over models, so this sum approximates an expectation over all models.

Next, we update our Dirichlet counts based on both the probability that a POMDP assigns to a particular state and the probability of that POMDP. Given an action a and observation o corresponding to time t, we would update our Dirichlet count for $\alpha_{o,s,a}$ in the following manner:

$$\alpha_{o,s,a} = \alpha_{o,s,a} + \hat{p}(s) \tag{13}$$

for each state s. This update combines prior knowledge about the parameters—the original value of $\alpha_{o,s,a}$—with new information from the current episode, $\hat{p}(s)$.

Resampling Models. As is standard in sequential Monte Carlo techniques, we begin by resampling models according to their weights w_i. Thus, a model with high weight may get selected many times for inclusion in the resampled set of models, while a model with low weight may disappear from the sample set since it is no longer representative of the posterior. Once resampled, each model has equal weight. Before we begin the next task, we perturb the models with the following transition kernel:

- Draw a sample m' from $p_{M|h}$.
- With probability p_k, replace m with m'
- With probability $1 - p_k$, take the convex combination of the model parameters of m and m' so that $m' = p \cdot m' + (1-p) \cdot m$ with the convexity parameter being chosen uniformly at random on $[0, a]$.

We reduce the probability p_k from 0.9 to 0.4 as the interactions continue, encouraging large exploration earlier on and fine-tuning in later interactions. We set a to 0.2 in our experiments. Based on this sampling procedure, the weight (keeping in mind that after resampling, all models had equal weight) of the transitioned model m' is given by:

$$w_t \propto \frac{p(Q|m')p_{M|h}(m')}{p(Q|m)p_M(m)K(m, m')}, \tag{14}$$

where, $K(m, m') = p_k \cdot p_{M|h}(m')$ if we keep the newly-sampled model and and $K(m, m') = (1-p_k) \cdot p_{M|h}(m')/a$ if we perturb m via a convex combination.

4.3. Performance Bounds

Let V^* be the value of the optimal policy under the true model. From our risk criterion, the expected loss at each action is no more than ξ. However, with probability δ, in the worst case, the agent may choose a bad action that takes it to an absorbing state in which it receives R_{min} forever.

To determine the expected discounted reward, we consider a two-state Markov chain. In state 1, the "normal" state, the agent receives a reward of $R - \xi$, where R is the value the agent would have received under the optimal policy. In state 2, the agent receives $R_{\min}$. Equation 15 describes the

transitions in this simple chain and the values of the states:

$$\begin{vmatrix} V_1 \\ V_2 \end{vmatrix} = \begin{vmatrix} R - \xi \\ R_{\min} \end{vmatrix} + \gamma \begin{vmatrix} 1-\delta & \delta \\ 0 & 1 \end{vmatrix} \begin{vmatrix} V_1 \\ V_2 \end{vmatrix}. \quad (15)$$

Solving this system and noting that the agent begins in state 1 with probability $1 - \delta$ and state 2 with probability δ, the lower bound V' on the expected value is

$$V' = \eta(V^* - \frac{\xi}{1-\gamma}) + (1-\eta)\frac{R_{min}}{1-\gamma}, \quad (16)$$

$$\eta = (1-\delta)(1-\gamma)(1-\gamma(1-\delta))^{-1}. \quad (17)$$

4.4. Model Convergence

Given the algorithm in Table 1, we would like to know if the learner will eventually stop asking meta-queries. We state that the model is *converged* if $BR(a') > -\xi$ for all histories (where ξ is the cost of a meta-query). Our convergence argument involves two steps. First, let us ignore the reward model and consider only the observation and transition models. As long as standard reinforcement learning conditions—periodic resets to a start state and information about all states (via visits or meta-queries)—hold, the prior will peak around some value (perhaps to a local extremum) in a bounded number of interactions from the properties of the online EM algorithm (Sato, 1999). We next argue that once the observation and transition parameters have converged, we can bound the meta-queries required for the reward parameters to converge.

Observation and Transition Convergence. To discuss the convergence of the observation and transition distributions, we apply a weaker sufficient condition than the convergence of the EM algorithm. We note that the number of interactions bounds the number of meta-queries, since we ask at most one meta-query for each normal interaction. We also note that the counts on the Dirichlet priors increase monotonically. Once the Dirichlet parameters are sufficiently large, the variance in the sampled models will be small; even if the mean of the Dirichlet distribution shifts with time, no additional meta-queries will be asked.

The specific convergence rate of the active learning will depend heavily upon the problem. However, we can check if k additional interactions are sufficient such that the probability of asking a meta-query is p_q with confidence δ_q. To do so, we will sample random beliefs and test if less than a p_q-proportion have a Bayes risk greater than ξ.

1. **Sampling a Sufficient Number of Beliefs.** To test if k interactions lead to a probability p_q of additional meta-queries with confidence δ_q, we compute the Bayes risk for n_b beliefs sampled uniformly. If fewer than $n_q = p_q n_b$ beliefs require meta-queries after k interactions, we accept the value of k. We sample from the posterior Dirichlet given k interactions and estimate $\hat{p}_q = n_q/n_b$. We desire $\hat{p}_q$ to be within ϵ_q of $p'_q = p_q - \epsilon_q$ with probability δ_q. Using the Chernoff bound $\delta_q = e^{-n_b p'_q \epsilon_q^2/3}$, we set ϵ_q to $2/3p_q$ to minimize the samples needed:

$$n_b > -27/4 \cdot (p_q)^{-3} \log \delta_q. \quad (18)$$

2. **Computing Bayes Risk from a Conservative Posterior.** We next compute the Bayes risk for each belief given a hypothesized set of k interactions. We do not know *a priori* the response to the interactions, so we use the maximum-entropy Dirichlet posterior to compute the posterior Bayes risk (that is, assign the k counts to assign an equal number of counts to each variable). We compute the Bayes risk of each belief from this posterior and accept k if $\hat{p}_q < p_q$.
3. **Correction for Approximate Bayes Risk.** Recall that we approximate the Bayes risk integral with a sum over sampled POMDP models, and the number of models n_m required is given by equation 8. We must correct for the error induced by this approximation. Section 4.1 tells us if a belief b has risk $BR(a) < -\xi$ with confidence δ. Suppose we sample n_b beliefs, and the true fraction of beliefs in which meta-queries are asked is p_q. Due to misclassifications, however, the expected value we will observe is only $(1-\delta)p_q$. We can then apply a second Chernoff bound to determine that with probability δ, no more than $2(1-\delta)n_b$ beliefs will be misclassified.[4] Let

$$p''_q = p_q(1 - 2(1-\delta)), \quad (19)$$

be the minimum fraction of beliefs queries we expect to observe requiring meta-queries if the true fraction is p_q.

Thus, to test if k interactions lead to a probability of p_q for meta-queries with confidence δ_q, we compute p''_q from equation 19, sample n_b beliefs uniformly from equation 18, update the Dirichlet posteriors to be maximum-entropy posteriors, sample the n_m models from equation 8, and finally compute the posterior Bayes risk for each belief. If less than a p_q-proportion of beliefs require meta-queries, then k is an upper bound on the number of remaining meta-queries with probability p_q and confidence δ_q.

Reward Convergence. The cost of a meta-query limits the reward resolution. Suppose a POMDP P has an optimal policy π with value V. If we adjusted all the rewards by some small ϵ_r, then the value of the same policy π will differ from V by at most $\frac{\epsilon_r}{1-\gamma}$ (since we will receive at worst ϵ_r less reward at each time step). This value is a lower-bound on the optimal policy in the new POMDP. Thus, a POMDP with all its rewards within $(1-\gamma)\xi$ of P will have a policy of value $V \pm \xi$. In this way, the value ξ imposes a minimal level of discretization over the reward space.

The rewards are bounded between $R_{\min}$ and $R_{\max}$. If our reward space has d dimensions, then our discretization will

[4] This bound requires $n_b > \frac{3}{\delta} \log \frac{1}{\delta}$, but we will find that our final bound for n_b is greater than this value.

yield at most $(\frac{R_{\max}-R_{\min}}{(1-\gamma)\xi})^d$ POMDPs. (Intuitively, the discretization involves limiting the precision of the sampled rewards.) Since each meta-query invalidates at least one POMDP, we must eventually stop asking meta-queries.

5. Results

We first solve a discretized model-uncertainty POMDP solved directly to show the utility of meta-queries. We next couple the meta-queries with our Bayes-risk criterion for learning with with continuous-valued unknown parameters.

5.1. Learning Discrete Parameters

In domains where model uncertainty is limited to a few, discrete parameters, we may be able to solve for the complete model-uncertainty POMDP using standard POMDP methods. We consider a simple POMDP-based dialog management task (Doshi & Roy, 2007) where the reward is unknown. We presume the correct reward is one of four (discrete) possible levels and that the meta-query had a fixed associated cost. Figure 1 compares the performance of the optimal policy *with* meta-queries (left column), an optimal policy *without* meta-queries (middle column), and our Bayes risk policy *with* meta-queries (right column). The difference in median performance is small, but the variance reduction from the meta-queries is substantial.[5]

Unfortunately, discretizing the model space does not scale; increasing from 4 to 48 possible reward levels, we could no longer obtain high-quality global solutions using standard techniques. Next, we present results using our Bayes-risk action selection criterion when we no longer discretize the parameter space and instead allow the parameters to take on continuous values within prespecified ranges.

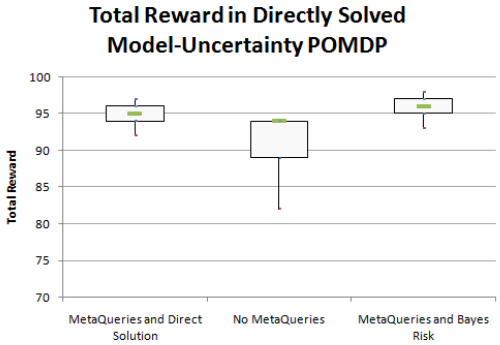

Figure 1. Boxplot of POMDP learning performance with a discrete set of four possible models. The medians of the policies are comparable, but the active learner (left) makes fewer mistakes than the passive learner (center). The Bayes risk action selection criterion (right) does not cause the performance to suffer.

[5]Although the Bayes risk approximation appears higher, the difference in performance in both median and variance is negligible between the optimal policy and the Bayes risk approximation.

5.2. Learning Continuous Parameters

Table 2 shows our approach applied to several standard POMDP problems (Littman et al., 1995). For each problem, between 50-200 POMDP samples were initially taken from the prior over models. The sampled POMDPs were solved very approximately, using relatively few belief points (500) and only 25 partial backups. The policy oracle used a solution to the true model with many more belief points (1000-5000) and 250 full backups. We took this solution to be the optimal policy. During a trial, which continued until either the task was completed or a maximum number of iterations was reached, the agent had the choice of either taking a normal action or asking a meta-query and then taking the supplied optimal action. POMDPs were resampled at the completion of each trial.

The non-learner (control) always used its initial samples to make decisions, using the Bayes-risk criterion to select an action from the policies of the sampled models. Its prior did not change based on the action-observation histories that it experienced, nor did it ask any meta-queries to gain additional information. The passive learner resampled its POMDP set after updating its prior over transitions and observations using the forward-backward algorithm. The active learner used both the action-observation histories and meta-queries for learning. None of the systems received explicit reward information, but the active learner used meta-queries to infer information about the reward model. The Hallway problem was too large for the agent to learn (after 50 repetitions, it still queried the oracle at nearly every step); in these results we provided the agent with possible successor states. The smarter prior seemed reasonable as a map and may be easier to obtain for a new environment than to the robot's dynamics. Depending on the problem, tasks required an average of 7 to 32 actions to complete.

Table 2. Mean difference between optimal (under the true model) and accrued rewards (smaller = better).

Problem	States	Control	Passive	Active
Tiger	2	46.5	50.7	33.3
Shuttle	8	10.0	10.0	2.0
Gridworld-5	26	33.1	102	21.4
Hallway	57	1.0	1.0	0.08

Figure 2 shows the performance of the three agents on the shuttle problem (a medium-sized standard POMDP). In each case, the agent began with observation and transition priors with high variance but peaked toward the correct value (that is, slightly better than uniform). We created these priors by applying a diffusion filter to the ground-truth transition and observation distributions and using the result as our initial Dirichlet parameters. All reward priors were uniform between the minimum and maximum reward values of the ground-truth model. The active learner started (and remained) with good performance because it used meta-queries when initially confused about the model. Thus, its performance was robust throughout.

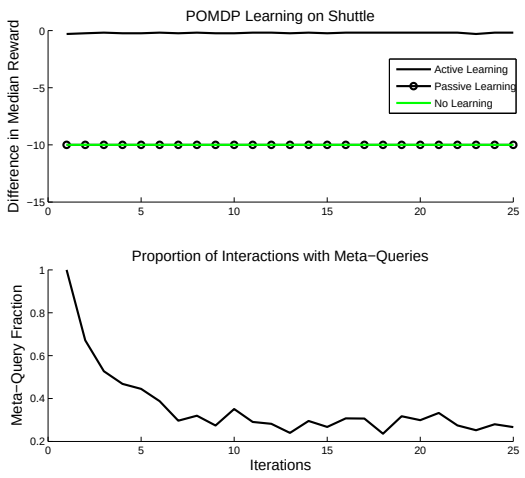

Figure 2. Performance of the non-learner, passive learner, and active learner on the shuttle problem.

6. Discussion and Conclusion

One recent approach to MDP model learning, the Beetle algorithm (Poupart et al., 2006), converts a discrete MDP into a continuous POMDP with state variables for each MDP parameter. However, their analytic solution does not scale to handle the entire model as a hidden state in POMDPs. Also, since the MDP is fully observable, Beetle can easily adjust its prior over the MDP parameters as it acquires experience; in our POMDP scenario, we needed to estimate the possible states that the agent had visited. Recently the authors have extended Beetle to partially observable domains (Poupart & Vlassis, 2008), providing similar analytic solutions to the POMDP case. The work outlines efficient approximations but results are not provided.

Prior work in MDP and POMDP learning has also considered sampling to approximate a distribution over uncertain models. Dearden et. al. (1999) discusses several approaches for representing and updating priors over MDPs using sampling and value function updates. Strens (2000) shows that in the MDPs, randomly sampling only one model from a prior over models, and using that model to make decisions, is guaranteed to converge to the optimal policy if one resamples the MDP sufficiently frequently from an updated prior over models. More recently, in the case of POMDPs, Medusa (Jaulmes et al., 2005) avoids the problem of knowing how to update the prior by occasionally requesting the true state based on model-uncertainty heuristics. It converges to the true model but may make several mistakes before convergence. Our risk-based heuristic and policy queries provide correctness and convergence guarantees throughout the learning process.

We developed an approach for active learning in POMDPs that can robustly determine a near-optimal policy. Meta-queries—questions about actions that the agent is thinking of taking—and a risk-averse action selection criterion allowed our agent to behave robustly even with uncertain knowledge of the POMDP model. We analyzed the theoretical properties of our algorithm, but also included several practical approximations that rendered the method tractable. Finally, we demonstrated the approach on several problems from the POMDP literature. In our future work, we hope to develop more efficient POMDP sampling schemes—as well as heuristics for allocating more computation to more promising solutions—to allow our approach to be deployed on larger, real-time applications.

Abstract

We introduce confidence-weighted linear classifiers, which add parameter confidence information to linear classifiers. Online learners in this setting update both classifier parameters and the estimate of their confidence. The particular online algorithms we study here maintain a Gaussian distribution over parameter vectors and update the mean and covariance of the distribution with each instance. Empirical evaluation on a range of NLP tasks show that our algorithm improves over other state of the art online and batch methods, learns faster in the online setting, and lends itself to better classifier combination after parallel training.

1. Introduction

Online learning algorithms operate on a single instance at a time, allowing for updates that are fast, simple, make few assumptions about the data, and perform well in wide range of practical settings. Online learning algorithms have become especially popular in natural language processing for tasks including classification, tagging, and parsing. In this paper, we revisit the design of linear classifier learning informed by the particularities of natural language tasks. Specifically, feature representations for natural language processing have very high dimension (millions of features derived from words and word combinations are common), and most features are observed on only a small fraction of instances. Nevertheless, those many rare features are important in classifying the instances in which they occur. Therefore, it is worth investigating whether online learning algorithms for linear classifiers could be improved to take advantage of these particularities of natural language data.

We introduce *confidence-weighted* (CW) learning, a new class of online learning methods that maintain a probabilistic measure of confidence in each parameter. Less confident parameters are updated more aggressively than more confident ones. Parameter confidence is formalized with a Gaussian distribution over parameter vectors, which is updated for each new training instance so that the probability of correct classification for that instance under the updated distribution meets a specified confidence. We show superior classification accuracy over state-of-the-art online and batch baselines, faster learning, and new classifier combination methods after parallel training.

We begin with a discussion of the motivating particularities of natural language data. We then derive our algorithm and discuss variants. A series of experiments shows CW learning's empirical benefits. We conclude with a discussion of related work.

2. Online Algorithms and NLP

In natural language classification tasks, many different features, most of which are binary and are infrequently on, can be weakly indicative of a particular class. Therefore, we have both data sparseness, which demands large training sets, and very high dimensional parameter vectors. For certain types of problems, such as structured prediction in tagging or parsing, the size and processing complexity of individual instances make it difficult to keep more than a small number of instances in main memory. These particularities make online algorithms, which process a single instance at a time, a good match for natural-language tasks. Processing large amounts of data is simple for online methods, which require observing each instance once — though in practice several iterations may be

[1]Work done at the University of Pennsylvania.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

necessary — and update parameter vectors using a single instance at a time. In addition, the simple nature of most online updates make them very fast.

However, while online algorithms do well with large numbers of features and instances, they are not designed for the heavy tailed feature distributions characteristic of natural language tasks. This type of feature distribution can have a detrimental effect on learning. With typical linear classifier training algorithms, such as the perceptron or passive-aggressive (PA) algorithms (Rosenblatt, 1958; Crammer et al., 2006), the parameters of binary features are only updated when the features occur. Therefore, frequent features typically receive more updates. Similarly, features that occur early in the data stream take more responsibility for correct prediction than those observed later. The result is a model that could have good parameter estimates for common features and inaccurate values for rare features. However, no distinction is made between these feature types in most online algorithms.

Consider an illustrative example from the problem of sentiment classification. In this task, a product review is represented as n-grams and the goal is to label the review as being positive or negative about the product. Consider a positive review that simply read *"I liked this author."* An online update would increase the weight of both "liked" and "author." Since both are common words, over several examples the algorithm would converge to the correct values, a positive weight for "liked" and zero weight for "author." Now consider a slightly modified negative example: *"I liked this author, but found the book dull."* Since "dull" is a rare feature, the algorithm has a poor estimate of its weight. An update would decrease the weight of both "liked" and "dull." The algorithm does not know that "dull" is rare and the changed behavior is likely caused by the poorly estimated feature ("dull") instead of the common well estimated feature ("liked.") This update incorrectly modified "liked" and does not attribute enough negative weight to "dull," thereby decreasing the rate of convergence.

This example demonstrates how a lack of memory for previous instances — a property that allows online learning — can hurt learning. A simple solution is to augment an online algorithm with additional information, a memory of past examples. Specifically, the algorithm can maintain a confidence parameter for each feature weight. For example, assuming binary features, the algorithm could keep a count of the number of times each feature has been observed, or, for general real-valued features, it could keep the cumulative second moment per feature. The larger the count or second moement, the more confidence in a feature's weight. These estimates are then used to influence parameter updates. Instead of equally updating every feature weight for the features present in an instance, the update favors changing more low-confidence weights than high-confidence ones. At each update, the confidence in all observed features is increased by focusing the update on low confidence features. In the example above, the update would decrease the weight of "dull" but make only a small change to "liked" since the algorithm already has a good estimate of this parameter.

3. Online Learning of Linear Classifiers

Online algorithms operate in rounds. On round i the algorithm receives an instance $\boldsymbol{x}_i \in \mathbb{R}^d$ to which it applies its current prediction rule to produce a prediction $\hat{y}_i \in \{-1, +1\}$ (for binary classification.) It then receives the true label $y_i \in \{-1, +1\}$ and suffers a loss $\ell(y_i, \hat{y}_i)$, which in this work will be the zero-one loss $\ell(y_i, \hat{y}_i) = 1$ if $y_i \neq \hat{y}_i$ and $\ell(y_i, \hat{y}_i) = 0$ otherwise. The algorithm then updates its prediction rule and proceeds to the next round.

Just as in many well known algorithms, such as the perceptron and support vector machines, in this work our prediction rules are linear classifiers

$$f_{\boldsymbol{w}}(\boldsymbol{x}) : f_{\boldsymbol{w}}(\boldsymbol{x}) = \text{sign}(\boldsymbol{x} \cdot \boldsymbol{w}) \ . \tag{1}$$

If we fix the norm of $\boldsymbol{w}$, we can identify $f_{\boldsymbol{w}}$ with $\boldsymbol{w}$, and we will use $\boldsymbol{w}$ in the rest of this work.

The *margin* of an example $(\boldsymbol{x}, y)$ with respect to a specific classifier $\boldsymbol{w}$ is given by $y(\boldsymbol{w} \cdot \boldsymbol{x})$. The sign of the margin is positive iff the classifier $\boldsymbol{w}$ predicts correctly the true label y. The absolute value of the margin $|y(\boldsymbol{w} \cdot \boldsymbol{x})| = |\boldsymbol{w} \cdot \boldsymbol{x}|$ is often thought of as the *confidence* in the prediction, with larger positive values corresponding to more confident correct predictions. We denote the margin at round i by $m_i = y_i(\boldsymbol{w}_i \cdot \boldsymbol{x}_i)$.

A variety of linear classifier training algorithms, including the perceptron and linear support vector machines, restrict $\boldsymbol{w}$ to be a linear combination of the input examples. Online algorithms of that kind typically have updates of the form

$$\boldsymbol{w}_{i+1} = \boldsymbol{w}_i + \alpha_i y_i \boldsymbol{x}_i \ , \tag{2}$$

for some non-negative coefficients α_i.

In this paper we focus on PA updates (Crammer et al., 2006) for linear classifiers. After predicting with $\boldsymbol{w}_i$ on the ith round and receiving the true label y_i, the

algorithm updates the prediction function such that the example $(\boldsymbol{x}_i, y_i)$ will be classified correctly with a fixed margin (which can always be scaled to 1):

$$\begin{aligned} \boldsymbol{w}_{i+1} = \min_{\boldsymbol{w}} \quad & \frac{1}{2}\left\|\boldsymbol{w}_i - \boldsymbol{w}\right\|^2 \\ \text{s.t.} \quad & y_i(\boldsymbol{w}\cdot\boldsymbol{x}_i) \geq 1 \ . \end{aligned} \tag{3}$$

The dual of (3) gives us the round coefficients for (2):

$$\alpha_i = \max\left\{\frac{1 - y_i\left(\boldsymbol{w}_i\cdot\boldsymbol{x}_i\right)}{\left\|\boldsymbol{x}_i\right\|^2}, 0\right\}$$

Crammer et al. (2006) provide a theoretical analysis of algorithms of this form, and they have been shown to work well in a variety of applications.

4. Distributions over Classifiers

We model parameter confidence for a linear classifier with a diagonal Gaussian distribution with mean $\boldsymbol{\mu} \in \mathbb{R}^d$ and standard deviation $\boldsymbol{\sigma} \in \mathbb{R}^d$. The values μ_j and σ_j represent our knowledge of and confidence in the parameter for feature j. The smaller σ_j, the more confidence we have in the mean parameter value μ_j. For simplicity of presentation, we use a covariance matrix $\Sigma \in \mathbb{R}^{d\times d}$ for the distribution, with diagonal $\boldsymbol{\sigma}$ and zero for off-diagonal elements. Note that while our motivation assumed sparse binary features, the algorithm does not depend on that assumption.

Conceptually, to classify an input instance $\boldsymbol{x}$, we draw a parameter vector $\boldsymbol{w} \sim \mathcal{N}\left(\boldsymbol{\mu}, \Sigma\right)$ and predict the label according to the sign of $\boldsymbol{w}\cdot\boldsymbol{x}$. This multivariate Gaussian distribution over parameter vectors induces a univariate Gaussian distribution over the margin viewed as a random variable:

$$M \sim \mathcal{N}\left(y_i(\boldsymbol{\mu}\cdot\boldsymbol{x}_i) \ , \ \boldsymbol{x}_i^\top\Sigma\boldsymbol{x}_i\right) \ .$$

The mean of the margin is the margin of the averaged parameter vector and its variance is proportional to the length of the projection of $\boldsymbol{x}_i$ on Σ_i. Since a prediction is correct iff the margin is non-negative, the probability of a correct prediction is

$$\Pr_{\boldsymbol{w}\sim\mathcal{N}(\boldsymbol{\mu},\Sigma)}\left[M \geq 0\right] = \Pr_{\boldsymbol{w}\sim\mathcal{N}(\boldsymbol{\mu},\Sigma)}\left[y_i\left(\boldsymbol{w}\cdot\boldsymbol{x}_i\right) \geq 0\right] \ .$$

When possible, we omit the explicit dependency on the distribution parameters and write $\Pr\left[y_i\left(\boldsymbol{w}\cdot\boldsymbol{x}_i\right) \geq 0\right]$.

4.1. Update

On round i, the algorithm adjusts the distribution to ensure that the probability of a correct prediction for training instance i is no smaller than the confidence hyperparameter $\eta \in [0, 1]$:

$$\Pr\left[y_i\left(\boldsymbol{w}\cdot\boldsymbol{x}_i\right) \geq 0\right] \geq \eta \ . \tag{4}$$

Following the intuition underlying the PA algorithms (Crammer et al., 2006), our algorithm chooses the distribution closest in the KL divergence sense to the current distribution $\mathcal{N}\left(\boldsymbol{\mu}_i, \Sigma_i\right)$. Thus, on round i, the algorithm sets the parameters of the distribution by solving the following optimization problem:

$$\left(\boldsymbol{\mu}_{i+1}, \Sigma_{i+1}\right) = \min \mathrm{D}_{\mathrm{KL}}\left(\mathcal{N}\left(\boldsymbol{\mu}, \Sigma\right) \left\| \mathcal{N}\left(\boldsymbol{\mu}_i, \Sigma_i\right)\right.\right) \tag{5}$$

$$\text{s.t. } \Pr\left[y_i\left(\boldsymbol{w}\cdot\boldsymbol{x}_i\right) \geq 0\right] \geq \eta \ . \tag{6}$$

We now develop both the objective and the constraint of this optimization problem following Boyd and Vandenberghe, (2004, page 158). We start with the constraint (6). As noted above, under the distribution $\mathcal{N}\left(\boldsymbol{\mu}, \Sigma\right)$, the margin for $(\boldsymbol{x}_i, y_i)$ has a Gaussian distribution with mean $\mu_M = y_i\left(\boldsymbol{\mu}\cdot\boldsymbol{x}_i\right)$ and variance $\sigma_M^2 = \boldsymbol{x}_i^\top\Sigma\boldsymbol{x}_i$. Thus the probability of a *wrong* classification is

$$\Pr\left[M \leq 0\right] = \Pr\left[\frac{M - \mu_M}{\sigma_M} \leq \frac{-\mu_M}{\sigma_M}\right] \ .$$

Since $\left(M - \mu_M\right)/\sigma_M$ is a normally distributed random variable, the above probability equals $\Phi\left(-\mu_M/\sigma_M\right)$, where Φ is the cumulative function of the normal distribution. Thus we can rewrite (6) as

$$\frac{-\mu_M}{\sigma_M} \leq \Phi^{-1}\left(1 - \eta\right) = -\Phi^{-1}\left(\eta\right) \ .$$

Substituting μ_M and σ_M by their definitions and rearranging terms we obtain:

$$y_i(\boldsymbol{\mu}\cdot\boldsymbol{x}_i) \geq \phi\sqrt{\boldsymbol{x}_i^\top\Sigma\boldsymbol{x}_i} \ ,$$

where $\phi = \Phi^{-1}\left(\eta\right)$.

Unfortunately, this constraint is not convex in Σ, so we linearize it by omitting the square root:

$$y_i(\boldsymbol{\mu}\cdot\boldsymbol{x}_i) \geq \phi\left(\boldsymbol{x}_i^\top\Sigma\boldsymbol{x}_i\right) \ . \tag{7}$$

Conceptually, this is a large-margin constraint, where the value of the margin requirement depends on the example $\boldsymbol{x}_i$ via a quadratic form.

We now study the objective (5). The KL divergence between two Gaussians is given by

$$\begin{aligned} &\mathrm{D}_{\mathrm{KL}}\left(\mathcal{N}\left(\boldsymbol{\mu}_0, \Sigma_0\right) \left\| \mathcal{N}\left(\boldsymbol{\mu}_1, \Sigma_1\right)\right.\right) = \\ &\quad \frac{1}{2}\left(\log\left(\frac{\det\Sigma_1}{\det\Sigma_0}\right) + \mathrm{Tr}\left(\Sigma_1^{-1}\Sigma_0\right)\right. \\ &\quad \left. + \left(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0\right)^\top\Sigma_1^{-1}\left(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0\right) - d\right) \ . \end{aligned} \tag{8}$$

Using the foregoing equations and omitting irrelevant constants, we obtain the following revised optimization problem:

$$(\boldsymbol{\mu}_{i+1}, \Sigma_{i+1}) = \min \frac{1}{2}\log\left(\frac{\det\Sigma_i}{\det\Sigma}\right) + \frac{1}{2}\mathrm{Tr}\left(\Sigma_i^{-1}\Sigma\right) + \frac{1}{2}\left(\boldsymbol{\mu}_i - \boldsymbol{\mu}\right)^\top \Sigma_i^{-1}\left(\boldsymbol{\mu}_i - \boldsymbol{\mu}\right)$$
$$\text{s.t. } y_i(\boldsymbol{\mu}\cdot\boldsymbol{x}_i) \geq \phi\left(\boldsymbol{x}_i^\top\Sigma\boldsymbol{x}_i\right) . \quad (9)$$

The optimization objective is convex in $\boldsymbol{\mu}$ and Σ simultaneously and the constraint is linear, so any convex optimization solver could be used to solve this problem. We call the corresponding update *Variance-Exact*. However, for efficiency we prefer a closed-form approximate update that we call *Variance*. In this approximation, we allow the solution for Σ_{i+1} in (9) to produce (implicitly) a full matrix, and then project it to a diagonal matrix, where the non-zero off-diagonal entries are dropped. The Lagrangian for this optimization is

$$\mathcal{L} = \frac{1}{2}\log\left(\frac{\det\Sigma_i}{\det\Sigma}\right) + \frac{1}{2}\mathrm{Tr}\left(\Sigma_i^{-1}\Sigma\right) + \frac{1}{2}\left(\boldsymbol{\mu}_i - \boldsymbol{\mu}\right)^\top \Sigma_i^{-1}\left(\boldsymbol{\mu}_i - \boldsymbol{\mu}\right) + \alpha\left(-y_i\left(\boldsymbol{\mu}\cdot\boldsymbol{x}_i\right) + \phi\left(\boldsymbol{x}_i^\top\Sigma\boldsymbol{x}_i\right)\right) . \quad (10)$$

At the optimum, we must have

$$\frac{\partial}{\partial\boldsymbol{\mu}}\mathcal{L} = \Sigma_i^{-1}\left(\boldsymbol{\mu} - \boldsymbol{\mu}_i\right) - \alpha y_i\boldsymbol{x}_i = 0 .$$

Assuming Σ_i is non-singular we get,

$$\boldsymbol{\mu}_{i+1} = \boldsymbol{\mu}_i + \alpha y_i\Sigma_i\boldsymbol{x}_i . \quad (11)$$

At the optimum, we must also have

$$\frac{\partial}{\partial\Sigma}\mathcal{L} = -\frac{1}{2}\Sigma^{-1} + \frac{1}{2}\Sigma_i^{-1} + \phi\alpha\boldsymbol{x}_i\boldsymbol{x}_i^\top = 0 .$$

Solving for Σ^{-1} we obtain

$$\Sigma_{i+1}^{-1} = \Sigma_i^{-1} + 2\alpha\phi\boldsymbol{x}_i\boldsymbol{x}_i^\top . \quad (12)$$

Finally, we compute the inverse of (12) using the Woodbury identity (Petersen & Pedersen, 2007, Eq. 135) and get,

$$\Sigma_{i+1} = \left(\Sigma_i^{-1} + 2\alpha\phi\boldsymbol{x}_i\boldsymbol{x}_i^\top\right)^{-1} = \Sigma_i - \Sigma_i\boldsymbol{x}_i\left(\frac{1}{2\alpha\phi} + \boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i\right)^{-1}\boldsymbol{x}_i^\top\Sigma_i = \Sigma_i - \Sigma_i\boldsymbol{x}_i\frac{2\alpha\phi}{1 + 2\alpha\phi\boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i}\boldsymbol{x}_i^\top\Sigma_i . \quad (13)$$

The KKT conditions for the optimization imply that the either $\alpha = 0$, and no update is needed, or the constraint (7) is an equality after the udpate. Substituting (11) and (13) into the equality version of (7), we obtain:

$$y_i\left(\boldsymbol{x}_i\cdot\left(\boldsymbol{\mu}_i + \alpha y_i\Sigma_i\boldsymbol{x}_i\right)\right) = \phi\left(\boldsymbol{x}_i^\top\left(\Sigma_i - \Sigma_i\boldsymbol{x}_i\frac{2\alpha\phi}{1 + 2\alpha\phi\boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i}\boldsymbol{x}_i^\top\Sigma_i\right)\boldsymbol{x}_i\right) . \quad (14)$$

Rearranging terms we get,

$$y_i\left(\boldsymbol{x}_i\cdot\boldsymbol{\mu}_i\right) + \alpha\boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i = \phi\boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i - \phi\left(\boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i\right)^2\frac{2\alpha\phi}{1 + 2\alpha\phi\boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i} . \quad (15)$$

For simplicity, let $M_i = y_i\left(\boldsymbol{x}_i\cdot\boldsymbol{\mu}_i\right)$ be the mean margin and $V_i = \boldsymbol{x}_i^\top\Sigma_i\boldsymbol{x}_i$ be the margin variance before the update. Substituting these into (15) we get,

$$M_i + \alpha V_i = \phi V_i - \phi V_i^2\frac{2\alpha\phi}{1 + 2\alpha\phi V_i} .$$

It is straightforward to see that this is a quadratic equation in α. Its smaller root is always negative and thus is not a valid Lagrange multiplier. Let γ_i be its larger root:

$$\gamma_i = \frac{-(1+2\phi M_i) + \sqrt{(1+2\phi M_i)^2 - 8\phi\left(M_i - \phi V_i\right)}}{4\phi V_i} . \quad (16)$$

The constraint (7) is satisfied before the update if $M_i - \phi V_i \geq 0$. If $1 + 2\phi M_i \leq 0$, then $M_i \leq \phi V_i$ and from (16) we have that $\gamma_i > 0$. If, instead, $1 + 2\phi M_i \geq 0$, then, again by (16), we have

$$\gamma_i > 0 \Leftrightarrow \sqrt{(1 + 2\phi M_i)^2 - 8\phi\left(M_i - \phi V_i\right)} > (1 + 2\phi M_i) \Leftrightarrow M_i < \phi V_i .$$

From the KKT conditions, either $\alpha_i = 0$ or (9) is satisfied as an equality. In the later case, (14) holds, and thus $\alpha_i = \gamma_i > 0$. To summarize, we have proved the following:

Lemma 1 *The optimal value of the Lagrange multiplier is given by* $\alpha_i = \max\{\gamma_i, 0\}$.

The above derivation yields a full covariance matrix. As noted above, we restrict ourself to diagonal matrices and thus we project the solution into the set of diagonal matrices to get our approximation. In practice, it is equivalent to compute α_i as above but update with the following rule instead of (12).

$$\Sigma_{i+1}^{-1} = \Sigma_i^{-1} + 2\alpha\phi\mathrm{diag}\left(\boldsymbol{x}_i\right) , \quad (17)$$

Algorithm 1 Variance Algorithm (Approximate)

Input: confidence parameter $\phi = \Phi^{-1}(\eta)$
initial variance parameter $a > 0$
Initialize: $\boldsymbol{\mu}_1 = \mathbf{0}$, $\Sigma_1 = aI$
for $i = 1, 2 \ldots$ **do**
Receive $\boldsymbol{x}_i \in \mathbb{R}^d$, $y_i \in \{+1, -1\}$
Set the following variables:
α_i as in Lemma 1
$\boldsymbol{\mu}_{i+1} = \boldsymbol{\mu}_i + \alpha_i y_i \Sigma_i \boldsymbol{x}_i$ (11)
$\Sigma_{i+1}^{-1} = \Sigma_i^{-1} + 2\alpha_i \phi \operatorname{diag}(\boldsymbol{x}_i)$ (17)
end for

where $\operatorname{diag}(\boldsymbol{x}_i)$ is a diagonal matrix with the square of the elements of $\boldsymbol{x}_i$ on the diagonal.

The pesudocode of the algorithm appears in Alg. 1. From the initalization of Σ_1 and the update rule of (12), we conclude that the eigenvalues of Σ_i are shirinking, but never set to zero explicltly, and thus the covariance matrices Σ_i are not singular.

5. Evaluation

We evaluated our Variance and Variance-Exact algorithms on three popular NLP datasets. Each dataset contains several binary classification tasks from which we selected a total of 12 problems, each contains a balanced mixture of instance labels.

20 Newsgroups The 20 Newsgroups corpus contains approximately 20,000 newsgroup messages, partitioned across 20 different newsgroups.[2] The dataset is a popular choice for binary and multi-class text classification as well as unsupervised clustering. Following common practice, we created binary problems from the dataset by creating binary decision problems of choosing between two similar groups, as shown in Table 1. Each message was represented as a binary bag-of-words. For each problem we selected 1800 instances.

Reuters The Reuters Corpus Volume 1 (RCV1-v2/LYRL2004) contains over 800,000 manually categorized newswire stories (Lewis et al., 2004). Each article

[2] `http://people.csail.mit.edu/jrennie/20Newsgroups/`

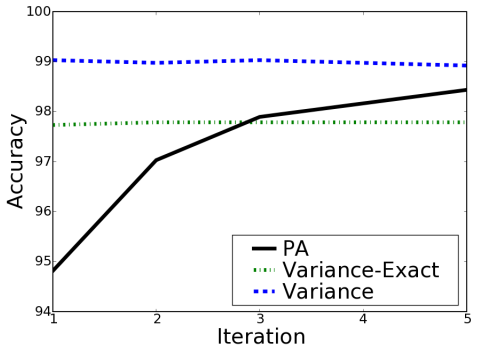

Figure 1. Accuracy on test data after each iteration on the "talk" dataset.

contains one or more labels describing its general topic, industry and region. We created the following binary decision tasks from the labeled documents: Insurance: Life (I82002) vs. Non-Life (I82003), Business Services: Banking (I81000) vs. Financial (I83000), and Retail Distribution: Specialist Stores (I65400) vs. Mixed Retail (I65600). These distinctions involve neighboring categories so they are fairly hard to make. Details on document preparation and feature extraction are given by Lewis et al. (2004). For each problem we selected 2000 instances using a bag of words representation with binary features.

Sentiment We obtained a larger version of the sentiment multi-domain dataset of Blitzer et al. (2007) containing product reviews from 6 Amazon domains (book, dvd, electronics, kitchen, music, video). The goal in each domain is to classify a product review as either positive or negative. Feature extraction follows Blitzer et al. (2007). For each problem we selected 2000 instances using uni/bi-grams with counts.

Each dataset was randomly divided for 10-fold cross validation experiments. Classifier parameters (ϕ for CW and C for PA) were tuned for each classification task on a single randomized run over the data. Results are reported for each problem as the average accuracy over the 10 folds. Statistical significance is computed using McNemar's test.

5.1. Results

We start by examining the performance of the Variance and Variance-Exact versions of our method, discussed in the preceding section, against a PA algorithm. All three algorithms were run on the datasets described above and each training phase consisted of five passes over the training data, which seemed to be

Table 2. Error on test data using batch training. Statistical significance (McNemar) is measured against PA or the batch method against Variance. (∗ p=.05, ⋆ p=.01, † p=.001)

enough to yield convergence. The average error on the test set for the three algorithms on all twelve datasets is shown in table 2.

Variance-Exact achieved about the same performance as PA, with each method achieving a lower error on half of the datasets. In contrast, Variance (approximate) significantly improves over PA, achieving lower error on all twelve datasets, with statistically significant results on nine of them.

As discussed above, online algorithms are attractive even for batch learning because of their simplicity and ability to operate on extremely large datasets. In the batch setting, these algorithms are run several times over the training data, which yields slower performance than single pass learning (Carvalho & Cohen, 2006). Our algorithm improves on both accuracy and learning speed by requiring fewer iterations over the training data. Such behavior can be seen on the "talk" dataset in Figure 1, which shows accuracy on test data after each iteration of the PA baseline and the two variance algorithms. While Variance clearly improves over PA, it converges very quickly, reaching near best performance on the first iteration. In contrast, PA benefits from multiple iterations over the data; its performance changes significantly from the first to fifth iteration. Across the twelve tasks, Variance yields a 3.7% error reduction while PA gives a 12.4% reduction between the first and fifth iteration, indicating that multiple iterations help PA more. The plot also illustrates Variance-Exact's behavior, which initially beats PA but does not improve. In fact, on eleven of the twelve datasets, Variance-Exact beats PA on the first iteration. The exact update results in aggressive behavior causing the algorithm to converge very quickly, even more so than Variance. It appears that the approximate update in Variance reduces overtraining and yields the best accuracy.

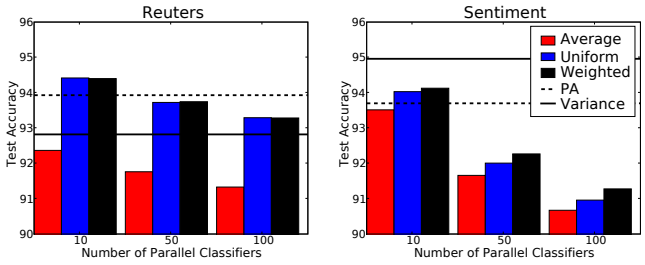

Figure 2. Results for Reuters (800k) and Sentiment (1000k) averaged over 4 runs. Horizontal lines show the test accuracy of a model trained on the entire training set. Vertical bars show the performance of n (10, 50, 100) classifiers trained on disjoint sections of the data as the average performance, uniform combination, or weighted combination. All improvements are statistically significant except between uniform and weighted for Reuters.

5.2. Batch Learning

While online algorithms are widely used, batch algorithms are still preferred for many tasks. Batch algorithms can make global learning decisions by examining the entire dataset, an ability beyond online algorithms. In general, when batch algorithms can be applied they perform better. We compare our new online algorithm (Variance) against two standard batch algorithms: maxent classification (default configuration of the maxent learner in McCallum (2002)) and support vector machines (LibSVM (Chang & Lin, 2001)). We also include stochastic gradient descent (SGD) (Blitzer et al., 2007), which performs well for NLP tasks. Classifier parameters (Gaussian prior for maxent, C for SVM and the learning rate for SGD) were tuned as for the online methods.

Results for batch learning are shown in Table 2. As expected, the batch methods tend to do better than PA,

with SVM doing better 9 times and maxent 11 times. However, in most cases Variance improves over the batch method, doing better than SVM and maxent 10 out of 12 times (7 statistically significant.) These results show that in these tasks, the much faster and simpler online algorithm performs better than the slower more complex batch methods.

We also evaluated the effects of commonly used techniques for online and batch learning, including averaging and TFIDF features, none of which improved accuracy. Although the above datasets are balanced with respect to labels and predictive features, we also evaluated the methods on variant datasets with unbalanced label or feature distributions, and still saw similar benefits from the Variance method.

5.3. Large Datasets

Online algorithms are especially attractive in tasks where training data exceeds available main memory. However, even a single sequential pass over the data can be impractical for extremely large training sets, so we investigate training different models on different portions of the data in parallel and combining the learned classifiers into a single classifier. While this often does not perform as well as a single model trained on all of the data, it is a cost effective way of learning from very large training sets.

Averaging models trained in parallel assumes that each model has an equally accurate estimate of the model parameters. However, our model provides a confidence value for each parameter, allowing for a more intelligent combination of parameters from multiple models. Specifically, we compute the combined model Gaussian that minimizes the total divergence to the set C of individually trained classifiers for some divergence operator D:

$$\min_{\boldsymbol{\mu},\Sigma} \sum_{c \in C} D((\boldsymbol{\mu}, \Sigma) || (\boldsymbol{\mu}_c, \Sigma_c)), \tag{18}$$

If D is the Euclidean distance, this is just the average of the individual models. If D is the KL divergence, the minimization leads to the following weighted combination of individual model means:
$\boldsymbol{\mu} = \left(\sum_{c \in C} \Sigma_c^{-1}\right)^{-1} \sum_{c \in C} \Sigma_c^{-1} \boldsymbol{\mu}_c$, $\Sigma^{-1} = \sum_{c \in C} \Sigma_c^{-1}$.

We evaluate the single model performance of the PA baseline and our method. For our method, we evaluate classifier combination by training n (10, 50, 100) models by dividing the instance stream into n disjoint parts and report the average performance of each of the n classifiers (average), the combined classifier from taking the average of the n sets of parameters (uniform) and the combination using the KL distance (weighted) on the test data across 4 randomized runs.

We evaluated classifier combination on two datasets. The combined product reviews for all the domains in Blitzer et al. (2007) yield one million sentiment instances. While most reviews were from the book domain, the reviews are taken from a wide range of Amazon product types and are mostly positive. From the Reuters corpus, we created a one vs. all classification task for the *Corporate* topic label, yielding 804,411 instances of which 381,325 are labeled corporate. For the two datasets, we created four random splits each with one million training instances and 10,000 test instances. Parameters were optimized by training on 5K random instances and testing on 10K.

The two datasets use very different feature representations. The Reuters data contains 288,062 unique features, for a feature to document ratio of 0.36. In contrast, the sentiment data contains 13,460,254 unique features, a feature to document ratio of 13.33. This means that Reuters features tend to occur several times during training while many sentiment features occur only once.

Average accuracy on the test sets are reported in Figure 2. For Reuters data, the PA single model achieves higher accuracy than Variance, possibly because of the low feature to document ratio. However, combining 10 Variance classifiers achieves the best performance. For sentiment, combining 10 classifiers beats PA but is not as good as a single Variance model. In every case, combining the classifiers using either uniform or weighted improves over each model individually. On sentiment weighted combination improves over uniform combination and in Reuters the models are equivalent.

Finally, we computed the actual run time of both PA and Variance on the large datasets to compare the speed of each model. While Variance is more complex, requiring more computation per instance, the actual speed is comparable to PA; in all tests the run time of the two algorithms was indistinguishable.

6. Related Work

The idea of using parameter-specific variable learning rates has a long history in neural-network learning (Sutton, 1992), although we do not know of a previous model that specifically models confidence in a way that takes into account the frequency of features. The second-order perceptron (SOP) (Cesa-Bianchi et al., 2005) is perhaps the closest to our CW algorithm. Both are online algorithms that maintain a weight vector and some statistics about previous examples. While the SOP models certainty with feature counts,

CW learning models uncertainty with a Gaussian distribution. CW algorithms have a probabilistic motivation, while the SOP is based on the geometric idea of replacing a ball around the input examples with a refined ellipsoid. Shivaswamy and Jebara (2007) used this intuition in the context of batch learning.

Gaussian process classification (GPC) maintains a Gaussian distribution over weight vectors (primal) or over regressor values (dual). Our algorithm uses a different update criterion than the the standard Bayesian updates used in GPC (Rasmussen & Williams, 2006, Ch. 3), avoiding the challenging issues in approximating posteriors in GPC. Bayes point machines (Herbrich et al., 2001) maintain a collection of weight vectors consistent with the training data, and use the single linear classifier which best represents the collection. Conceptually, the collection is a non-parametric distribution over the weight vectors. Its online version (Harrington et al., 2003) maintains a finite number of weight-vectors updated simultaneously.

Finally, with the growth of available data there is an increasing need for algorithms that process training data very efficiently. A similar approach to ours is to train classifiers incrementally (Bordes & Bottou, 2005). The extreme case is to use each example once, without repetitions, as in the multiplicative update method of Carvalho and Cohen (2006).

Conclusion: We have presented confidence-weighted linear classifiers, a new learning method designed for NLP problems based on the notion of parameter confidence. The algorithm maintains a distribution over parameter vectors; online updates both improve the parameter estimates and reduce the distribution's variance. Our method improves over both online and batch methods and learns faster on a dozen NLP datasets. Additionally, our new algorithms allow more intelligent classifier combination techniques, yielding improved performance after parallel learning. We plan to explore theoretical properties and other aspects of CW classifiers, such as multi-class and structured prediction tasks, and other data types.

Abstract

We describe efficient algorithms for projecting a vector onto the ℓ_1-ball. We present two methods for projection. The first performs exact projection in $O(n)$ expected time, where n is the dimension of the space. The second works on vectors k of whose elements are perturbed outside the ℓ_1-ball, projecting in $O(k \log(n))$ time. This setting is especially useful for online learning in sparse feature spaces such as text categorization applications. We demonstrate the merits and effectiveness of our algorithms in numerous batch and online learning tasks. We show that variants of stochastic gradient projection methods augmented with our efficient projection procedures outperform interior point methods, which are considered state-of-the-art optimization techniques. We also show that in online settings gradient updates with ℓ_1 projections outperform the exponentiated gradient algorithm while obtaining models with high degrees of sparsity.

1. Introduction

A prevalent machine learning approach for decision and prediction problems is to cast the learning task as penalized convex optimization. In penalized convex optimization we seek a set of parameters, gathered together in a vector $\mathbf{w}$, which minimizes a convex objective function in $\mathbf{w}$ with an additional penalty term that assesses the complexity of $\mathbf{w}$. Two commonly used penalties are the 1-norm and the square of the 2-norm of $\mathbf{w}$. An alternative but mathematically equivalent approach is to cast the problem as a *constrained* optimization problem. In this setting we seek a minimizer of the objective function while constraining the solution to have a bounded norm. Many recent advances in statistical machine learning and related fields can be explained as convex optimization subject to a 1-norm constraint on the vector of parameters $\mathbf{w}$. Imposing an ℓ_1 constraint leads to notable benefits. First, it encourages sparse solutions, *i.e* a solution for which many components of $\mathbf{w}$ are zero. When the original dimension of $\mathbf{w}$ is very high, a sparse solution enables easier interpretation of the problem in a lower dimension space. For the usage of ℓ_1-based approach in statistical machine learning see for example (Tibshirani, 1996) and the references therein. Donoho (2006b) provided sufficient conditions for obtaining an optimal ℓ_1-norm solution which is sparse. Recent work on compressed sensing (Candes, 2006; Donoho, 2006a) further explores how ℓ_1 constraints can be used for recovering a sparse signal sampled below the Nyquist rate. The second motivation for using ℓ_1 constraints in machine learning problems is that in some cases it leads to improved generalization bounds. For example, Ng (2004) examined the task of PAC learning a sparse predictor and analyzed cases in which an ℓ_1 constraint results in better solutions than an ℓ_2 constraint.

In this paper we re-examine the task of minimizing a convex function subject to an ℓ_1 constraint on the norm of the solution. We are particularly interested in cases where the convex function is the average loss over a training set of m examples where each example is represented as a vector of high dimension. Thus, the solution itself is a high-dimensional vector as well. Recent work on ℓ_2 constrained optimization for machine learning indicates that gradient-related projection algorithms are more efficient in approaching a solution of good generalization than second-order algorithms when the number of examples and

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

the dimension are large. For instance, Shalev-Shwartz et al. (2007) give recent state-of-the-art methods for solving large scale support vector machines. Adapting these recent results to projection methods onto the ℓ_1 ball poses algorithmic challenges. While projections onto ℓ_2 balls are straightforward to implement in linear time with the appropriate data structures, projection onto an ℓ_1 ball is a more involved task. The main contribution of this paper is the derivation of gradient projections with ℓ_1 domain constraints that can be performed almost as fast as gradient projection with ℓ_2 constraints.

Our starting point is an efficient method for projection onto the probabilistic simplex. The basic idea is to show that, after sorting the vector we need to project, it is possible to calculate the projection exactly in linear time. This idea was rediscovered multiple times. It was first described in an abstract and somewhat opaque form in the work of Gafni and Bertsekas (1984) and Bertsekas (1999). Crammer and Singer (2002) rediscovered a similar projection algorithm as a tool for solving the dual of multiclass SVM. Hazan (2006) essentially reuses the same algorithm in the context of online convex programming. Our starting point is another derivation of Euclidean projection onto the simplex that paves the way to a few generalizations. First we show that the same technique can also be used for projecting onto the ℓ_1-ball. This algorithm is based on sorting the components of the vector to be projected and thus requires $O(n \log(n))$ time. We next present an improvement of the algorithm that replaces sorting with a procedure resembling median-search whose expected time complexity is $O(n)$.

In many applications, however, the dimension of the feature space is very high yet the number of features which attain non-zero values for an example may be very small. For instance, in our experiments with text classification in Sec. 7, the dimension is two million (the bigram dictionary size) while each example has on average one-thousand non-zero features (the number of unique tokens in a document). Applications where the dimensionality is high yet the number of "on" features in each example is small render our second algorithm useless in some cases. We therefore shift gears and describe a more complex algorithm that employs red-black trees to obtain a linear dependence on the number of non-zero features in an example and only logarithmic dependence on the full dimension. The key to our construction lies in the fact that we project vectors that are the sum of a vector in the ℓ_1-ball and a sparse vector—they are "almost" in the ℓ_1-ball.

In conclusion to the paper we present experimental results that demonstrate the merits of our algorithms. We compare our algorithms with several specialized interior point (IP) methods as well as general methods from the literature for solving ℓ_1-penalized problems on both synthetic and real data (the MNIST handwritten digit dataset and the Reuters RCV1 corpus) for batch and online learning. Our projection based methods outperform competing algorithms in terms of sparsity, and they exhibit faster convergence and lower regret than previous methods.

2. Notation and Problem Setting

We start by establishing the notation used throughout the paper. The set of integers 1 through n is denoted by $[n]$. Scalars are denoted by lower case letters and vectors by lower case bold face letters. We use the notation $\mathbf{w} \succ b$ to designate that all of the components of $\mathbf{w}$ are greater than b. We use $\|\cdot\|$ as a shorthand for the Euclidean norm $\|\cdot\|_2$. The other norm we use throughout the paper is the 1-norm of the vector, $\|\mathbf{v}\|_1 = \sum_{i=1}^n |v_i|$. Lastly, we consider order statistics and sorting vectors frequently throughout this paper. To that end, we let $v_{(i)}$ denote the i^{th} order statistic of $\mathbf{v}$, that is, $v_{(1)} \geq v_{(2)} \geq \ldots \geq v_{(n)}$ for $\mathbf{v} \in \mathbb{R}^n$.

In the setting considered in this paper we are provided with a convex function $L : \mathbb{R}^n \to \mathbb{R}$. Our goal is to find the minimum of $L(\mathbf{w})$ subject to an ℓ_1-norm constraint on $\mathbf{w}$. Formally, the problem we need to solve is

$$\underset{\mathbf{w}}{\text{minimize}}\, L(\mathbf{w}) \quad \text{s.t.} \quad \|\mathbf{w}\|_1 \leq z \ . \tag{1}$$

Our focus is on variants of the projected subgradient method for convex optimization (Bertsekas, 1999). Projected subgradient methods minimize a function $L(\mathbf{w})$ subject to the constraint that $\mathbf{w} \in X$, for X convex, by generating the sequence $\{\mathbf{w}^{(t)}\}$ via

$$\mathbf{w}^{(t+1)} = \Pi_X \left(\mathbf{w}^{(t)} - \eta_t \nabla^{(t)} \right) \tag{2}$$

where $\nabla^{(t)}$ is (an unbiased estimate of) the (sub)gradient of L at $\mathbf{w}^{(t)}$ and $\Pi_X(\mathbf{x}) = \operatorname{argmin}_{\mathbf{y}} \{\|\mathbf{x} - \mathbf{y}\| \mid \mathbf{y} \in X\}$ is Euclidean projection of $\mathbf{x}$ onto X. In the rest of the paper, the main algorithmic focus is on the projection step (computing an unbiased estimate of the gradient of $L(\mathbf{w})$ is straightforward in the applications considered in this paper, as is the modification of $\mathbf{w}^{(t)}$ by $\nabla^{(t)}$).

3. Euclidean Projection onto the Simplex

For clarity, we begin with the task of performing Euclidean projection onto the positive simplex; our derivation naturally builds to the more efficient algorithms. As such, the most basic projection task we consider can be formally described as the following optimization problem,

$$\underset{\mathbf{w}}{\text{minimize}}\, \frac{1}{2}\|\mathbf{w} - \mathbf{v}\|_2^2 \quad \text{s.t.} \quad \sum_{i=1}^n w_i \ = \ z \ , \ \ w_i \geq 0 \ . \tag{3}$$

When $z = 1$ the above is projection onto the probabilistic simplex. The Lagrangian of the problem in Eq. (3) is

$$\mathcal{L}(\mathbf{w}, \boldsymbol{\zeta}) \;=\; \frac{1}{2}\|\mathbf{w} - \mathbf{v}\|^2 + \theta\left(\sum_{i=1}^{n} w_i - z\right) - \boldsymbol{\zeta}\cdot\mathbf{w} \;\;,$$

where $\theta \in \mathbb{R}$ is a Lagrange multiplier and $\boldsymbol{\zeta} \in \mathbb{R}^n_+$ is a vector of non-negative Lagrange multipliers. Differentiating with respect to w_i and comparing to zero gives the optimality condition, $\frac{d\mathcal{L}}{dw_i} \;=\; w_i - v_i + \theta - \zeta_i \;=\; 0$. The complementary slackness KKT condition implies that whenever $w_i > 0$ we must have that $\zeta_i = 0$. Thus, if $w_i > 0$ we get that

$$w_i \;=\; v_i - \theta + \zeta_i \;=\; v_i - \theta \;. \tag{4}$$

All the non-negative elements of the vector $\mathbf{w}$ are tied via a single variable, so knowing the indices of these elements gives a much simpler problem. Upon first inspection, finding these indices seems difficult, but the following lemma (Shalev-Shwartz & Singer, 2006) provides a key tool in deriving our procedure for identifying non-zero elements.

Lemma 1. *Let $\mathbf{w}$ be the optimal solution to the minimization problem in Eq. (3). Let s and j be two indices such that $v_s > v_j$. If $w_s = 0$ then w_j must be zero as well.*

Denoting by I the set of indices of the non-zero components of the sorted optimal solution, $I = \{i \in [n] : v_{(i)} > 0\}$, we see that Lemma 1 implies that $I = [\rho]$ for some $1 \le \rho \le n$. Had we known ρ we could have simply used Eq. (4) to obtain that

$$\sum_{i=1}^{n} w_i = \sum_{i=1}^{n} w_{(i)} = \sum_{i=1}^{\rho} w_{(i)} = \sum_{i=1}^{\rho} \left(v_{(i)} - \theta\right) = z$$

and therefore

$$\theta = \frac{1}{\rho}\left(\sum_{i=1}^{\rho} v_{(i)} - z\right) \;\;. \tag{5}$$

Given θ we can characterize the optimal solution for $\mathbf{w}$ as

$$w_i \;=\; \max\left\{v_i - \theta \;,\; 0\right\} \;\;. \tag{6}$$

We are left with the problem of finding the optimal ρ, and the following lemma (Shalev-Shwartz & Singer, 2006) provides a simple solution once we sort $\mathbf{v}$ in descending order.

Lemma 2. *Let $\mathbf{w}$ be the optimal solution to the minimization problem given in Eq. (3). Let $\boldsymbol{\mu}$ denote the vector obtained by sorting $\mathbf{v}$ in a descending order. Then, the number of strictly positive elements in $\mathbf{w}$ is*

$$\rho(z, \boldsymbol{\mu}) \;=\; \max\left\{j \in [n] \;:\; \mu_j - \frac{1}{j}\left(\sum_{r=1}^{j}\mu_r - z\right) > 0\right\} \;\;.$$

The pseudo-code describing the $O(n \log n)$ procedure for solving Eq. (3) is given in Fig. 1.

INPUT: A vector $\mathbf{v} \in \mathbb{R}^n$ and a scalar $z > 0$

Sort $\mathbf{v}$ into $\boldsymbol{\mu} : \mu_1 \ge \mu_2 \ge \ldots \ge \mu_p$

Find $\rho = \max\left\{j \in [n] : \mu_j - \frac{1}{j}\left(\sum_{r=1}^{j}\mu_r - z\right) > 0\right\}$

Define $\theta = \frac{1}{\rho}\left(\sum_{i=1}^{\rho}\mu_i - z\right)$

OUTPUT: $\mathbf{w}$ s.t. $w_i = \max\left\{v_i - \theta \;,\; 0\right\}$

Figure 1. Algorithm for projection onto the simplex.

4. Euclidean Projection onto the ℓ_1-Ball

We next modify the algorithm to handle the more general ℓ_1-norm constraint, which gives the minimization problem

$$\underset{\mathbf{w}\in\mathbb{R}^n}{\text{minimize}} \;\; \|\mathbf{w} - \mathbf{v}\|_2^2 \quad \text{s.t.} \quad \|\mathbf{w}\|_1 \le z \;\;. \tag{7}$$

We do so by presenting a reduction to the problem of projecting onto the simplex given in Eq. (3). First, we note that if $\|\mathbf{v}\|_1 \le z$ then the solution of Eq. (7) is $\mathbf{w} = \mathbf{v}$. Therefore, from now on we assume that $\|\mathbf{v}\|_1 > z$. In this case, the optimal solution must be on the boundary of the constraint set and thus we can replace the inequality constraint $\|\mathbf{w}\|_1 \le z$ with an equality constraint $\|\mathbf{w}\|_1 = z$. Having done so, the sole difference between the problem in Eq. (7) and the one in Eq. (3) is that in the latter we have an additional set of constraints, $\mathbf{w} \ge 0$. The following lemma indicates that each non-zero component of the optimal solution $\mathbf{w}$ shares the sign of its counterpart in $\mathbf{v}$.

Lemma 3. *Let $\mathbf{w}$ be an optimal solution of Eq. (7). Then, for all i, $w_i\, v_i \ge 0$.*

Proof. Assume by contradiction that the claim does not hold. Thus, there exists i for which $w_i\, v_i < 0$. Let $\hat{\mathbf{w}}$ be a vector such that $\hat{w}_i = 0$ and for all $j \ne i$ we have $\hat{w}_j = w_j$. Therefore, $\|\hat{\mathbf{w}}\|_1 = \|\mathbf{w}\|_1 - |w_i| \le z$ and hence $\hat{\mathbf{w}}$ is a feasible solution. In addition,

$$\begin{aligned}\|\mathbf{w} - \mathbf{v}\|_2^2 - \|\hat{\mathbf{w}} - \mathbf{v}\|_2^2 \;&=\; (w_i - v_i)^2 - (0 - v_i)^2 \\ &=\; w_i^2 - 2w_i v_i > w_i^2 > 0 \;\;.\end{aligned}$$

We thus constructed a feasible solution $\hat{\mathbf{w}}$ which attains an objective value smaller than that of $\mathbf{w}$. This leads us to the desired contradiction. □

Based on the above lemma and the symmetry of the objective, we are ready to present our reduction. Let $\mathbf{u}$ be a vector obtained by taking the absolute value of each component of $\mathbf{v}$, $u_i = |v_i|$. We now replace Eq. (7) with

$$\underset{\boldsymbol{\beta}\in\mathbb{R}^n}{\text{minimize}} \;\; \|\boldsymbol{\beta} - \mathbf{u}\|_2^2 \quad \text{s.t.} \quad \|\boldsymbol{\beta}\|_1 \le z \;\text{ and }\; \boldsymbol{\beta} \ge 0 \;\;. \tag{8}$$

Once we obtain the solution for the problem above we construct the optimal of Eq. (7) by setting $w_i = \text{sign}(v_i)\,\beta_i$.

INPUT A vector $\mathbf{v} \in \mathbb{R}^n$ and a scalar $z > 0$

OUTPUT $\mathbf{w}$ s.t. $v_i = \max\{v_i - \theta\ ,\ 0\}$

Figure 2. Linear time projection onto the simplex.

5. A Linear Time Projection Algorithm

In this section we describe a more efficient algorithm for performing projections. To keep our presentation simple and easy to follow, we describe the projection algorithm onto the simplex. The generalization to the ℓ_1 ball can straightforwardly incorporated into the efficient algorithm by the results from the previous section (we simply work in the algorithm with a vector of the absolute values of $\mathbf{v}$, replacing the solution's components w_i with $\text{sign}(v_i) \cdot w_i$).

For correctness of the following discussion, we add another component to $\mathbf{v}$ (the vector to be projected), which we set to 0, thus $v_{n+1} = 0$ and $v_{(n+1)} = 0$. Let us start by examining again Lemma 2. The lemma implies that the index ρ is the largest integer that still satisfies $v_{(\rho)} - \frac{1}{\rho}\left(\sum_{r=1}^{\rho} v_{(r)} - z\right) > 0$. After routine algebraic manipulations the above can be rewritten in the following somewhat simpler form:

$$\sum_{i=1}^{\rho} \left(v_{(i)} - v_{(\rho)}\right) < z \ \text{ and } \ \sum_{i=1}^{\rho+1} \left(v_{(i)} - v_{(\rho+1)}\right) \geq z. \quad (9)$$

Given ρ and $v_{(\rho)}$ we slightly rewrite the value θ as follows,

$$\theta = \frac{1}{\rho}\left(\sum_{j:v_j \geq v_{(\rho)}} v_j - z\right) \ . \quad (10)$$

The task of projection can thus be distilled to the task of finding θ, which in turn reduces to the task of finding ρ and the pivot element $v_{(\rho)}$. Our problem thus resembles the task of finding an order statistic with an additional complicating factor stemming from the need to compute summations (while searching) of the form given by Eq. (9). Our efficient projection algorithm is based on a modification of the randomized median finding algorithm (Cormen et al., 2001). The algorithm computes partial sums just-in-time and has expected linear time complexity.

The algorithm identifies ρ and the pivot value $v_{(\rho)}$ without sorting the vector $\mathbf{v}$ by using a divide and conquer procedure. The procedure works in rounds and on each round either eliminates elements shown to be strictly smaller than $v_{(\rho)}$ or updates the partial sum leading to Eq. (9). To do so the algorithm maintains a set of unprocessed elements of $\mathbf{v}$. This set contains the components of $\mathbf{v}$ whose relationship to $v_{(\rho)}$ we do not know. We thus initially set $U = [n]$. On each round of the algorithm we pick at random an index k from the set U. Next, we partition the set U into two subsets G and L. G contains all the indices $j \in U$ whose components $v_j > v_k$; L contains those $j \in U$ such that v_j is smaller. We now face two cases related to the current summation of entries in $\mathbf{v}$ greater than the hypothesized $v_{(\rho)}$ (i.e. v_k). If $\sum_{j:v_j \geq v_k}(v_j - v_k) < z$ then by Eq. (9), $v_k \geq v_{(\rho)}$. In this case we know that all the elements in G participate in the sum defining θ as given by Eq. (9). We can discard G and set U to be L as we still need to further identify the remaining elements in L. If $\sum_{j:v_j \geq v_k}(v_j - v_k) \geq z$ then the same rationale implies that $v_k < v_{(\rho)}$. Thus, all the elements in L are smaller than $v_{(\rho)}$ and can be discarded. In this case we can remove the set L and v_k and set U to be $G \setminus \{k\}$. The entire process ends when U is empty.

Along the process we also keep track of the sum and the number of elements in $\mathbf{v}$ that we have found thus far to be no smaller than $v_{(\rho)}$, which is required in order not to recalculate partial sums. The pseudo-code describing the efficient projection algorithm is provided in Fig. 2. We keep the set of elements found to be greater than $v_{(\rho)}$ only *implicitly*. Formally, at each iteration of the algorithm we maintain a variable s, which is the sum of the elements in the set $\{v_j : j \notin U, v_j \geq v_{(\rho)}\}$, and overload ρ to designate the cardinality of the this set throughout the algorithm. Thus, when the algorithms exits its main while loop, ρ is the maximizer defined in Lemma 1. Once the while loop terminates, we are left with the task of calculating θ using Eq. (10) and performing the actual projection. Since $\sum_{j:v_j \geq \mu_\rho} v_j$ is readily available to us as the variable s, we simply set θ to be $(s - z)/\rho$ and perform the projection as prescribed by Eq. (6).

Though omitted here for lack of space, we can also extend the algorithms to handle the more general constraint that $\sum a_i|w_i| \leq z$ for $a_i \geq 0$.

6. Efficient Projection for Sparse Gradients

Before we dive into developing a new algorithm, we remind the reader of the iterations the minimization algorithm takes from Eq. (2): we generate a sequence $\{\mathbf{w}^{(t)}\}$

```
INPUT A balanced tree T and a scalar z > 0
INITIALIZE v* = ∞, ρ* = n + 1, s* = z
CALL PIVOTSEARCH(root(T), 0, 0)
PROCEDURE PIVOTSEARCH(v, ρ, s)
  COMPUTE  ρ̂ = ρ + r(v) ; ŝ = s + σ(v)

  ELSE                // v < pivot
    IF  leaf_T(v)
      RETURN  θ = (s* − z)/ρ*
    ENDIF
    CALL PIVOTSEARCH(right_T(v), ρ, s)
  ENDIF
ENDPROCEDURE
```

Figure 3. Efficient search of pivot value for sparse feature spaces.

by iterating

$$\mathbf{w}^{(t+1)} = \Pi_W \left(\mathbf{w}^{(t)} + \mathbf{g}^{(t)} \right)$$

where $\mathbf{g}^{(t)} = -\eta_t \nabla^{(t)}$, $W = \{\mathbf{w} \mid \|\mathbf{w}\|_1 \leq z\}$ and Π_W is projection onto this set.

In many applications the dimension of the feature space is very high yet the number of features which attain a non-zero value for each example is very small (see for instance our experiments on text documents in Sec. 7). It is straightforward to implement the gradient-related updates in time which is proportional to the number of non-zero features, but the time complexity of the projection algorithm described in the previous section is linear in the dimension. Therefore, using the algorithm verbatim could be prohibitively expensive in applications where the dimension is high yet the number of features which are "on" in each example is small. In this section we describe a projection algorithm that updates the vector $\mathbf{w}^{(t)}$ with $\mathbf{g}^{(t)}$ and scales linearly in the number of non-zero entries of $\mathbf{g}^{(t)}$ and only *logarithmically* in the total number of features (*i.e.* non-zeros in $\mathbf{w}^{(t)}$).

The first step in facilitating an efficient projection for sparse feature spaces is to represent the projected vector as a "raw" vector $\mathbf{v}$ by incorporating a global shift that is applied to each non-zero component. Specifically, each projection step amounts to deducting θ from each component of $\mathbf{v}$ and thresholding the result at zero. Let us denote by θ_t the shift value used on the t^{th} iteration of the algorithm and by Θ_t the cumulative sum of the shift values, $\Theta_t = \sum_{s \leq t} \theta_s$. The representation we employ enables us to perform the step in which we deduct θ_t from all the elements of the vector *implicitly*, adhering to the goal of performing a sub-linear number of operations. As before, we assume that the goal is to project onto the simplex. Equipped with these variables, the j^{th} component of the projected vector after t projected gradient steps can be written as $\max\{v_j - \Theta_t, 0\}$.

The second substantial modification to the core algorithm is to keep only the *non-zero* components of the weight vector in a red-black tree (Cormen et al., 2001). The red-black tree facilitates an efficient search for the pivot element ($v_{(\rho)}$) in time which is logarithmic in the dimension, as we describe in the sequel. Once the pivot element is found we implicitly deduct θ_t from all the non-zero elements in our weight vector by updating Θ_t. We then remove all the components that are less than $v_{(\rho)}$ (i.e. less than Θ_t); this removal is efficient and requires only logarithmic time (Tarjan, 1983).

The course of the algorithm is as follows. After t projected gradient iterations we have a vector $\mathbf{v}^{(t)}$ whose non-zero elements are stored in a red-black tree $\mathcal{T}$ and a global deduction value Θ_t which is applied to each non-zero component just-in-time, *i.e.* when needed. Therefore, each non-zero weight is accessed as $v_j - \Theta_t$ while $\mathcal{T}$ does not contain the zero elements of the vector. When updating $\mathbf{v}$ with a gradient, we modify the vector $\mathbf{v}^{(t)}$ by adding to it the gradient-based vector $\mathbf{g}^{(t)}$ with k non-zero components. This update is done using k deletions (removing v_i from $\mathcal{T}$ such that $g_i^{(t)} \neq 0$) followed by k re-insertions of $v'_i = (v_i + g_i^{(t)})$ into $\mathcal{T}$, which takes $O(k \log(n))$ time. Next we find in $O(\log(n))$ time the value of θ_t. Fig. 3 contains the algorithm for this step; it is explained in the sequel. The last step removes all elements of the new raw vector $\mathbf{v}^{(t)} + \mathbf{g}^{(t)}$ which become zero due to the projection. This step is discussed at the end of this section.

In contrast to standard tree-based search procedure, to find θ_t we need to find a pair of consecutive values in $\mathbf{v}$ that correspond to $v_{(\rho)}$ and $v_{(\rho+1)}$. We do so by keeping track of the smallest element that satisfies the left hand side of Eq. (9) while searching based on the condition given on the right hand side of the same equation. $\mathcal{T}$ is keyed on the values of the un-shifted vector $\mathbf{v}_t$. Thus, all the children in the left (right) sub-tree of a node v represent values in $\mathbf{v}_t$ which are smaller (larger) than v. In order to efficiently find θ_t we keep at each node the following information: (a) The value of the component, simply denoted as v. (b) The number of elements in the right sub-tree rooted at v, denoted $r(v)$, including the node v. (c) The sum of the elements in the right sub-tree rooted at v, denoted $\sigma(v)$, including the value v itself. Our goal is to identify the pivot element $v_{(\rho)}$ and its index ρ. In the previous section we described a simple condition for checking whether an element in $\mathbf{v}$ is greater or smaller than the pivot value. We now rewrite this expression yet one more time. A component with value v is *not*

smaller than the pivot iff the following holds:

$$\sum_{j:v_j \geq v} v_j > |\{j : v_j \geq v\}| \cdot v + z \; . \tag{11}$$

The variables in the red-black tree form the infrastructure for performing efficient recursive computation of Eq. (11). Note also that the condition expressed in Eq. (11) still holds when we do *not* deduct Θ_t from all the elements in $\mathbf{v}$.

The search algorithm maintains recursively the number ρ and the sum s of the elements that have been shown to be greater or equal to the pivot. We start the search with the root node of $\mathcal{T}$, and thus initially $\rho = 0$ and $s = 0$. Upon entering a new node v, the algorithm checks whether the condition given by Eq. (11) holds for v. Since ρ and s were computed for the parent of v, we need to incorporate the number and the sum of the elements that are larger than v itself. By construction, these variables are $r(v)$ and $\sigma(v)$, which we store at the node v itself. We let $\hat{\rho} = \rho + r(v)$ and $\hat{s} = s + \sigma(v)$, and with these variables handy, Eq. (11) distills to the expression $\hat{s} < v\hat{\rho} + z$. If the inequality holds, we know that v is either larger than the pivot or it may be the pivot itself. We thus update our current hypothesis for μ_ρ and ρ (designated as $v^\star$ and $\rho^\star$ in Fig. 3). We continue searching the left sub-tree ($\text{left}_{\mathcal{T}}(v)$) which includes all elements smaller than v. If inequality $\hat{s} < v\hat{\rho} + z$ does not hold, we know that $v < \mu_\rho$, and we thus search the right subtree ($\text{right}_{\mathcal{T}}(v)$) and keep ρ and s intact. The process naturally terminates once we reach a leaf, where we can also calculate the correct value of θ using Eq. (10).

Once we find θ_t (if $\theta_t \geq 0$) we update the global shift, $\Theta_{t+1} = \Theta_t + \theta_t$. We need to discard all the elements in $\mathcal{T}$ smaller than Θ_{t+1}, which we do using Tarjan's (1983) algorithm for splitting a red-black tree. This step is logarithmic in the total number of non-zero elements of $\mathbf{v}_t$. Thus, as the additional variables in the tree can be updated in constant time as a function of a node's child nodes in $\mathcal{T}$, each of the operations previously described can be performed in logarthmic time (Cormen et al., 2001), giving us a total update time of $O(k \log(n))$.

7. Experiments

We now present experimental results demonstrating the effectiveness of the projection algorithms. We first report results for experiments with synthetic data and then move to experiments with high dimensional natural datasets.

In our experiment with synthetic data, we compared variants of the projected subgradient algorithm (Eq. (2)) for ℓ_1-regularized least squares and ℓ_1-regularized logistic regression. We compared our methods to a specialized coordinate-descent solver for the least squares problem due to Friedman et al. (2007) and to very fast interior point

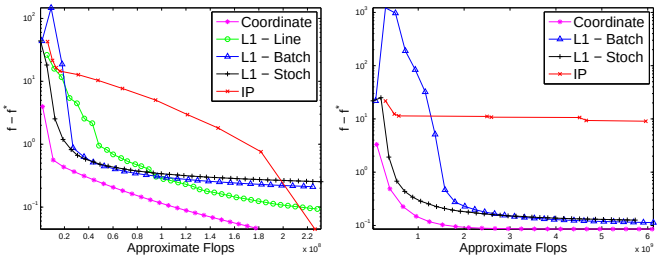

Figure 4. Comparison of methods on ℓ_1-regularized least squares. The left has dimension $n = 800$, the right $n = 4000$

methods for both least squares and logistic regression (Koh et al., 2007; Kim et al., 2007). The algorithms we use are batch projected gradient, stochastic projected subgradient, and batch projected gradient augmented with a backtracking line search (Koh et al., 2007). The IP and coordinate-wise methods both solve regularized loss functions of the form $f(\mathbf{w}) = L(\mathbf{w}) + \lambda\|\mathbf{w}\|_1$ rather than having an ℓ_1-domain constraint, so our objectives are not directly comparable. To surmount this difficulty, we first minimize $L(\mathbf{w}) + \lambda\|\mathbf{w}\|_1$ and use the 1-norm of the resulting solution $\mathbf{w}^*$ as the constraint for our methods.

To generate the data for the least squares problem setting, we chose a $\mathbf{w}$ with entries distributed normally with 0 mean and unit variance and randomly zeroed 50% of the vector. The data matrix $X \in \mathbb{R}^{m \times n}$ was random with entries also normally distributed. To generate target values for the least squares problem, we set $\mathbf{y} = X\mathbf{w} + \boldsymbol{\nu}$, where the components of $\boldsymbol{\nu}$ were also distributed normally at random. In the case of logistic regression, we generated data X and the vector $\mathbf{w}$ identically, but the targets y_i were set to be $\text{sign}(\mathbf{w} \cdot \mathbf{x}_i)$ with probability 90% and to $-\text{sign}(\mathbf{w} \cdot \mathbf{x}_i)$ otherwise. We ran two sets of experiments, one each for $n = 800$ and $n = 4000$. We also set the number of examples m to be equal to n. For the subgradient methods in these experiments and throughout the remainder, we set $\eta_t = \eta_0/\sqrt{t}$, choosing η_0 to give reasonable performance. (η_0 too large will mean that the initial steps of the gradient method are not descent directions; the noise will quickly disappear because the step sizes are proportional to $1/\sqrt{t}$).

Fig. 4 and Fig. 5 contain the results of these experiments and plot $f(\mathbf{w}) - f(\mathbf{w}^*)$ as a function of the number of floating point operations. From the figures, we see that the projected subgradient methods are generally very fast at the outset, getting us to an accuracy of $f(\mathbf{w}) - f(\mathbf{w}^*) \leq 10^{-2}$ quickly, but their rate of convergence slows over time. The fast projection algorithms we have developed, however, allow projected-subgradient methods to be very competitive with specialized methods, even on these relatively small problem sizes. On higher-dimension data sets interior point methods are infeasible or very slow. The rightmost graphs in Fig. 4 and Fig. 5 plot $f(\mathbf{w}) - f(\mathbf{w}^*)$ as functions of floating point operations for least squares and logistic re-

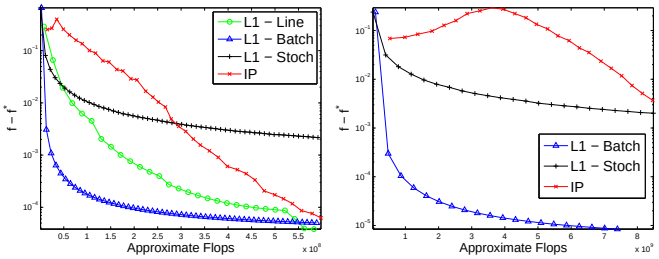

Figure 5. Comparison of methods on ℓ_1-regularized logistic regression. The left has dimension $n = 800$, the right $n = 4000$

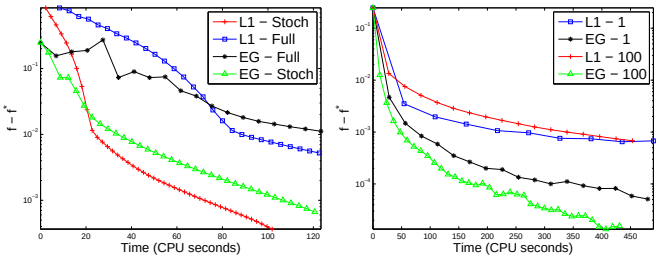

Figure 6. EG and projected subgradient methods on RCV1.

gression with dimension $n = 4000$. These results indicate that in high dimensional feature spaces, the asymptotically faster convergence of IP methods is counteracted by their quadratic dependence on the dimension of the space.

We also ran a series of experiments on two real datasets with high dimensionality: the Reuters RCV1 Corpus (Lewis et al., 2004) and the MNIST handwritten digits database. The Reuters Corpus has 804,414 examples; with simple stemming and stop-wording, there are 112,919 unigram features and 1,946,684 bigram features. With our preprocessing, the unigrams have a sparsity of 1.2% and the bigrams have sparsity of .26%. We performed ℓ_1-constrained binary logistic regression on the CCAT category from RCV1 (classifying a document as corporate/industrial) using unigrams in a batch setting and bigrams in an online setting. The MNIST dataset consists of 60,000 training examples and a 10,000 example test set and has 10-classes; each image is a gray-scale 28×28 image, which we represent as $\mathbf{x}_i \in \mathbb{R}^{784}$. Rather than directly use the input $\mathbf{x}_i$, however, we learned weights $\mathbf{w}_j$ using the following Kernel-based "similarity" function for each class $j \in \{1, \ldots, 10\}$:

$$k(\mathbf{x}, j) = \sum_{i \in S} w_{ji} \sigma_{ji} K(\mathbf{x}_i, \mathbf{x}), \; \sigma_{ji} = \begin{cases} 1 & \text{if } y_i = j \\ -1 & \text{otherwise.} \end{cases}$$

In the above, K is a Gaussian kernel function, so that $K(\mathbf{x}, \mathbf{y}) = \exp(-\|\mathbf{x} - \mathbf{y}\|^2/25)$, and S is a 2766 element support set. We put an ℓ_1 constraint on each $\mathbf{w}_j$, giving us the following multiclass objective with dimension 27,660:

$$\begin{array}{ll} \text{minimize}_{\mathbf{W}} & \frac{1}{m} \sum_{i=1}^m \log \left(1 + \sum_{r \neq y_i} e^{k(\mathbf{x}_i, r) - k(\mathbf{x}_i, y_i)}\right) \\ \text{s.t.} & \|\mathbf{w}_j\|_1 \leq z, \mathbf{w}_j \succeq 0. \end{array} \tag{12}$$

As a comparison to our projected subgradient methods on real data, we used a method known in the literature as either entropic descent, a special case of mirror descent (Beck & Teboulle, 2003), or exponentiated gradient (EG) (Kivinen & Warmuth, 1997). EG maintains a weight vector $\mathbf{w}$ subject to the constraint that $\sum_i w_i = z$ and $\mathbf{w} \succeq 0$; it can easily be extended to work with negative weights under a 1-norm constraint by maintaining two vectors $\mathbf{w}^+$ and $\mathbf{w}^-$. We compare against EG since it works well in very high dimensional spaces, and it very quickly identifies and shrinks weights for irrelevant features (Kivinen & Warmuth, 1997). At every step of EG we update

$$w_i^{(t+1)} = \frac{w_i^{(t)} \exp\left(-\eta_t \nabla_i f(\mathbf{w}^{(t)})\right)}{Z_t} \tag{13}$$

where Z_t normalizes so that $\sum_i w_i^{(t+1)} = z$ and $\nabla_i f$ denotes the i^{th} entry of the gradient of f, the function to be minimized. EG can actually be viewed as a projected subgradient method using generalized relative entropy ($D(\mathbf{x}\|\mathbf{y}) = \sum_i x_i \log \frac{x_i}{y_i} - x_i + y_i$) as the distance function for projections (Beck & Teboulle, 2003). We can replace $\nabla_i f$ with $\hat{\nabla}_i f$ in Eq. (13), an unbiased estimator of the gradient of f, to get stochastic EG. A step size $\eta_t \propto 1/\sqrt{t}$ guarantees a convergence rate of $O(\sqrt{\log n / T})$. For each experiment with EG, however, we experimented with learning rates proportional to $1/t$, $1/\sqrt{t}$, and constant, as well as different initial step-sizes; to make EG as competitive as possible, we chose the step-size and rate for which EG performed best on each individual test..

Results for our batch experiments learning a logistic classifier for CCAT on the Reuters corpus can be seen in Fig. 6. The figure plots the binary logistic loss of the different algorithms minus the optimal log loss as a function of CPU time. On the left side Fig. 6, we used projected gradient descent and stochastic gradient descent using 25% of the training data to estimate the gradient, and we used the algorithm of Fig. 2 for the projection steps. We see that ℓ_1-projections outperform EG both in terms of convergence speed and empirical log-loss. On the right side of the figure, we performed stochastic descent using only 1 training example or 100 training examples to estimate the gradient, using Fig. 3 to project. When the gradient is sparse, updates for EG are $O(k)$ (where k is the number of non-zeros in the gradient), so EG has a run-time advantage over ℓ_1-projections when the gradient is very sparse. This advantage can be seen in the right side of Fig. 6.

For MNIST, with dense features, we ran a similar series of tests to those we ran on the Reuters Corpus. We plot the multiclass logistic loss from Eq. (12) over time (as a function of the number gradient evaluations) in Fig. 7. The left side of Fig. 7 compares EG and gradient descent using

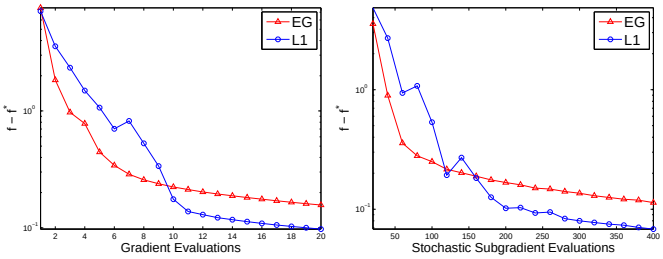

Figure 7. MNIST multiclass logistic loss as a function of the number of gradient steps. The left uses true gradients, the right stochastic subgradients.

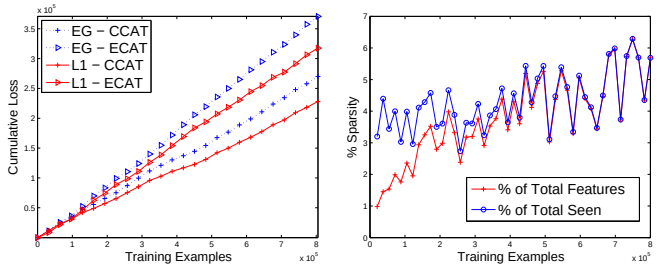

Figure 8. Online learning of bigram classifier on RCV1. Left is the cumulative loss, right shows sparsity over time.

the true gradient while the right figure compares stochastic EG and stochastic gradient descent using only 1% of the training set to estimate the gradient. On top of outperforming EG in terms of convergence rate and loss, the ℓ_1-projection methods also gave sparsity, zeroing out between 10 and 50% of the components of each class vector $\mathbf{w}_j$ in the MNIST experiments, while EG gives no sparsity.

As a last experiment, we ran an online learning test on the RCV1 dataset using bigram features, comparing ℓ_1-projections to using decreasing step sizes given by Zinkevich (2003) to exponential gradient updates. The ℓ_1-projections are computationally feasible because of algorithm 3, as the dimension of our feature space is nearly 2 million (using the expected linear-time algorithm of Fig. 2 takes 15 times as long to compute the projection for the sparse updates in online learning). We selected the bound on the 1-norm of the weights to give the best online regret of all our experiments (in our case, the bound was 100). The results of this experiment are in Fig. 8. The left figure plots the cumulative log-loss for the CCAT and ECAT binary prediction problems as a function of the number of training examples, while the right hand figure plots the sparsity of the ℓ_1-constrained weight vector both as a function of the dimension and as a function of the number of features actually seen. The ℓ_1-projecting learner maintained an active set with only about 5% non-zero components; the EG updates have no sparsity whatsoever. Our online ℓ_1-projections outperform EG updates in terms of the online regret (cumulative log-loss), and the ℓ_1-projection updates also achieve a classification error rate of 11.9% over all the examples on the CCAT task and 14.9% on ECAT (versus more than 15% and 20% respectively for EG).

Pointwise Exact Bootstrap Distributions of Cost Curves

Charles Dugas DUGAS@DMS.UMONTREAL.CA
David Gadoury GADOURY@DMS.UMONTREAL.CA
Department of Mathematics and Statistic, Université de Montréal, Canada

Abstract

Cost curves have recently been introduced as an alternative or complement to ROC curves in order to visualize binary classifiers performance. Of importance to both cost and ROC curves is the computation of confidence intervals along with the curves themselves so that the reliability of a classifier's performance can be assessed. Computing confidence intervals for the difference in performance between two classifiers allows the determination of whether one classifier performs *significantly* better than another. A simple procedure to obtain confidence intervals for costs or the difference between two costs, under various *operating conditions*, is to perform bootstrap resampling of the test set. In this paper, we derive *exact* bootstrap distributions for these values and use these dstributions to obtain confidence intervals, under various operating conditions. Performances of these confidence intervals are measured in terms of coverage accuracies. Simulations show excellent results.

1. Introduction

A cost curve (Drummond & Holte, 2000; Drummond & Holte, 2006) is a plot of a classifier's expected cost as a function of operating conditions, i.e. misclassification costs and class probabilities. Performance assessment in terms of expected cost is paramount but cannot be visualized through ROC analysis although knowledge of the distribution of a classifier's total misclassification error cost is often among the enduser's interests.

Cost curve analysis can be enhanced if dispersion measures of the curve are provided along with the curve itself, thereby allowing the enduser to assess the reliability of the estimated performance of the classifier considered for implementation. In order to obtain confidence intervals from a single test set, resampling methods such as the bootstrap (Efron & Tibshirani, 1993) technique can be used: from the test set, a certain number of samples are drawn with remplacement and from these samples, a distribution of the cost can be obtained. In certain cases, the bootstrap technique lends itself to analytic derivations for the limit case where the number of samples tends to infinity. Distributions thus obtained are referred to as *exact bootstrap* distributions. The purpose of this paper is to derive exact bootstrap distributions for a classifier's total cost of misclassification errors as well as the difference between two classifiers' total costs, for varying operating conditions.

Except for Drummond & Holte (2006), little attention has been given to developing and evaluating the performance of confidence intervals for cost curves. ROC curves have received much more attention. Arguably, the recency of cost curves explains in part this situation. Recent literature on the derivations of confidence intervals for ROC curves can be segmented in three categories: parametric, semi-parametric or empirical. Semi-parametric methods mainly refer to kernel-based methods (Hall & Hyndman, 2003; Hall et al., 2004; Lloyds, 1998; Lloyds & Wong, 1999). Bootstrap resampling has been used for ROC curves as an empirical method but to date, exact bootstrap distributions for the ROC curve have not been presented.

A technical difficulty arises from the fact that, when sampling from the entire test set, a procedure we shall refer to as *full* sampling, relative proportions of classes will vary from one sample to another. Mathematical derivations of exact bootstrap distributions, in the context of full sampling, are thus more complicated. In this paper, we first use a procedure referred to as *stratified sampling* according to which proportions of positive and negative instances of each bootstrap sam-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

ple are fixed as equal to those of the original test set. Here, an *instance* is an element of the test set. Instances of the class for which the event has (not) taken place are called *positive* (*negative*). For example, for a credit card fraud detection application, fraudulous transactions would be labelled as positive whereas legitimate transactions would be labelled as negative. Within the stratified sampling framework, each sample is obtained from the combination of two independent bootstrap samples: one drawn from the set of positive instances and the other drawn from the set of negative instances. This procedure has previously been used in the context of ROC (Bandos, 2005) as well as cost curves (Drummond & Holte, 2006). After obtaining results under this simplified stratified sampling approach, we derive exact bootstrap distributions for the *full* sampling approach.

From the user's perspective, the two sampling procedures, stratified and full, provide different information so that the difference between the two approaches reaches beyond mere mathematical derivations. According to stratified sampling, the user is provided with a cost distribution conditional on the operating conditions that will eventually prevail once the model is implemented. We refer to these as the *deployment* conditions. This corresponds to the view of Drummond & Holte (2006) who argue in favor of plotting cost curves in terms of all possible values of the unknown future deployment conditions. Within the stratified sampling approach, cost dispersion measures obtained for a specific value of the deployment conditions make no provision for uncertainty around expected deployment conditions. On the other hand, according to the full sampling approach, class proportions are implicitly assumed to be binomially distributed around those of the test set so that cost dispersion measures incorporate uncertainty around class proportions. Since the two approaches provide different information that may both be of interest, both are treated in this paper.

The rest of the paper is as follows: in section 2, we briefly review the main aspects of ROC and cost curves. Then, mathematical derivations are presented in section 3 for stratified sampling and in section 4 for full sampling. In section 5, we perform simulations and measure coverage accuracies of the confidence intervals. Limitations of the proposed approach are discussed in section 6. Finally, we conclude in section 7.

2. ROC and cost curves

An ROC curve is a plot of the probability of correctly identifying a positive instance (a true positive) against the probability of mistakenly identifying a negative instance as positive (a false positive), for various threshold values. Fawcett (2004) provides an excellent introduction to ROC curves along with descriptions of the essential elements of ROC graph analysis. Classifier performance assessment in terms of expected total error cost cannot be done using ROC curves and for this reason (and others (Drummond & Holte, 2006)), cost curves have been introduced as an alternative (or a complement) to ROC curves.

The main objective of cost curves is to visualize classifier performance in terms of expected cost rather than through a tradeoff between misclassification error probabilities. Expected cost is plotted against operating conditions where, as mentionned above, operating conditions include two factors: class probabilities and misclassification costs. Once these values are fixed, all possibly attainable true and false positive rates pairs are considered. Given class probabilities, misclassification costs, and true and false positive rates, a cost is obtained. The pair that minimizes the cost is selected. It is assumed that given certain operating conditions, the enduser would select the cost minimizing pair and set the classifier's threshold accordingly. In order to obtain a cost curve, this optimization process is repeated for all possible operating conditions values. As shown below, a set of operating conditions can be summarized through a single normalized scalar value ranging between 0 and 1. Figure 1 illustrates this process.

Cost curves are obtained assuming the enduser selects the threshold that minimizes expected cost, given operating conditions, *based on the test set*. One approach to obtain cost distributions is to draw bootstrap samples from the test set, obtain a cost curve for each of the samples and derive a distribution for the cost from these cost curves. Now consider a specific set of values for the operating conditions. Each of the samples will lead a possibly different optimal threshold for this set of operating conditions. This can be viewed in Figure 1 by comparing the left- and right-hand columns.

Thus, averaging cost curves (fixed operating conditions but varying thresholds) in order to obtain an estimate of the expected cost would correspond to the enduser being able to select the optimal thresholds, depending on the actually observed sample of instances. In other words, the enduser would be required to have knowledge of the test set *before* deciding on a threshold value, something that can't be done in practice. Ob-

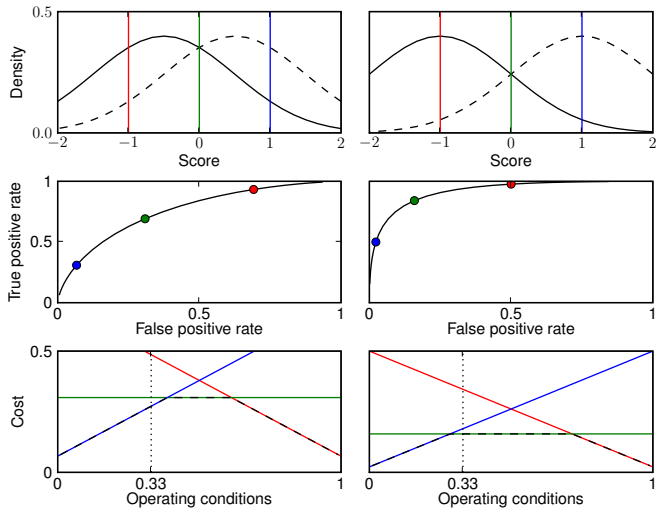

Figure 1. Derivation of ROC and cost curves for two classifiers with relatively low (left) and high (right) discrimination power. Top: score distributions for negative (solid) and positive (dashed) instances. Three colored vertical lines represent possible thresholds, from low (red) to high (blue). Middle: ROC curves associated to top row distributions. Three true and false positive pairs are identified with colored dots. Bottom: each dot of the middle row plotted in ROC space is uniquely associated to a line in cost curve space. Given specific operating conditions, the cost minimizing threshold may vary from one curve to another. Here, with $w = 0.33$, the optimal threshold is the highest (blue) of the three considered value on the left-hand side. On the right-hand side, it is the second largest threshold value (green) that leads to the lowest expected cost.

viously, thresholds must somehow be selected *prior* to test set cost measurements. This can be done through the standard machine learning process of splitting the data in three sets: training, validation and test. In our simulations, we assume the user chooses the optimal *theoretical* thresholds for all operating conditions, thus implicitely assuming an infinite sized validation set. The impact of this assumption is discussed later, in section 6. Our approach can therefore be considered as a form of threshold averaging of the costs. But since both operating conditions (abscissa values) and thresholds are fixed for each computed distribution, then the approach could be considered as vertical averaging as well. We now turn to more formal derivations of the cost curves and associated exact bootstrap distributions.

3. Stratified sampling

Consider a test set consisting of n instances from which stratified bootstrap samples are drawn. In this paper, we shall assume bootstrap samples are of the same size as the test set itself, a common procedure. Let n^+ and n^- be the numbers of positive and negative instances in the test set. According to the stratified bootstrap procedure and since we assume sample size equals test set size, the numbers of sampled positive and negative instances are fixed for all samples and also equal to n^+ and n^-, respectively. Let n_t^+ denote the number of instances, among the n^+ positive instances of the test set, with score greater or equal to the threshold $t = t(w)$ associated to operating conditions w, where w will be defined shortly. The corresponding value for a set of sampled positive instances is noted N_t^+ and follows binomial distribution with parameters n_t^+/n^+ and n^+ which we note as $N_t^+ \sim \text{Bin}(n_t^+/n^+, n^+)$. The random variable for the true positive rate, at threshold t, is denoted $TP_t^+ = N_t^+/n^+$. Similarly for negative instances, n_t^- refers to the number of instances with score greater or equal to t among the n^- negative instances of the test set, N_t^- is the random variable for the corresponding number of sampled instances and $FP_t^- = N_t^-/n^-$ is the false positive rate, at threshold t, with $N_t^- \sim \text{Bin}(n_t^-/n^-, n^-)$. Note that, according to the stratified sampling procedure, samples from positive and negative instances are drawn independently so that TP_t^+ and FP_t^- are independent as well.

Let us now formalize the above mentionned operating conditions and define w. Let $p_+ = n^+/n$ and $p_- = n^-/n$ represent class probabilities for positive and negative instances, respectively. Misclassification costs are noted $c_{+/-}$ and $c_{-/+}$ for false positive and false negative errors, respectively. Total cost is therefore given by the following:

$$C_t^T = p_+ c_{-/+}(1 - TP_t^+) + p_- c_{+/-} FP_t^- . \quad (1)$$

Drummond & Holte (2006) divide the total cost by its maximum possible value, in order to obtain a normalized cost with maximum value of one. This maximum total cost value is reached when $1 - TP_t^+ = FP_t^- = 1$ and the total cost is then equal to $p_+ c_{-/+} + p_- c_{+/-}$. Defining w as

$$w = \frac{p_+ \cdot c_{-/+}}{p_+ \cdot c_{-/+} + p_- \cdot c_{+/-}}, \quad (2)$$

the normalized cost is given by

$$C_t^N = w(1 - TP_t^+) + (1 - w) FP_t^- \quad (3)$$

with $w \in [0, 1]$. As mentionned above, true and false positive rates are independent when stratified sampling is used. Thus, the expected value and variance

of C_t^N follow as:

$$E[C_t^N] = w(1-n_t^+/n^+)+(1-w)n_t^-/n^-. \quad (4)$$

$$V[C_t^N] = w^2 n_t^+/n^+(1-n_t^+/n^+) + (1-w)^2 n_t^-/n^-(1-n_t^-/n^-). \quad (5)$$

We use these expectation and variance of the distribution of C_t^N to fit a gaussian distribution from which confidence intervals are easily obtained.

Now, in order to assess the statistical significance of the difference in performance of two classifiers, we need to obtain the distribution of the difference in their normalized costs:

$$\Delta C^N_{t_1,t_2} = C^N_{t_2} - C^N_{t_1} = w(TP^+_{t_1} - TP^+_{t_2}) + (1-w)(FP^-_{t_2} - FP^-_{t_1}) \quad (6)$$

where we use subscripts 1 and 2 to differentiate values obtained for the two classifiers. The values of $C^N_{t_2}$ and $C^N_{t_1}$ cannot be assumed independent since it is possible that the scores assigned by two different classifiers are correlated: for example, obvious fraudulous transactions will likely obtain high scores on all classifiers. Also note that only instances that are falsely labelled by one and only one of the two classifiers will affect the difference in costs. Errors made by both classifiers will offset each other when computing cost differences. Let $n^+_{t_1}$ represent the number of positive test set instances labelled as positive by the first classifier and negative by the second classifier, given operating conditions w. Similarly, let $n^+_{t_2}$ represent the number of positive test set instances labelled as positive by classifier 2 and negative by classifier 1. Note that thresholds $t_1 = t_1(w)$ and $t_2 = t_2(w)$ associated to operating conditions w may differ from one classifier to the other since score distributions and scales may vary from one classifier to the other. Values $n^-_{t_1}$ and $n^-_{t_2}$ are defined similarly for negative instances, given the same operating conditions value w.

Let $N^+_{t_1}$, $N^+_{t_2}$, $N^-_{t_1}$, and $N^-_{t_2}$ be the associated random variables for the number of instances in a bootstrap sample. Values $N^+_{t_1}$ and $N^+_{t_2}$ jointly follow a multinomial distribution. This also applies to $N^-_{t_1}$ and $N^-_{t_2}$. Accordingly, moments of $\Delta C^N_{t_1,t_2}$ are easily obtained:

$$E[\Delta C^N_{t_1,t_2}] = w\left(\frac{n^+_{t_1}-n^+_{t_2}}{n^+}\right) + (1-w)\left(\frac{n^-_{t_2}-n^-_{t_1}}{n^-}\right) \quad (7)$$

$$V[\Delta C^N_{t_1,t_2}] = w^2\left(\frac{n^+_{t_1}+n^+_{t_2}-\frac{(n^+_{t_1}-n^+_{t_2})^2}{n^+}}{(n^+)^2}\right) + (1-w)^2\left(\frac{n^-_{t_1}+n^-_{t_2}-\frac{(n^-_{t_1}-n^-_{t_2})^2}{n^-}}{(n^-)^2}\right). \quad (8)$$

Let us now evaluate the computational time required to obtain confidence intervals for the performance of a single classifier and for the difference between the performances of two classifiers. Here, we assume the number of different operating conditions considered, i.e. the number of different values for w is proportional to n. Also, as explained above, we assume the thresholds associated to each of these operating conditions have previously been determined through a validation process. For the case of a single classifier performance, we first need to sort instances with respect to their score, which requires time $O(n \ln n)$. Then, values of n_t^+ and n_t^- are easily obtained in linear time. There remains to compute expectations and variances, using equations (4) and (5), and derive confidence intervals using these values. This is realized in constant time for each value of w, thus overall linear time. Globally, the entire process is therefore dominated by the sorting phase and total computational time is $O(n \ln n)$. Confidence intervals for the difference in performance between two classifiers can be obtained in $O(n \ln n)$ computational time as well, although less trivially. Naive solutions lead to quadratic time but, given careful sorting preprocessing, values $n^+_{t_1}, n^+_{t_2}, n^-_{t_1}$, and $n^-_{t_2}$ are computed in linear time. Then, moments and confidence intervals for $\Delta C^N_{t_1,t_2}$ are obtained in linear time (for all values of w) using equations (7) and (8).

4. Full sampling

Within the framework of full sampling, the proportions of positive and negative instances vary from one sample to another. Whereas with stratified sampling, the number of positive and negative instances in each sample, n^+ and n^-, were set as equal to those of the test set, we now consider these numbers as random variables, and accordingly use capital notation N^+ and N^-. Here again, these values follow binomial distributions: $N^+ \sim \text{Bin}(n^+/n, n)$. Thus, full sampling implicitly assumes a binomial distribution for the observed class proportions $P_+ = N^+/n$ and $P_- = N^-/n$ but this distribution could easily be replaced.

Equation (1) still holds in the case of full sampling, but with the difference that P_+ and P_- are now treated as random variables. In the previous section the normalized version of the total cost was obtained by dividing the total cost by the largest possible cost: $p_+c_{-/+}+p_-c_{+/-}$, a weighted average between misclassification costs $c_{-/+}$ and $c_{+/-}$. Since P_+ and P_- are

no longer fixed, we must consider the largest possible weighted average which simply is the maximum of the two misclassification costs, $c_{\max} = \max[c_{-/+}, c_{+/-}]$. The case where $C_t^T = c_{-/+}$ is obtained when $N^+ = n$ and $TP_t^+ = 0$. Similarly, we have $C_t^T = c_{+/-}$ if $N^- = n$ and $FP_t^- = 1$. Thus, for full sampling, the normalized cost can be written as

$$C_t^N = \frac{N^+ \cdot c_{-/+} \cdot (1 - TP_t^+) + N^- \cdot c_{+/-} \cdot FP_t^-}{n \cdot c_{\max}}.$$

Then, expected normalized cost and normalized cost variance are obtained through iterated expectations:

$$\begin{aligned} E[C_t^N] &= E_{N^+}\{E[C_t^N|N^+]\} \\ &= \frac{c_{-/+}(n^+ - n_t^+) + c_{+/-} \cdot n_t^-}{n \cdot c_{\max}} \end{aligned} \quad (9)$$

$$\begin{aligned} V[C_t^N] &= V_{N^+}\{E[C_t^N|N^+]\} + E_{N^+}\{V[C_t^N|N^+]\} \\ &= \frac{c_{-/+}^2 \alpha_t^+ + c_{+/-}^2 \alpha_t^- + \delta_t^2}{(n \cdot c_{\max})^2} \end{aligned} \quad (10)$$

where

$$\begin{aligned} \alpha_t^+ &= n_t^+ - \frac{(n_t^+)^2}{n^+} \\ \alpha_t^- &= n_t^- - \frac{(n_t^-)^2}{n^-} \\ \delta_t^2 &= \left(c_{-/+} \frac{n^+ - n_t^+}{n^+} - c_{+/-} \frac{n_t^-}{n^-} \right)^2 \frac{n^+ \cdot n^-}{n} \end{aligned}$$

Here again, equations (9) and (10) can be used to obtain a fitted gaussian distribution from which confidence intervals are easily derived.

Let us now turn to the difference in performance between two classifiers. In the case of full sampling, this difference is

$$\Delta C_{t_1,t_2}^N = \frac{c_{-/+}(N_{t_1}^+ - N_{t_2}^+) + c_{+/-}(N_{t_2}^- - N_{t_1}^-)}{n \cdot c_{\max}} \quad (11)$$

Again, expected normalized cost and normalized cost variance are obtained through iterated expectations:

$$\begin{aligned} E[\Delta C_{t_1,t_2}^N] &= E_{N^+}\{E[\Delta C_{t_1,t_2}^N|N^+]\} \\ &= \frac{c_{-/+}(n_{t_1}^+ - n_{t_2}^+) + c_{+/-} \cdot (n_{t_2}^- - n_{t_1}^-)}{n \cdot c_{\max}} \end{aligned} \quad (12)$$

$$\begin{aligned} V[\Delta C_{t_1,t_2}^N] &= V_{N^+}\{E[\Delta C_{t_1,t_2}^N|N^+]\} \\ &\quad + E_{N^+}\{V[\Delta C_{t_1,t_2}^N|N^+]\} \\ &= \frac{c_{-/+}^2 \alpha_{t_1,t_2}^+ + c_{+/-}^2 \alpha_{t_1,t_2}^- + \delta_{t_1,t_2}^2}{(n \cdot c_{\max})^2} \end{aligned} \quad (13)$$

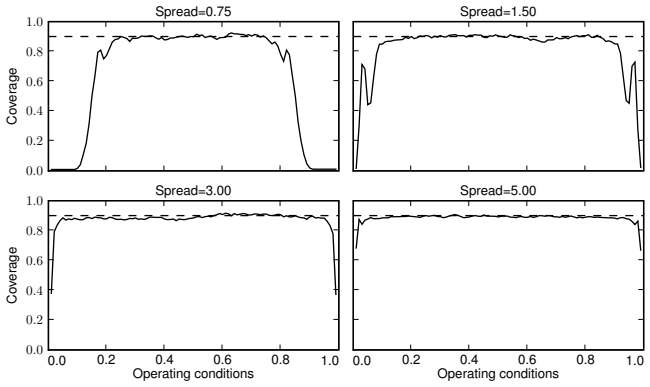

Figure 2. Effect of spread between distributions on coverage. Stratified sampling is used. Confidence intervals are derived for a classifier's cost. Location (spread) parameter for positive instances is set equal to 0.75 (up and left), 1.50 (up and right), 3.00 (down and left), and 5.00 (down and right). Sample size is 1,000. Confidence intervals are built with significance level $\alpha = 10\%$. Coverage proportion (solid) for 1,000 simulations and target coverage of 90% (dashed) are plotted against operating conditions.

where

$$\begin{aligned} \alpha_{t_1,t_2}^+ &= n_{t_1}^+ + n_{t_2}^+ - \frac{(n_{t_1}^+ - n_{t_2}^+)^2}{n^+} \\ \alpha_{t_1,t_2}^- &= n_{t_1}^- + n_{t_2}^- - \frac{(n_{t_1}^- - n_{t_2}^-)^2}{n^-} \\ \delta_{t_1,t_2}^2 &= \left(c_{-/+} \frac{n_{t_1}^+ - n_{t_2}^+}{n^+} - c_{+/-} \frac{n_{t_2}^- - n_{t_1}^-}{n^-} \right)^2 \frac{n^+ \cdot n^-}{n} \end{aligned}$$

This completes mathematical derivations. A total of four distributions have been obtained. For all four distributions, computation of confidence intervals is dominated by the need to sort instances so that computational time is $O(n \ln n)$ in all cases. Note that such time efficiency is obtained because we rely on the gaussian fitting of the variables' distributions. Computing true exact bootstrap distributions would lead to higher computational time orders. But as we show in the next section, results obtained with gaussian fitting are already excellent.

5. Numerical results

In this section, we conduct a series of experiments in order to assess the performance of the confidence intervals derived in sections 3 and 4. Performance is measured in terms of coverage accuracy of confidence intervals.

The first experiment is based on the framework used

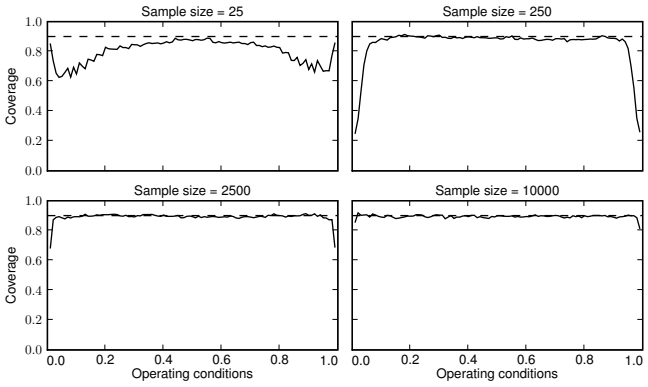

Figure 3. Effect of sample size on coverage. Stratified sampling is used. Confidence intervals are derived for a classifier's cost. Sample sizes of 25 (up and left), 250 (up and right), 2,500 (down and left), and 1,000, (down and right) are considered. Confidence intervals are built for significance level $\alpha = 10\%$. Location parameter for positive instances is set to $\theta = 3.0$. Coverage proportion (solid) for 1,000 simulations and target coverage of 90% (dashed) are plotted against operating conditions.

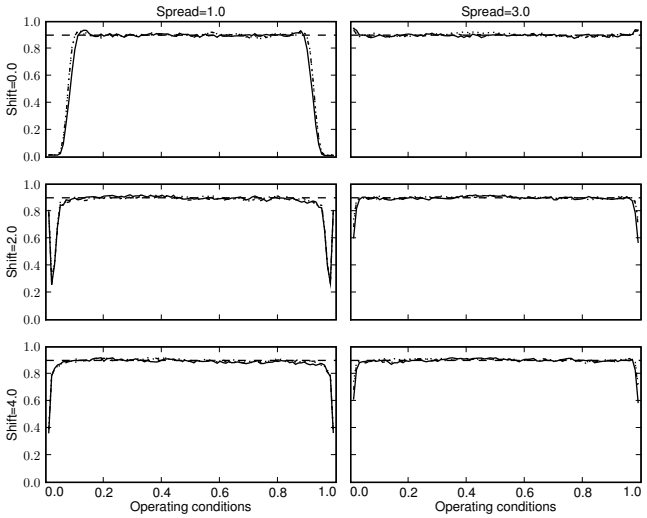

Figure 4. Coverage accuracy of confidence intervals for the difference in performance between two classifiers. Stratified sampling is used. Sample size is 1000, and significance level is $\alpha = 10\%$. Location parameter for positive instances of first classifier is set to $\theta = 1.0$ (left) and $\theta = 3.0$ (right). Location parameter for the score of positive instances according to the second classifier is θ (top), $\theta + 2.00$ (middle) and $\theta + 4.00$ (bottom). Within each plot, correlation factor is equal to 0.3 (dotted), 0.6 (dash-dotted) and 0.9 (solid). Coverage proportions for 1,000 simulations and target coverage of 90% (dashed) are plotted against operating conditions.

by Macskassy et al. (2005) in which four methods for obtaining pointwise confidence intervals for ROC curves are compared: threshold averaging, vertical averaging, kernel smoothing (Hall et al., 2004) and Working-Hotelling bounds. Positive and negative instance scores follow normal distributions but with various parameter values. We set the scale parameter to 3.00 for both positive and negative instances scores. The location parameter θ for positive instances varies within the set $\{0.75, 1.5, 3.0, 5.0\}$ and the location parameter for negative instances is set equal to $-\theta$. Sample size is set to 1,000, i.e. a set of 1,000 instances is drawn from the positive instances distribution and another set of 1,000 negative instances is drawn from the negative instances distribution. The sampling procedure is repeated 1,000 times, i.e. 1,000 simulations are performed for each value of θ. We shall refer to this experiment as the *spread* experiment. Confidence intervals are obtained for a significance level of 10%.

Figure 2 provides simulation results which clearly show that better results are obtained when score distributions of positive and negative instances have few overlap, i.e. for high values of θ. Breaks in coverage accuracy appear as w is close to 0 or 1. This recurring pattern is discussed in section 6.

As a second experiment, we consider the effect of sample size on coverage accuracy. This experiment is everywhere similar to the previous one except for two modifications: (1) the location parameter not longer varies: it is set to $\theta = 3.0$ and (2) the sample size takes values in $\{25; 250; 2,500; 10,000\}$ instead of being fixed at 1,000. We shall refer to this experiment as the *size* experiment. Simulation results appear in Figure 3. As the sample size increases, the range of operating condition values with good coverage accuracy widens. For sample sizes of 25, only a very narrow range of operating condition values lead to a coverage rate that is on target.

Our third experiment addresses the modeling of the difference in performance between two classifiers. The experiment design is similar to the ones used for the previous two experiments, i.e. the spread and size experiments. Scores are distributed according to a binormal distribution with scale of 3.00. Confidence intervals are obtained for a significance level of $\alpha = 10\%$. The location parameters are set as follows: for positive instances of the first classifier, we consider two values: $\theta \in \{1.0, 3.0\}$. For negative instances of both classifiers the parameter is set equal to $-\theta$. Finally, for positive instances of the second classifier we consider three values: θ, $\theta + 2.0$ and $\theta + 4.0$. The difference between the location parameters of the two classifiers'

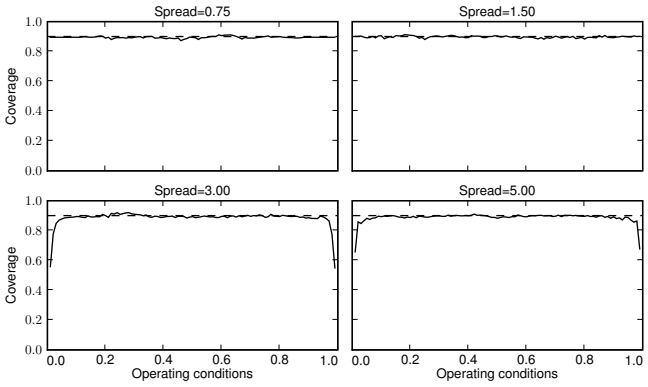

Figure 5. Effect of spread between distributions on coverage. Full sampling is used. Confidence intervals are derived for a classifier's cost. Location parameter for positive instances is set equal to 0.75 (up and left), 1.50 (up and right), 3.00 (down and left), and 5.00 (down and right). Sample size is 1,000. Confidence intervals are built with significance level $\alpha = 10\%$. Coverage proportion (solid) for 1,000 simulations and target coverage of 90% (dashed) are plotted against operating conditions.

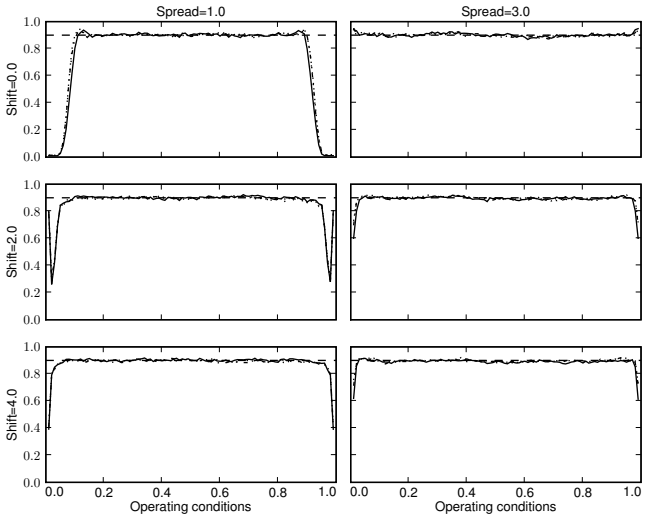

Figure 6. Coverage accuracy of confidence intervals for the difference in performance between two classifiers. Full sampling is used. Sample size is 1000, and significance level is $\alpha = 10\%$. Location parameter for positive instances of first classifier is set to $\theta = 1.0$ (left) and $\theta = 3.0$ (right). Location parameter for the score of positive instances according to the second classifier is θ (top), $\theta + 2.00$ (middle) and $\theta + 4.00$ (bottom). Within each plot, correlation factor is equal to 0.3 (dotted), 0.6 (dash-dotted) and 0.9 (solid). Coverage proportions for 1,000 simulations and target coverage of 90% (dashed) are plotted against operating conditions.

positive instances distributions, either 0.0, 2.0 or 4.0, is referred to as the *shift* parameter. In order to include some form of dependency between the scores of the two classifiers, three values of a correlation factor are considered: $\rho \in \{0.3, 0.6, 0.9\}$. We shall refer to this experiment as the *difference* experiment.

Results appear in Figure 4. As in the previous two experiments, coverage accuracy breaks for very low or high total positive rates. Comparing curves on the left of Figure 4 with those on the right, we see the spread parameter θ has some impact: higher values of θ cause the range of total positive rate values with good coverage accuracy to widen. With $\theta = 1.0$, higher shift parameter values lead to better coverage accuracy whereas with $\theta = 3.0$, the shift parameter has the opposite, but less pronounced, effect. The correlation coefficient seems to have very little effect on coverage accuracy which is a welcome property: the performances of the confidence intervals seem independent of the level of correlation between the scores of two models.

Figure 5 and 6 repeat the spread (first) and diffrence (third) experiments described above, but with the use of full sampling. Looking at Figure 5, it it clear that full sampling leads to better coverage accuracy than stratified sampling for low values of the spread parameter ($\theta = 0.75$). In fact, the effect of the spread parameter seems to have reversed although performance at $\theta = 5.00$ is better than with $\theta = 3.0$. Finally, Figure 6 indicates that both stratified and full sampling perform equally well for modeling the difference between two classifiers' performances.

6. Limitations of the approach

A first consideration is whether actually performing a certain number of bootstrap resamplings of the test set instances would allow us to reach coverage accuracy similar to that obtained in the previous experiments, using exact bootstrap distributions. Let b be the number of empirical bootstrap samples drawn. Computational time is dominated by the need to sort instances, as a preprocessing, for each sample and is thus within $O(b\,n \ln n)$. Obtaining confidence intervals through empirical bootstrap is therefore both an order of magnitude slower and less precise than using the exact bootstrap approach. Obviously, coverage accuracies similar to those presented here could be obtained with a large number of resamples but at high computational cost.

Another issue is the presence of breaks in coverage accuracy for extreme values of operating conditions.

When considering operating conditions close to 0 or 1, optimal thresholds are likely to lie outside the range of observed scores of the simulated test sets. For such thresholds and simulations, variances are either zero (equations 5,8, and 13) in which case coverage is impossible or very close to zero (equation 10) in which case coverage is very unlikely. Coverage accuracy breaks appear as the probability that the optimal threshold is outside the range of observed score values rises. Also, as is apparent from Figure 1, the expected value of the cost (thus the cost difference as well) drops to zero as operating conditions reach extreme values.

Finally, we may wonder how the assumption of optimal threshold selection impacts the results presented in this paper. Instead of assuming optimal threshold selection, consider selecting the thresholds, for each simulation of the previous experiments, based on a randomly generated finite-sized validation set which leading to suboptimal thresholds. Of course, expected costs are, by definition, higher for suboptimal thresholds than for optimal thresholds but what is of interest here is whether we can develop reliable confidence intervals for the cost, at the chosen thresholds, whether optimal or not. Given certain operating conditions, the selected suboptimal threshold follows a distribution centered around the optimal value so that coverage accuracy, given these operating conditions, is the expected coverage accuracy where the expectation is taken over the distribution of the suboptimal threshold. This results in a smoothing of the coverage accuracy breaks observed in the experiments above.

7. Conclusion

In this paper, we have derived exact bootstrap distributions for the (normalized) cost of the misclassification errors of a classifier's decisions. We have also derived exact bootstrap distributions for the difference between the costs of two classifiers. The first and second moments of these distributions have been used to fit gaussian distributions and thus approximate the true exact bootstrap distributions. From these approximated distributions, we were able to obtain confidence intervals for the variables of interest. Table 1 summarizes these results. All confidence intervals can be derived in $O(n \ln n)$ time.

Results obtained in this paper are excellent but limited to a few simulations. In a few cases, severe breaks in coverage accuracy appear when operating conditions values close to 0 or 1. These breaks can be avoided if cost distribution computations are limited to thresholds within the range of sampled scores. Another possibility is to extrapolate score distributions beyond observed values, an area for future work.

Abstract

In this study we introduce a novel algorithm for learning a polyhedron to describe the target class. The proposed approach takes advantage of the limited subclass information made available for the negative samples and jointly optimizes multiple hyperplane classifiers each of which is designed to classify positive samples from a subclass of the negative samples. The flat faces of the polyhedron provides robustness whereas multiple faces contributes to the flexibility required to deal with complex datasets. Apart from improving the prediction accuracy of the system, the proposed polyhedral classifier also provides run-time speedups as a by-product when executed in a cascaded framework in real-time. We evaluate the performance of the proposed technique on a real-world Colon dataset both in terms of prediction accuracy and online execution speed.

1. Problem Specification

In target detection the objective is to determine whether or not a given example is from a target class. Obtaining ground truth for the target class usually involves a tedious process of manual labeling. If samples belonging to the target class are labeled as positive, then negative class covers everything else. Due to the nature of the problem and the labeling process, the number of samples representing the target class is usually scarce whereas abundant data is potentially available to represent the negative class. In other words the data is highly unbalanced between classes favoring the negative class.

In this process the actual labels of the counter-examples are ignored and the negative class is formed by pooling samples of potentially different characteristics together within a single class. In other words samples of the negative class do not cluster well since they can belong to different subclasses.

One promising approach that has been heavily explored in this domain is the one-class classifiers. One-class classification simply omits the negative class (if it exists) and aims to learn a model with the positive examples only. Several techniques have been proposed in this direction. Support vector domain description technique aims to fit a tight hyper-sphere in the feature space to include most of the positive training samples and reject outliers (Tax & Duin, 1999). In this approach the nonlinearity of the data can be addressed implicitly through the kernel evaluation of the technique. One-class SVM generates an artificial point through kernel transformation for representing the negative class and then using relaxation parameters it aims to separate the image of the one-class from the origin (Scholkopf et al., 1999). Compression Neural Network constructs a three-layer feed-forward neural network and trains this network with a standard back-propogation algorithm to learn the identity function on the positive examples (Manevitz & Yousef, 2001).

Discriminative techiques such as Support Vector Machines (Vapnik, 1995), Kernel Fisher Discriminant (Mika et al., 2000), Relevance Vector Machines (Tipping, 2000) to name few are also used in this domain. These techniques deal with the unbalanced nature of the data by assigning different cost factors to the negative and positive samples in the objective function. The kernel evaluation of these techniques yields nonlinear decision boundaries suitable for classifying multi-mode data from the target class.

In this study we aim to learn a polyhedron in the feature

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

space to describe the positive training samples. Polyhedral decision boundaries such as boundaries that are drawn parallel to the axes of the feature space as in decision trees or skewed decision boundaries (Murth et al., 1994) have existed for quite some time. Our approach is similar in some sense to the Support vector domain description technique but there are two major differences. First instead of a hypersphere, a polyhedron is used to fit positive training samples. Second, positive and negative samples are used together in this process. The target polyhedron is learned through joint optimization of multiple hyperplane classifiers, each of which is designed to classify positive samples from a subgroup of negative samples. The number of such hyperplane classifiers is equivalent to the number of subclasses identified in the negative class. The proposed technique requires labeling of a small portion of the negative samples to collect training data for the subclasses that exist in the negative class.

Our approach does not intend to precisely identify each and every subclass in the dataset. By manual labeling we aim to identify major subclasses. Subclasses with similar characteristics or with only few labeled samples can be grouped together. During annotation one may also encounter positive look alikes, i.e. samples do not appear as negative but not yet confirmed as positive. A new subclass can be introduced for these samples.

In Figure 1 the proposed algorithm is demonstrated with a toy example. Positive samples are depicted by the dark circles in the middle, whereas negative samples are depicted with the numbers with each number corresponding to a different subclass. All eight classifiers are optimized simultaneously and polygon shown with dark lines is obtained as a decision boundary that classifies positive samples from the negative ones.

Kernel-based classifiers have the capacity to learn higly nonlinear decision boundaries allowing great flexibility. However it is well-known that in real-world applications where feature noise and redundancy is a problem, too much capacity usually hurts the generalizability of a classifier by enabling the classifier to easily overfit the training data. The proposed approach is capable of addressing nonlinearities by fitting the positive class through a series of linear hyperplanes, all of which are optimized jointly to form a polyhedral decision boundary. The flat faces provides robustness whereas multiple faces contributes to the flexibility.

The problem described above is commonly encountered in areas like content-base image retrieval (Chen et al., 2001), document classification (Manevitz & Yousef, 2001) and speech recognition (Brew et al., 2007). A similar scheme is also observed in Computer Aided Detection (CAD). In this study we explore the proposed idea for a CAD application, namely Colon CAD.

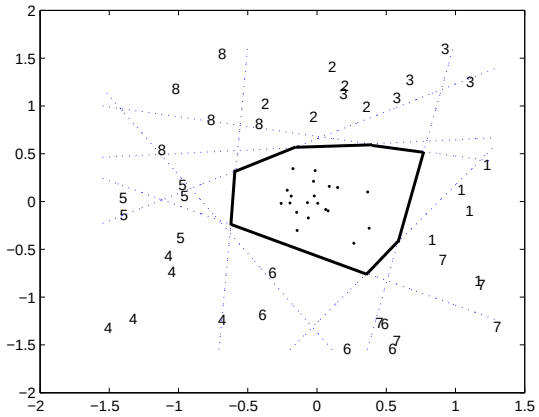

Figure 1. A Toy example demonstrating the proposed algorithm. Dark circles depicting positive samples, numbers representing negative samples. The decision boundary is shown with the solid lines.

2. Hyperplane Classifiers

We are given a training dataset $\{(x_i, y_i)\}_{i=1}^{\ell}$, where $x_i \in \Re^d$ are input variables and $y_i \in \{-1, 1\}$ are class labels. We consider a class of models of the form $f(x) = \alpha^T x$, with the sign of $f(x)$ predicting the label associated with the point x. An hyperplane classifier with hinge loss can be designed by minimizing the following cost function.

$$\mathcal{J}(\alpha) = \Phi(\alpha) + \sum_{i=1}^{\ell} w_i \left(1 - \alpha^T y_i x_i\right)_+ \qquad (1)$$

where the function $\Phi : \Re^{(d)} \Rightarrow \Re$ is a regularization function or regularizer on the hyperplane coefficients and $(k)_+ = max(0, k)$ represents the hinge loss, and $\{w_i : w_i \geq 0, \forall i\}$ is the weight preassigned to the loss associated with x_i. For balanced data usually $w_i = w$, but for unbalanced data it is a common practice to weight positive and negative classes differently, i.e. $\{w_i = w_+,\ \forall i \in C^+\}$ and $\{w_i = w_-,\ \forall i \in C^-\}$ where C^+ and C^- are the corresponding sets of indices for the positive and negative classes respectively.

The function $\left(1 - \alpha^T y_i x_i\right)_+$ is a convex function. The weighted sum of convex functions is also convex. Therefore for a convex function $\Phi(\alpha)$ (1) is also convex. The problem in (1) can be formulated as a mathematical pro-

gramming problem as follows:

$$\begin{array}{rcl} \min\limits_{(\alpha,\xi)\in R^{d+\ell}} & \Phi(\alpha) + \sum_{i=1}^{\ell} w_i\xi_i & \\ \text{s.t.} & \xi_i \geq 1-\alpha^T y_i x_i & \\ & \xi_i \geq 0,\ \forall i & \end{array} \tag{2}$$

For $\Phi(\alpha) = \|\alpha\|_2^2$, where $\|.\|_2$ is the 2-norm, (2) results in the conventional Quadratic-Programming-SVM, and for $\Phi(\alpha) = |\alpha|$, where $|.|$ is the 1-norm it yields the sparse Linear-Programming-SVM.

3. Polyhedral Decision Boundaries

3.1. Training a Classifier with an AND Structure

We aim to optimize the following cost function

$$\begin{aligned} \mathcal{J}(\alpha_1,\dots\alpha_K) &= \sum_{k=1}^{K}\Phi_k(\alpha_k) \\ &+ \nu_1\sum_{k=1}^{K}\sum_{i\in C_k^-}(e_{ik})_+ \\ &+ \nu_2\sum_{i\in C^+}\max(0,e_{i1},\dots,e_{iK}) \end{aligned} \tag{3}$$

where $e_{ik} = 1+\alpha_k^T x_{ik}$ and $(e_{ik})_+$ defines the hinge loss of the i-th training example $\{(x_{ik}, y_{ik})\}$ in subclass-k induced by classifier k. C_k^- is the set of indices of the negative samples in subclass-k. Note that classifier k is designed to classify positive examples from the negative examples in the subclass-k. The first term in (3) is a summation of the regularizers for each of the classifiers in the cascade and the second and third terms accounts for the losses induced by the negative and positive samples respectively. Unlike (1) the loss function here is different for the positive samples. The loss induced by a positive sample i, $i \in C^+$ is zero only if $\forall k : 1-\alpha_k^T x_i \leq 0$, which corresponds to the "AND" operation. The problem (3) can be formulated as follows

$$\begin{array}{rcl} \min\limits_{(\alpha,\xi)\in R^{Kd+\ell}} & \sum_{k=1}^{K}\Phi_k(\alpha_k) + \nu_1\sum_{k=1}^{K}\sum_{i\in C_k^-}\xi_{ik} & \\ & + \nu_2\sum_{i\in C^+}\xi_i & \\ \text{s.t.} & \xi_{ik} \geq 1+\alpha_k^T x_{ik} & \\ & \xi_{ik} \geq 0 & \\ & \xi_i \geq 1-\alpha_k^T x_i & \\ & \xi_i \geq 0 & \end{array} \tag{4}$$

where the first two constraints are imposed for $\forall i \in C_k^-$, $k = 1,...,K$ and the last two constraints are imposed for $\forall i \in C^+$, $k = 1,...,K$. Note that for a convex function $\Phi(\alpha)$ the problem in (4) is convex. In a nutshell we designed K classifiers, one for each of the binary classification problems, i.e. positive class vs subclass-k of the negative class. Then we construct a learning algorithm to jointly optimize these classifiers such that the cost induced by a positive sample is zero if and only if all of the K classifiers classifies this sample correctly, i.e. $\forall k : 1-\alpha_k^T x_i \leq 0$. Since each negative sample is only used once for training the classifier k, the cost induced for a negative sample is zero as long as it is classified correctly by the corresponding classifier k, i.e. $1+\alpha_k^T x_{ik} \leq 0$. Each classifier can use an arbitrary subset of the original feature set. This provides run time advantages in real-time when the classification architecture is implemented in a cascaded framework. This will be explained later in the paper. For now to keep the notation clean and tractable we assumed each classifier uses the entire feature set in the formulation (4) above.

3.2. Training a Classifier with an AND-OR Structure

The AND algorithm is developed with the assumption that the negative class is fully labeled. That is to say, the subclass membership of each of the negative sample is known apriori. For most real world applications this is not a very realistic scenario as it is almost impractical to label all of the negative samples due to the time limitations. However one can label a small subset of the negative class to discover different type of subclasses as well as pool the training data for each subgroup. To accommodate for the unlabeled samples we modify the equation (3) for the unlabeled negative samples as follows.

$$\begin{aligned} \mathcal{J}(\alpha_1,\dots\alpha_K) &= \sum_{k=1}^{K}\Phi_k(\alpha_k) \\ &+ \nu_1\sum_{k=1}^{K}\sum_{i\in C_k^-}(e_{ik})_+ \\ &+ \nu_1\sum_{i\in \acute{C}^-}\prod_{k=1}^{K}(e_{ik})_+ \\ &+ \nu_2\sum_{i\in C^+}\max(0,e_{i1},\dots,e_{iK}) \end{aligned}$$

where $\acute{C}^-$ is the set of indices of the unlabeled negative samples. The first term in (5) requires a labeled sample from a subclass-k to be correctly classified by the classifier k. In other words if a sample is known to be a member of subclass-k, ideally it should be classified as negative by the corresponding classifier k. On the other hand the second term requires an unlabeled negative sample to be correctly classified by any of the classifiers. As long as an unlabeled sample is classified as negative it does not matter which classifier does it, i.e. $\exists k : 1-\alpha_k^T x_{ik} \leq 0$ which corresponds to a "OR" operation. The third term requires a positive sample is classified as positive by all of the K classifiers, i.e. $\forall k : 1-\alpha_k^T x_i \leq 0$, which corresponds to the "AND" operation.

Due to the product operation in the objective function for unlabeled samples, unlike equation (3), equation (5) can not be cast as a convex programming problem. In the next section we propose an efficient alternating optimization algorithm to solve this problem.

4. Cyclic Optimization of AND-OR Algorithm

We develop an iterative algorithm which, at each iteration, carries out K steps, each aiming to optimize one classifier at a time. This type of algorithms is usually called alternating or cyclic optimization approaches. At any iteration, we fix all of the classifiers but the classifier k. The fixed terms have no effect on the optimization of the problem once they are fixed. Hence solving (5) is equivalent to solving the following problem by dropping the fixed terms in (5):

$$\begin{aligned}\mathcal{J}(\alpha_k) &= \Phi_k(\alpha_k) \\ &+ \nu_1 \sum_{i\in C_k^-} (e_{ik})_+ \\ &+ \nu_1 \sum_{i\in \acute{C}^-} w_i\ (e_{ik})_+ \\ &+ \nu_2 \sum_{i\in C^+} \max(0, e_{i1}, \ldots, e_{ik}, \ldots, e_{iK})\end{aligned}$$

where $w_i = \prod_{k=1,k\neq k}^{K} (e_{ik})_+$. This can be cast into a constrained problem as follows

$$\begin{aligned}\min_{(\alpha_k,\xi)\in R^{d+\ell_k+\ell_+}} \quad & \Phi_k(\alpha_k) + \nu_1 \textstyle\sum_{i\in C_k^-} \xi_i \\ & + \nu_1 \textstyle\sum_{i\in \acute{C}^-} w_i\xi_i \\ & + \nu_2 \textstyle\sum_{i\in C^+} \xi_i \\ \text{s.t.} \quad & \xi_i \geq e_{ik},\ \forall i \\ & \xi_i \geq 0,\ \forall i \in \acute{C}^- \cup C_k^- \\ & \xi_i \geq \gamma_i,\ \forall i \in C^+\end{aligned} \tag{5}$$

where $\gamma_i = max\left(0, e_{i1}, \ldots, e_{i(k-1)}, e_{i(k+1)}, \ldots, e_{iK}\right)$ and ℓ_k is the number of samples in subclass-k. The subproblem in (5) is a convex problem and differs from the problem in (2) by two small changes. First the weight assigned to the loss induced by the negative samples is now adjusted by the term $w_i = \prod_{k=1,k\neq k}^{K} (e_{ik})_+$. This term multiplies out to zero for negative samples correctly classified by one of the other classifiers. For these samples $e_{ik} < 0$ and $\xi_i = 0$ making the constraints on ξ_i in (5) redundant. As a result there is no need to include these samples when training for the *classifier-k*, which yields significant computational advantages. Second the lower bound for ξ is now $max\left(0, e_{i1}, \ldots, e_{i(k-1)}, e_{i(k+1)}, \ldots, e_{iK}\right)$. This implies that if any of the classifiers in the cascade misclassifies x_{ik} the lower bound on ξ is no longer zero relaxing the constraint on x_{ik}.

4.1. An Algorithm for AND-OR Learning

(0) Initialize e_{ik} in (5) such that all candidates are classified as positive, i.e. 100% sensitivity, 0% specificity. Set counter $c = 1$.

(i) Fix all the classifiers in the cascade except classifier k and solve (5) for α_k^c using the training dataset $\left\{\left(x_i^k, y_i\right)\right\}_{i=1}^{\ell}$. Repeat this for all $k = 1, \ldots, K$.

(ii) Compute $J^c(\alpha_1, \ldots, \alpha_K)$ by replacing α_k^{c-1} by α_k^c in (5), for all $k = 1, \ldots, K$.

(iii) Stop if $J^c - J^{c-1}$ is less than some desired tolerance. Else replace α_k^{c-1} by α_k^c for all $k = 1, \ldots, K$, c by $c + 1$ and go to *step i*.

The initial objective function in (5) is neither convex nor twice differentiable due to the product of the hinge loss term. Therefore the convergence theorem introduced in (Bezdek & Hathaway, 2003) for cyclic optimization does not hold here. On the other hand the subproblem in (5) is convex and hence at each iteration $J^c <= J^{c-1}$ holds and also (5) is bounded below. These guarantee convergence of the algorithm from any initial point to the set of suboptimal solutions. The solution is suboptimal if the objective function J can not be further improved following any directions. For a more detailed discussion on this topic please see (Dundar & Bi, 2007).

An unseen sample x can be classified as positive if $max(1 - \alpha_1^T x, \ldots, 1 - \alpha_K^T x) \leq \tau$ and as negative if vice versa for a threshold τ. The receiver operating characteristics (ROC) curve can be plotted by varying the value of τ.

5. Cascade Design for Run-Time Speedups

In Figure 2 a cascade classification scheme is shown. The key insight here is to reduce the computation time and speed-up online learning. This is achieved by designing simpler classifiers in the earlier stages of the cascade to reject as many negative candidates as possible before calling upon classifiers with more features to further reduce the false positive rate. A positive result from the first classifier activates the second classifier and a positive result from the second classifier activates the third classifier, and so on (Viola & Jones., 2004). A negative outcome for a candidate at any stage in the cascade leads to an immediate rejection of that candidate. Under this scenario $T_{k-1} = T_k \cup F_k$ and $T_0 = T_K \cup \bigcup_1^K F_k$ where T_k and F_k are the sets of candidates labeled as positive and negative respectively by classifier k.

The proposed algorithm learns a polyhedron through jointly optimizing a series of sparse linear classifiers. Since

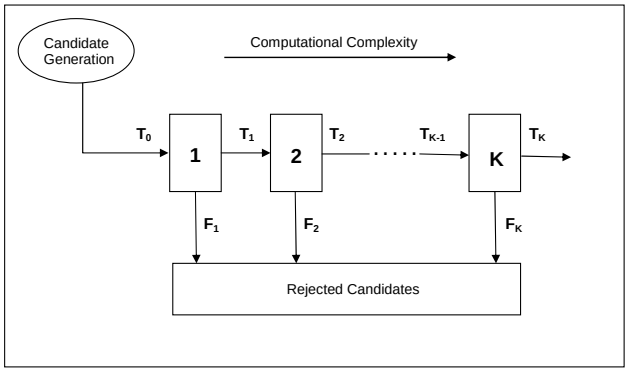

Figure 2. A general cascade framework used for online classification

the order these classifiers are executed in real-time does not matter in terms of the overall prediction accuracy of the system, we can arrange the execution sequence of these classifiers in a way to optimize the run-time. Let Γ_k be the set of indices of nonzero coefficients for *classifier-k*, t_i be the time required to compute *feature i* for a given candidate, $i = 1, \ldots, d$ and n_{k-1} is the number of samples in set T_{k-1}, then the total time required for the online execution of the algorithm is

$$\mathcal{T} = \sum_{k=1}^{K} n_{k-1} \sum_{i \in \left(\Gamma_{k-1} \setminus \bigcup_{i=0}^{k-2} \Gamma_i\right)} t_i \qquad (6)$$

The sets Γ_k are learned during offline training of the polyhedral classifier and are fixed for online execution. However the sets T_k is a function of the *classifier 1* through *classifier k-1*. Therefore this is a combinatorial optimization problem with $K!$ different outcomes, where $K!$ is the factorial of K. For small K one can try the exhaustive number of orderings between classifier to find the optimum sequence. However when K is large we can start with the *most sparse* classifier, i.e. the linear classifier with the least number of nonzero coefficients and choose the next classifier as the one that will require computing least number of additional features.

6. Computer Aided Detection

The goal of a Computer Aided Detection (CAD) system is to detect potentially malignant tumors and lesions in medical images (CT scans, X-ray, MRI etc). In an almost universal paradigm for CAD algorithms, this problem is addressed by a 3 stage system: A typical CAD system consists of a candidate generation phase, a feature extraction module and a classifier. The task of the candidate generation module is to create a list of potential polyps with a high sensitivity but low specificity. Features are then extracted for each candidate and eventually passed to a classifier where each candidate is labeled as normal or diseased.

In order to train a CAD system, a set of medical images (eg CT scans, MRI, X-ray etc) is collected from archives of community hospitals that routinely screen patients, *e.g.* for colon cancer. These medical images are then read by expert radiologists; the regions that they consider unhealthy are marked as ground-truth in the images. After the data collection stage, a CAD algorithm is designed to learn to diagnose images based on the expert opinions of the radiologists on the database of training images. First, domain knowledge engineering is employed to (a) identify all potentially suspicious regions in a candidate generation stage, and (b) to describe each such region quantitatively using a set of medically relevant features based on for example, texture, shape, intensity and contrast. Then, a classifier is trained using the features computed for each candidate in the training data and the corresponding ground truth.

When training a classifier for a CAD system for detection of colonic polyps, the only information that is usually available is the location of polyps, since radiologists only mark unhealthy regions when they are reading cases. This, of course, is very important for training a CAD system. But for all other structures that are picked up during candidate generation phase that are not pointing to a known lesion there is no other information available and they all have to be treated equally as negative examples. This introduces two complications. First all the negative candidates are clustered in one group although variation in size and shape among them is very big and valuable information about those candidates, e.g. type category, is not used. Second, radiologists only mark lesions of clinical importance, i.e. polyps greater than 6mm in colon. It is also possible that some lesions are overlooked during clinical evaluation. So potentially there are unidentified lesions in our dataset with no matching ground truth. If the candidate generation algorithm generates candidates for these lesions then these candidates are also marked as negative together with all the other candidates with no corresponding radiologist marks. In other words negative class may also contain unidentified samples of the target class.

In the rest of this section we will discuss some motivation for the proposed algorithm within the scope of a CAD system designed to detect colorectal cancer. Colorectal cancer is the second leading cause of cancer-related death in the western world (Jemal et al., 2004). Early detection of polyps through colorectal screening can help to prevent colon cancer by removing the polyps before they can turn malignant.

Typical examples of different polyp morphologies are given in Figure 3.

The commonly encountered false positive types in colon are fold, stool, tagged stool, meniscus, illeocecal valve, rectum etc. Some of these are shown in Figure 4. Ideally we can label all of the negative candidates in the training data and use the proposed AND algorithm in (4) to jointly train classifiers one for each of the subclasses of negative samples. However an exhaustive annotation of all negative examples is not feasible. Therefore we first select a very small subset of the negative candidates and annotate them manually through visual inspection. Then this set together with the positive samples and the remaining negative samples, i.e. unlabeled samples is used in the proposed $AND-OR$ framework to train the classifiers.

7. Experimental Results

We validate the proposed polyhedral classifier *(*polyhedral) with respect to its generalization performance and run-time efficiency. We compared our algorithm to a Support Vector Domain Description technique *(*svdd) (Tax & Duin, 1999), nonlinear SVM with Radial Basis Function *(*rbf), and one-norm SVM *(*sparse). To achieve sparseness we set the $\Phi_k(\alpha_k) = |\alpha_k|$ for the polyhedral classifier.

7.1. Data and Experimental Settings

The database of high-resolution CT images used in this study were obtained from two different sites across US. The 370 patients were randomly partitioned into two groups: training (n=167) and test (n=199). The test group was sequestered and only used to evaluate the performance of the final system.

Training Data Patient and Polyp Info: There were 167 patients with 316 volumes. The candidate generation (CG) algorithm identifies a total of 226 polyps at the volume level across all sizes while generating a total of 64890 candidates or an average of 205 false positives per volume. *Testing Data Patient and Polyp Info:* There were 199 patients with 385 volumes. The candidate generation (CG) algorithm identifies a total of 245 polyps at the volume level across all sizes while generating an average of 75946 samples or 194 false positives per volume (fp/vol).

A total of 98 features are extracted to capture shape and intensity characteristics of each candidate. The proposed algorithm requires a small set of false positives annotated. Rather than labeling false positives randomly across a dataset with 64890 samples we used the output of the most recent prototype classifier for labeling. This classifier is trained using a naive SVM and optimized for the 0-5 fp/vol range. This way we only focus on the most challenging false positives. This classifier marks a total of 1432 candidates as positive. Out of these candidates 1249 are false positives. A small subset of the volumes from this set is chosen for labeling and a total of 177 false positives (out of 1249) are annotated and ten different subcategories are identified.

7.2. Performance Evaluation

The classifiers are trained with the combination of 1249 false positives generated by the prototype classifier and all the polyps the candidade generation detects in the training data. A total of 1560 candidates are used for training. Classifiers are evaluated on the 1920 candidates the prototype classifier marked as positive in the testing data. The corresponding Receiver Operating Characteristics (ROC) curves for each algorithm is plotted in Figure 5.

The classifier parameters are estimated using a 10-fold patient cross validation from a set of discrete values using the training data. These are namely the width of the kernel (γ=[0.01 0.03 0.05 0.1 0.3 0.5 1 5]) for *rbf*, *svdd*, the cost factor (c=[5 10 15 20 25 50 75 100]) for *rbf*, *polyhedral*, *sparse* and the ν=[0.001 0.005 0.01 0.05 0.1 0.2] parameter for *svdd*. The desired tolerance value for Algorithm 4.1 is set to 0.001. The algorithm converged in less than 10 iterations.

As shown in Figure 5 the ROC curve corresponding to the proposed *polyhedral* classifier is consistently dominating all the other curves. The curve associated with the *sparse SVM* is almost linear implying a random behavior. This is not surprising to a greater extent as both the training and testing data sets used in this experiment are derived from the initial datasets via a linear SVM classifier. In other words the datasets are composed of samples marked as positive by the linear SVM, a significant portion of which are false positives. The *one-class SVM* is only slightly better than the *sparse SVM*. Even though the *rbf SVM* is the best of the three competitor algorithms, the difference in sensitivity between the *rbf SVM* and the proposed *polyhedral* classifier can be as high as 5% (10 polyps) in favor of the proposed algorithm.

7.3. Run-time Evaluation

As stated earlier in the paper, run-time speedups can be achieved as a by-product of the proposed algorithm when the real-time classification is implemented in a cascaded framework as in Figure 2. For a more detailed discussion of cascade classifiers in the CAD domain we refer the interested readers to these recent works (Dundar & Bi, 2007), (Bi et al., 2006).

To avoid any delays in the workflow of a physician the CAD results should be ready by the time physician completes his own review of the case. Therefore there is a run-time requirement a CAD system needs to satisfy. Among the stages involved during online processing of a volume,

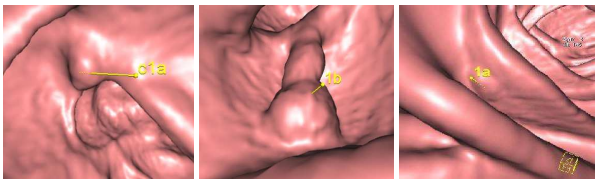

Figure 3. Polyp morphologies (from left to right): Sessile, pedunculated, and flat polyp

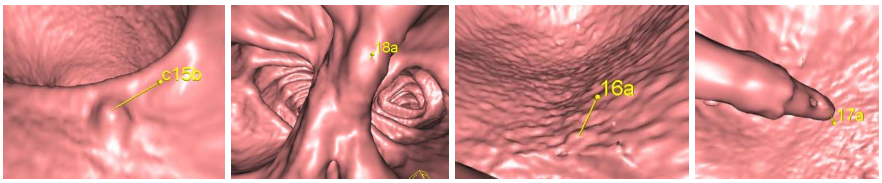

Figure 4. Negative examples (from left to right): stool, fold, noisy data and rectal tube

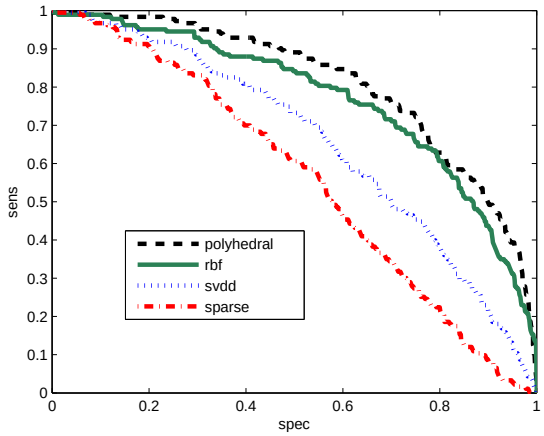

Figure 5. ROC curves obtained by the four classifiers on the test data.

feature computation is by far the most computational stage of online processing. A cascaded framework for executing the classifier in the order of increasing feature complexity may bring significant computational advantages in this case. In this framework the cascade is designed so as to execute classifiers with less number of features earlier in the sequence. This way the additional features required for the succeeding classifiers will only be computed on the remaining candidates, i.e. candidates marked as positive by all of the previous classifiers.

In this section we evaluate the speedups achieved by the proposed classifier. We set the operating point at 60% specificity, around 2.2fp/vol. At this specificity the proposed polyhedral classifier yields 85% sensitivity (see Figure 5). Assuming each feature takes on the average t seconds per candidate to compute we came up with the table in 1. This table shows the aggregate number of features used, feature computation time and number of candidates rejected at each stage in the sequence.

Feature computation for the proposed approach on average takes 452t secs per volume. On the other hand for *svdd* and *rbf*, which require computation of all the features at once, this stage takes 595t secs. This represents a roughly 25% improvement in run-time execution speed of the system. For the one-norm SVM *sparse*, this time is 437t secs. However the corresponding sensitivity at this operating point for one-norm SVM is around 40% vs 85% for the proposed technique.

8. Conclusions

In this study we have presented a methodology to take advantage of the subclass information information available in the negative class to achieve a more robust description of the target class. The subclass information which is neglected in conventional binary classifiers provides a better insight of the dataset and when incorporated into the learning mechanism acts as an implicit regularizer on the classifier coefficients. We believe this is an important contribution for applications where feature noise is prevalent. Highly nonlinear kernel classifiers provides flexibility for modeling complex data but they tend to overfit when there are too many redundant and irrelevant features in the data. Linear classifiers on the other hand do not have enough capacity to model complex data but they are more robust when there is noise. The polyhedral classifier is proposed as a midway solution. The linear faces of the polyhedron achieves robustness whereas multiple faces provides flexibility.

The order in which the classifiers are executed during online execution does not matter. Even though finding the globally optimum sequence is an open research problem for a large number of subclasses, the ordering of the clas-

sequence order	1	2	3	4	5	6	7	8	9
aggregate number of features	48	67	73	75	76	78	81	84	87
aggregate number of rejected candidates (avg. per volume)	1.08	2.37	2.57	2.82	2.90	2.93	3.06	3.07	3.40
aggregate feature computation time in t (avg. per volume)	291	386	408	414	418	424	434	443	452

Table 1. Run-time Results obtained for the Polyhedral classifier. The classifiers are executed in the order of increasing number of features required by each classifier.

sifiers can be arranged in a cascaded manner to reduce the total run-time of the system.

Abstract

When the transition probabilities and rewards of a Markov Decision Process (MDP) are known, an agent can obtain the optimal policy without any interaction with the environment. However, exact transition probabilities are difficult for experts to specify. One option left to an agent is a long and potentially costly exploration of the environment. In this paper, we propose another alternative: given initial (possibly inaccurate) specification of the MDP, the agent determines the sensitivity of the optimal policy to changes in transitions and rewards. It then focuses its exploration on the regions of space to which the optimal policy is most sensitive. We show that the proposed exploration strategy performs well on several control and planning problems.

1. Introduction

When the transition probabilities and rewards of an MDP are known, the optimal policy can be computed offline. However, it is unrealistic to expect a domain expert to accurately specify thousands of MDP parameters. The optimal policy computed offline in an imperfectly modeled world may turn out to be suboptimal when executed in the actual environment. To fix this problem in practice, both rewards and transition probabilities are tweaked by domain experts until the desired performance is achieved. An alternative approach is to allow the agent to explore the world in a model-free fashion using reinforcement learning (RL). However, reinforcement learning in the actual environment is time-consuming, expensive, and sometimes dangerous (Abbeel and Ng (2005), for example, describe a helicopter crash which occurred during an overly aggressive exploration).

In this work, we introduce an approach called active reinforcement learning which combines the strengths of offline planning and online exploration. In particular, our framework allows domain experts to specify possibly inaccurate models of the world offline. However, instead of using this model for planning, our algorithm uses it as a blueprint for exploration. Our approach is based on the observation that, while all of the transition probabilities and rewards in the model may be misspecified, it is not important to know all of them to determine the optimal policy. Consider a surveillance helicopter flying agent. Does it make a difference if it crashes with probability 0.9 or 0.95 when it flies close to the ground? It seems unlikely that the optimal policy would be very sensitive to this value. However, the probability of the agent taking a good photograph of its target from a given viewing angle is extremely important. Therefore, the primary goal of the agent's experimentation, given a description of the problem, should be to determine the probabilities of capturing a photo of the target as opposed to trying to determine the exact probability of crashing. Active reinforcement learning enables this type of exploration. It uses sensitivity analysis to determine how the optimal policy in the expert-specified MDP is affected by changes in transition probabilities and rewards of individual actions. This analysis guides the exploration process by forcing the agent to sample the most sensitive actions first. We will present experimental results demonstrating the effectiveness of active RL. In addition, we will show that, while our algorithm is approximate, it produces near-optimal results in polynomial time for a special class of MDPs.

2. Related Work

Many strategies have been proposed to address the difficulty of specifying MDPs offline. Givan's bounded-parameter MDP framework (Givan et al., 2000) allows

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

the designer to specify uncertainty intervals around MDP's transition probabilities and rewards. The agent then finds the best policy in a game against adversarial nature which picks the worst possible world in which to evaluate it. (Alternative specifications of prior uncertainty in the same framework are given in Nilim and Ghaoui (2003).) While intuitively appealing, this approach may pick an overly conservative policy which is far from optimal for a given environment. Moreover, it places an excessive demand on the designer to quantify not only the prior model, but also his uncertainty about its transition probabilities.

In the online RL setting, there are plenty of reinforcement learning approaches that use optimistic exploration in face of uncertainty, such as E^3 (Kearns & Singh, 2002), $R-MAX$ (Brafman & Tennenholtz, 2002), and model-based interval exploration (Strehl & Littman, 2005). The main idea of these algorithms is to explore the actions the agent has experienced the fewest number of times in the past. This criterion does not apply to prior knowledge. In this paper, we focus on the problem of determining which states are worth exploring based solely on the prior MDP specification.

An approach similar in spirit to ours is Bayesian reinforcement learning (Dearden et al., 1999), which imposes a prior distribution over possible worlds and updates it based on interactions with the environment. However, this approach makes use of unrealistic assumptions on the shapes of probability distributions and approximate sampling to ensure tractability. The largest problem to which it was applied is two orders of magnitude smaller than the problems we solve in this work. In addition, we present an approximate version of our algorithm which is able to handle much larger (possibly continuous) state/action spaces.

The idea of using a prior MDP specification to reduce the amount of exploration in RL has also been explored by Abbeel et al. (2006). However, they only handle deterministic environments and their exploration is driven by the perceived optimal policy, not sensitivity analysis.

3. Preliminaries

The Markov decision process is defined by a tuple $(S, A, T, Next, R, \alpha)$, where $S = \{1, .., |S|\}$ is a finite set of states, A is a finite set of actions, $R(s,a)$ is a reward function, $T(s'|s,a)$ is a transition probability function, $\alpha \in (0,1)$ is the discount factor. $Next(s,a) = \{s' : T(s'|s,a) > 0\}$ defines a set of states reachable in one step with nonzero probability after taking action $a \in A$ in a state $s \in S$. Since transition probabilities of all the states in $Next(s,a)$ are constrained to lie in the probability simplex $\Delta(Next(s,a))$, $T(\cdot|s,a)$ is a function with $|Next(s,a)|-1$ degrees of freedom. To make this explicit, let $\underline{Next}(s,a)$ denote an arbitrary state such that $T(\underline{Next}(s,a)|s,a) = 1 - \sum_{s' \in \overline{Next}(s,a)} T(s'|s,a)$, where $\overline{Next}(s,a) = Next(s,a) \backslash \underline{Next}(s,a)$ is the set of states in $Next(s,a)$ other than the state $\underline{Next}(s,a)$, and let $T|_{\overline{s,a}}$ denote the restriction of $T(\cdot|s,a)$ to $\overline{Next}(s,a)$.

Let $\pi(s)$ define a deterministic policy which maps states to actions. Let $T^\pi(s,s') = T(s'|s,\pi(s))$ be the $|S| \times |S|$ transition probability matrix and $R^\pi(s) = R(s,\pi(s))$ be the $|S| \times 1$ reward vector under π. Then the value matrix $V^\pi(T,R)$ is given by the Bellman equation $V^\pi = \alpha T^\pi V^\pi + R^\pi$. V^π can be computed efficiently via iterative application of the Bellman equation, known as policy evaluation.

The utility of a policy π, $U^\pi(T,R)$, is given by the expected discounted rewards: $U^\pi(T,R) = E_{s_0 \sim D} V^\pi(s_0; T, R)$, with initial state s_0 drawn from the distribution D. *The utility of a policy explicitly depends on the transition and reward model of the MDP.*

We need one more piece of notation to describe the algorithm. We want to be able to take a transition probability function T and replace the transition probabilities $T(\cdot|\hat{s},\hat{a})$ of a fixed state/action pair $\hat{s},\hat{a}$ with a given probability distribution $X \in \Delta(Next(\hat{s},\hat{a}))$, leaving the rest of the probabilities the same. To do this, we define the replacement function $W_{\hat{s},\hat{a}}[T,X](s'|s,a) \triangleq \begin{cases} X(s'), & \text{if } s,a = \hat{s},\hat{a} \\ T(s'|s,a), & \text{otherwise} \end{cases}$. Similarly, the function $Y_{\hat{s},\hat{a}}[R,r](s,a) \triangleq \{r \text{ if } s,a = \hat{s},\hat{a} \text{ and } R(s,a) \text{ otherwise}\}$ replaces the reward of the chosen state/action pair with r.

4. Active RL Algorithm

In this section, we give a general overview of the active reinforcement learning algorithm.

Let T_0, R_0 be the user-supplied model of transition probabilities and rewards for an MDP. We can use Taylor's approximation to model the local sensitivity of $U^\pi(T_0,R_0)$ as the transition probabilities $\mathbf{X} \in \Delta(Next(\hat{s},\hat{a}))$ are perturbed around some specified value $\mathbf{T_1}$ for a *single* state/action pair $\hat{s},\hat{a}$:

$$\hat{U}^\pi_{T_1}(W_{\hat{s},\hat{a}}[T_0,\mathbf{X}]) \approx U^\pi(W_{\hat{s},\hat{a}}[T_0,\mathbf{T_1}],R_0) + \nabla_{\mathbf{X}|_{\overline{\hat{s},\hat{a}}}} U^\pi(W_{\hat{s},\hat{a}}[T_0,\mathbf{T_1}],R_0)(\mathbf{X}|_{\overline{\hat{s},\hat{a}}} - \mathbf{T_1}|_{\overline{\hat{s},\hat{a}}})$$

Transition probabilities for all the actions other than the action $\hat{a}$ in state $\hat{s}$ are held fixed at the values

defined by the user-supplied model T_0. Similarly, the rewards of all the actions are held fixed at the user-supplied values R_0. Sensitivity of the utility function to changes in rewards $R(s, a)$ of individual actions is modeled in an analogous fashion.

The above approximation fixes the transition probabilities for all the actions except one, and approximates the utility of the best policy around any specified point $\mathbf{T_1}$ in the transition probability simplex of that one action. In this section, we assume that it is possible to compute this Taylor's expansion efficiently and explain the main idea of our algorithm, deferring the details of computing the gradient to Section 5.

Taylor's approximation makes it possible to determine how the payoff from following a fixed policy is affected by the changes in the MDP parameters. However, even large changes in payoffs do not necessarily mean that the agent is acting suboptimally. An extreme illustration of this is a gridworld agent who is rewarded only upon getting to the goal state. Even if the agent is wrong about the magnitude of the reward, its optimal policy remains the same: always move towards the goal. Thus, an agent could be completely wrong about the environment and still act optimally. The key goal of the sensitivity analysis is to determine how the *optimal policy* changes in response to the changes in the transition probabilities and rewards. One way to measure this sensitivity is by asking the question: how much do transition probabilities/rewards of a given action have to change before the currently optimal policy becomes suboptimal?

To make this question precise, let us first focus on the sensitivity to transition probabilities. We will use $\Pi_{T_1;\hat{s},\hat{a}} = \arg\max_\pi U^\pi(W_{\hat{s},\hat{a}}[T_0, \mathbf{T_1}], R_0)$ to denote the optimal policy in the MDP in which all transitions except for those of action $\hat{a}$ in state $\hat{s}$ are held fixed at T_0, and transitions of $\hat{s}, \hat{a}$ are given by $\mathbf{T_1}$. Let $C = \{T : U^{\Pi_{T_0;\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{T}], R_0) \geq U^{\Pi_{T;\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{T}], R_0)\}$ define a region in the transition probability space in which the optimal policy Π_{T_0} for the user-specified MDP dominates every other policy. The goal of sensitivity analysis is to find the radius of the largest ball which we can position at $\mathbf{T_0}$ and expand without leaving the confines of C along the dimensions $T(\cdot|\hat{s}, \hat{a})$ corresponding to the transitions for a given action $\hat{a}$ in $\hat{s}$. The larger the ball, the more robust the optimal policy is to the changes in the transition probabilities of the given action $\hat{a}$. However, it is not obvious how to compute this quantity exactly. Instead, we approximate it via a variant of Newton's root-finding method which starts out at some point T_0' in the transition probability space outside of C and converges to a point on the boundary of C. The method is illustrated in Figure 1. Each application of the method consists of starting out at some point T_0', replacing the utility function $U^{\Pi_{T_0';\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{T_0'}], R_0)$ of the best policy at T_0' with its tangent, finding the "zero" of this tangent, i.e., a point T_1' closest to T_0 in the intersection of this tangent and the tangent to the utility function at T_0, replacing the initial estimate T_0' with the new estimate T_1', and iterating.

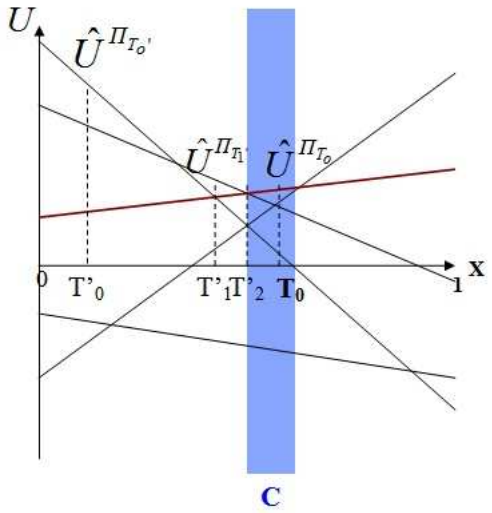

Figure 1. Newton's method for sensitivity analysis of MDPs. The $\mathbf{X}$-axis is the probability of transition to s' for a single chosen $\hat{s}, \hat{a}$ pair that leads to one of two states s' or s'' (the probability of transition to s'' is $1 - \mathbf{X}$). The utilities of policies are linear functions of $\mathbf{X}$. Function $U^{\Pi_T}(\mathbf{X})$ is the utility of the policy which is optimal when $\mathbf{X} = T$. It is given by the upper envelope of the set of all value functions. C is the (blue) region where the optimal policy at T_0 (red line) dominates every other policy. The algorithm starts at T_0' and converges to T_2' on the boundary of C.

The pseudocode for this algorithm consists of the following steps:

1. Determine the optimal policy $\Pi_{T_0;\hat{s},\hat{a}}$ for the user-provided model using any MDP solver.
2. Determine the Taylor approximation of the utility of this policy $\hat{U}_{T_0}^{\Pi_{T_0;\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}])$ as a function of transition probabilities $\mathbf{X} \in \Delta(Next(\hat{s}, \hat{a}))$.
3. Select the starting point $T_0' \in \Delta(Next(\hat{s}, \hat{a}))$ and let $i \leftarrow 0$.
4. Using any MDP solver, determine the optimal policy $\Pi_{T_i';\hat{s},\hat{a}}$ for the user-provided model with transition probabilities of action $\hat{a}$ in state $\hat{s}$ replaced by T_i'.

5. Determine the Taylor approximation of the utility of this policy $\hat{U}_{T_i'}^{\Pi_{T_i';\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}])$ as a function of transition probabilities $\mathbf{X} \in \Delta(Next(\hat{s}, \hat{a}))$.

6. Let T'_{i+1} be the point in the intersection of $\hat{U}_{T_0}^{\Pi_{T_0;\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}])$ and $\hat{U}_{T_i'}^{\Pi_{T_i';\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}])$ closest to the user-specified model T_0. Find T'_{i+1} by solving the following second-order cone program[1]:

$$T'_{i+1} = \arg\min_{\mathbf{X}} \left\| \mathbf{X}|\overline{\hat{s},\hat{a}} - \mathbf{T_0}|\overline{\hat{s},\hat{a}} \right\|$$

$$\text{s.t.} \hat{U}_{T_0}^{\Pi_{T_0;\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}]) = \hat{U}_{T_i'}^{\Pi_{T_i';\hat{s},\hat{a}}}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}])$$

$$[\mathbf{X}|\overline{\hat{s},\hat{a}}] \succeq \mathbf{0}; [\mathbf{X}|\overline{\hat{s},\hat{a}}]^T \boldsymbol{e} \leq 1,$$

where $\boldsymbol{e}$ is a vector of all 1's

The last set of constraints ensures that T'_{i+1} is a valid probability distribution.

7. Let $i \leftarrow i+1$ and repeat steps 4-7 while $\Pi_{T_i;\hat{s},\hat{a}} \neq \Pi_{T_0;\hat{s},\hat{a}}$.

8. Return $\left\| T_i'|\overline{\hat{s},\hat{a}} - T_0|\overline{\hat{s},\hat{a}} \right\|$

The algorithm returns an estimate of the maximum-radius sensitivity ball about the user-specified transition model T_0. The estimate is the minimum over a set of restarts of Newton's method, initializing T_0' to each vertex of the probability simplex $\Delta(Next(\hat{s}, \hat{a}))$. The quality of the estimate is limited both by the finite number of iterations of Newton's method and by the limited number of restarts. The algorithm is executed for every state/action pair $\hat{s}, \hat{a}$ to find which actions are most sensitive to changes in transition probabilities of the user-supplied model. We confirmed experimentally that the estimates of the radius of the sensitivity ball produced by our algorithm are very close to the true values when the dimensionality of the probability simplex is small.

An analogous algorithm is used to determine the sensitivity of the MDP to perturbations in individual rewards. We have not yet described how to compute the Taylor approximation of the utility function. We will do so in the next section.

5. Sensitivity of a Policy

By definition of the gradient and linearity of expectation, the gradient of the utility function is given by $\nabla_{\mathbf{X}|\overline{\hat{s},\hat{a}}} U^{\pi}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}], R_0) =$ $[E_{s_0 \sim D} \frac{\partial V^{\pi}(s_0; W_{\hat{s},\hat{a}}[T_0,\mathbf{X}], R_0)}{\partial X(s'_j)}]_{j=1}^{|\overline{Next}(\hat{s},\hat{a})|}; s'_j \in \overline{Next}(\hat{s}, \hat{a})$. To compute the gradient of the value function, we need the following lemma:

Lemma 5.1. *For a given policy π, a [state,action,next state] tuple $[\hat{s}, \hat{a}, s'] : s' \in \overline{Next}(\hat{s}, \hat{a})$, a transition function for the given $[\hat{s}, \hat{a}]$: $\mathbf{X} \in \Delta(Next(s, a))$, reward function R_0, let transition function $T = W_{\hat{s},\hat{a}}[T_0, \mathbf{X}]$. Then $\frac{\partial V^{\pi}(s_0;T,R_0)}{\partial X(s')} \triangleq 0$ for $\hat{a} \neq \pi(\hat{s})$. For $\hat{a} = \pi(\hat{s})$, let V^{π} be the policy value function which satisfies the Bellman equation and let an $|S| \times |S|$ matrix L^{π} define the directional vector for the derivative: $L^{\pi}(s_i, s_j) \triangleq \begin{cases} 1, & \text{if } s_j = s' \\ -1, & \text{if } s_j = \underline{Next}(\hat{s}, \hat{a}) \\ 0, & \text{otherwise} \end{cases}$. Then the partial derivative $\frac{\partial V^{\pi}(s_0;T,R_0)}{\partial X(s')}$ can be computed from the recurrence $\frac{\partial V^{\pi}(T,R_0)}{\partial X(s')} = \alpha T^{\pi} \frac{\partial V^{\pi}(T,R_0)}{\partial X(s')} + \alpha L^{\pi} V^{\pi}$. The form of this recurrence is exactly the same as that of the Bellman equation, with the value function replaced by its derivative and the reward function replaced by $\alpha L^{\pi} V^{\pi}$. Therefore, policy evaluation can be used to compute $\frac{\partial V^{\pi}(s_0;T,R_0)}{\partial X(s')}$.*

Proof. (sketch) A slight modification of the analysis given in (Cao, 2003) shows that $\frac{\partial V^{\pi}(T,R_0)}{\partial X(s')} = \alpha(I - \alpha T^{\pi})^{-1} L^{\pi} V^{\pi}$, where I is the $|S| \times |S|$ identity matrix. In order to compute the directional derivatives efficiently, note that this equation can be rewritten as the above recurrence. □

Applying a similar analysis to calculate the derivative of the utility function with respect to the reward x for a given state/action pair $[\hat{s}, \hat{a}]$, we obtain (letting the reward function $R = Y_{\hat{s},\hat{a}}(R_0, x)$): $\frac{\partial V^{\pi}(T_0,R)}{\partial x} = \alpha T_0^{\pi} \frac{\partial V^{\pi}(T_0,R)}{\partial x} + M$ where $M(s_i) \triangleq \begin{cases} 1, \text{ if } s_i = \hat{s} \\ 0, \text{ otherwise} \end{cases}$ for $\hat{a} = \pi(\hat{s})$ and $\frac{\partial V^{\pi}(T,R)}{\partial x} \triangleq 0$ for $\hat{a} \neq \pi(\hat{s})$.

6. Convergence and Complexity

In this section, we consider the algorithm's convergence and complexity. The geometric structure of our algorithm is similar to policy iteration which has well-known connections to Newton's method (Puterman, 1994; Madani, 2000). Just like in policy iteration, the known local quadratic convergence of Newton's method does not ensure global polynomial time complexity. Unlike policy iteration, we cannot rely on properties of contractions to establish convergence. However, we can establish convergence for MDPs whose structures (given by transitions with nonzero probabilities) are directed acyclic graphs (DAGs). For

[1] Second-order cone programs (SOCPs) are a special case of semidefinite programs which can be solved more efficiently, see (Lobo et al., 1998) for an overview.

such MDPs, the values $U^\pi(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}], R_0)$ are linear functions of $\mathbf{X}|\hat{s},\hat{a}$ for single state/action pairs $[\hat{s},\hat{a}]$. We have the following result which follows from the Intermediate Value Theorem:

Theorem 6.1. *Suppose that for a given $\hat{s},\hat{a}$ and for every policy π, $U^\pi(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}]; R_0)$ is a linear function of $\mathbf{X}|\hat{s},\hat{a}$. Then, for any initial point $T'_0 \in \Delta(Next(\hat{s},\hat{a}))$, the sequence $\{T'_i\}$ generated by the active RL algorithm converges to the boundary of C in a finite number of steps.*

For DAG-structured MDPs such that the maximum number of $Next$ states for any state/action pair is two, much stronger guarantees are available. As pointed out in (Madani, 2000), any DAG-structured MDP can be converted in polynomial time into an MDP of this form by introducing extra states and transitions as necessary. The significance of these MDPs is that, since $\overline{Next}(\hat{s},\hat{a})$ is a singleton, $U^\pi(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}], R_0)$ is a linear function of a single variable $\mathbf{X}|\hat{s},\hat{a}$. The following theorem shows that our algorithm can determine the radius of the region C in logarithmic time in this degenerate case:

Theorem 6.2. *Define the distance between two policies π and π' as $max_{\mathbf{X}}|U^\pi(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}], R_0) - U^{\pi'}(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}], R_0)|$. Let γ be the smallest distance larger than 0 between any policy and $\Pi_{T_0;\hat{s},\hat{a}}$. Let the MDP have bounded rewards: $|R_0(s,a)| \leq M$ for $\forall s,a$. Then, after $t = O(\log(\frac{M}{\gamma\epsilon(1-\alpha)}))$ iterations, the iterates $T'_{i\geq t}$ of Newton's method are within ϵ of the limit point on the boundary of C.*

Proof. (sketch) The proof follows from a known fact that one-dimensional Newton's method makes progress in each iteration by either exponentially decreasing the height or exponentially increasing the slope of the function $U^\pi(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}], R_0)$. (Madani, 2000). □

If the structure of an MDP is not a DAG, then $U^\pi(W_{\hat{s},\hat{a}}[T_0, \mathbf{X}], R_0)$ is not linear in $\mathbf{X}|\hat{s},\hat{a}$ and the above convergence results no longer apply. However, as the discount factor $\alpha \to 0$, the value function for any MDP will become approximately linear as the influence of distant rewards becomes negligible. Thus, Newton's method offers a way to find an approximate solution to our problem which becomes more accurate as the discount factor decreases. For general root-finding problems, Newton's method need not converge (i.e., it may cycle or diverge to infinity). It is possible that our variant may also exhibit this undesirable behavior when applied to arbitrary MDPs. However, our experimental results in Section 8 demonstrate that our method works well in practice on a wide range of problems even when strong assumptions required to obtain theoretical guarantees for convergence are significantly violated.

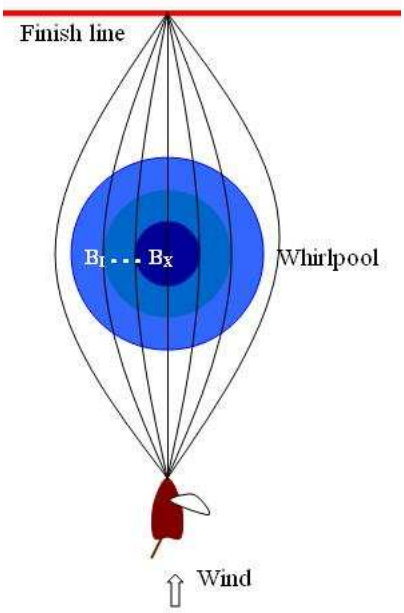

Figure 2. Sailboat Domain. Black lines indicate the paths of the boat for a set of possible initial policies. The boat is controlled by the rudder and the sail.

7. Approximate Active RL

In worlds with very large or continuous state/action spaces, the exact Active RL algorithm of Section 4 is intractable. Moreover, in continuous state spaces, sensitivity of individual state/action pairs no longer applies. Instead, we consider the case where the state space is partitioned into regions $\mathbb{B}$ with the uncertainty in our transition model for each region generated by a random variable.

Formally, we assume that the world is governed by the control model $s_{t+1} = f(s_t, a, d(\mathbb{B}(s_t))$. The agent's state s at time $t+1$ is a (possibly nonlinear) function f of the agent's state at time t, its action a, and the disturbance input d. In every region $\hat{B} \in \mathbb{B}$, the disturbance $d(\hat{B})$ is a random variable with a probability distribution $T \in \Delta(Next(\hat{B}))$ defined on a discrete set $Next(\hat{B}) = \underline{Next}(\hat{B}) \cup \overline{Next}(\hat{B})$. The approximate active RL procedure determines which regions $\hat{B} \in \mathbb{B}$ affect the optimal policy the most.

Consider, for example, the sailing problem illustrated in Figure 2. The agent's goal in this domain is to get

the sailboat to the finish line. The sailboat is controlled by the rudder and the sail. The problem is complicated by a probabilistic whirlpool which could aid the agent by increasing its speed or detain it by deviating the boat from its course. In this case, the function f describes the sailboat dynamics given the boat's position, the rudder/sail action, the deterministic wind, and the whirlpool current d. The strength of the current and its direction are given by a distribution T which depends on the band $\hat{B}$ inside the whirlpool in which the agent finds itself. Approximate active RL helps us find a small number of bands in which the current determines which one of the policies shown in Figure 2 is optimal.

The approximate active RL procedure is the same as its exact variant, except that: 1) local policy search is used in place of an MDP solver[2], 2) the utility $\widetilde{U}^{\pi}(T,R)$ of any policy π is approximated by Markov Chain Monte Carlo, and 3) the Taylor approximation of a policy's utility is given by $\hat{U}^{\pi}_{T_1}(W_{\hat{B}}[T_0,\mathbf{X}]) \approx \widetilde{U}^{\pi}(W_{\hat{B}}[T_0,\mathbf{T_1}],R_0) + \nabla_{\mathbf{X}|\overline{\hat{B}}} U^{\pi}(W_{\hat{B}}[T_0,\mathbf{T_1}],R_0)(\mathbf{X}|\overline{\hat{B}} - \mathbf{T_1}|\overline{\hat{B}})$, where $W_{\hat{B}}[T_0;\mathbf{T_1}]$ is a world in which the disturbance distribution in band $\hat{B}$ is replaced with $\mathbf{T_1}$, and the gradient of the utility function is approximated linearly by perturbing the transition probabilities by a small value ϵ in each dimension of the probability simplex: $\nabla_{\mathbf{X}|\overline{\hat{B}}} U^{\pi}(W_{\hat{B}}[T_0,\mathbf{T_1}],R_0) \approx \frac{1}{\epsilon}[\widetilde{U}^{\pi}(W_{\hat{B}}[T_0,\mathbf{T_1^{j;\hat{B}}}],R_0) - \widetilde{U}^{\pi}(W_{\hat{B}}[T_0,\mathbf{T_1}],R_0)]_{j=1}^{\overline{Next}(\hat{B})}$ where $\mathbf{T_1^{j;\hat{B}}}$ denotes the world in which the transitions in region $\hat{B}$ are perturbed by ϵ as follows:

$$\mathbf{T_1^{j;\hat{B}}}(d') \triangleq \begin{cases} \mathbf{T_1}(d') + \epsilon, & \text{if } d' = d_j \\ \mathbf{T_1}(d') - \epsilon, & \text{if } d' = \underline{Next}(\hat{B}) \\ \mathbf{T_1}(d'), & \text{otherwise} \end{cases}$$

8. Experiments

Exact RL experiments were performed on the following domains:

- In the mountain-car task (231 states), the problem is to drive a car up a steep mountain (Sutton & Barto, 1998). The engine power is a uniform random variable on the interval $[.15,.3]$.
- The task in the cart-pole problem (5832 states) is to balance a pole on a moving cart. The power of the cart is random, uniformly distributed in the interval $[20,75]$.
- Windy gridworld is a simple 10×7 gridworld with agent's movement affected by stochastic wind (Sutton & Barto, 1998).
- Pizza delivery problem (4769 states) is based on the racetrack example (Sutton & Barto, 1998). The agent's goal is to drive a car to the finish line, while delivering as many pizzas and avoiding as many randomly placed potholes as possible.
- The drunkard's walk problems are two 10×10 gridworlds with random rewards and penalties. When the agent moves in some direction, it is equally likely to deviate diagonally from it.

In all the setups, $\alpha = 0.9$ was used. The structure of the MDPs varies widely from one problem to another (and none of them are DAGs). In the first set of experiments, the effectiveness of active reinforcement learning for transition probabilities was evaluated. The system was provided with an initial description of the problem, as given above. It then performed the sensitivity analysis and sorted state/action pairs based on their sensitivity values. A different problem specification was then generated by randomly perturbing all the transition probabilities. This new specification represented the actual world in which transition probabilities are different from the expert-provided MDP specification. The agent was allowed to sample one action at a time in this actual world[3], replace user-specified transition probabilities with their maximum likelihood estimates (based on 10,000 samples), use an MDP solver to find the optimal policy in this "corrected" MDP, and evaluate this policy in the actual world. We tested two different ways of selecting the order in which actions were tested: 1) the active RL agent which samples the actions in order of decreasing sensitivity, with sensitivities computed by the algorithm in Section 4, and 2) the random agent which samples actions randomly. For comparison, we also tested two agents applying fixed policies: 1) the prior agent which applies the optimal policy for the expert-provided MDP specification, and 2) the omniscient agent which knows the transition probabilities in the actual test world and selects the optimal policy for this world. In addition, we tested the Q-learning agent with $\epsilon-$greedy exploration ($\epsilon = 0.1$) and full backups (full backups means that after taking an action in a state, the agent gets full information about all the

[2] Any local policy search algorithm, such as policy gradient or dynamic programming, can be used for this procedure.

[3] This exploration strategy (sampling with resets) assumes that the agent can execute any action in any state and observe its outcome without having to plan how to get to that state.

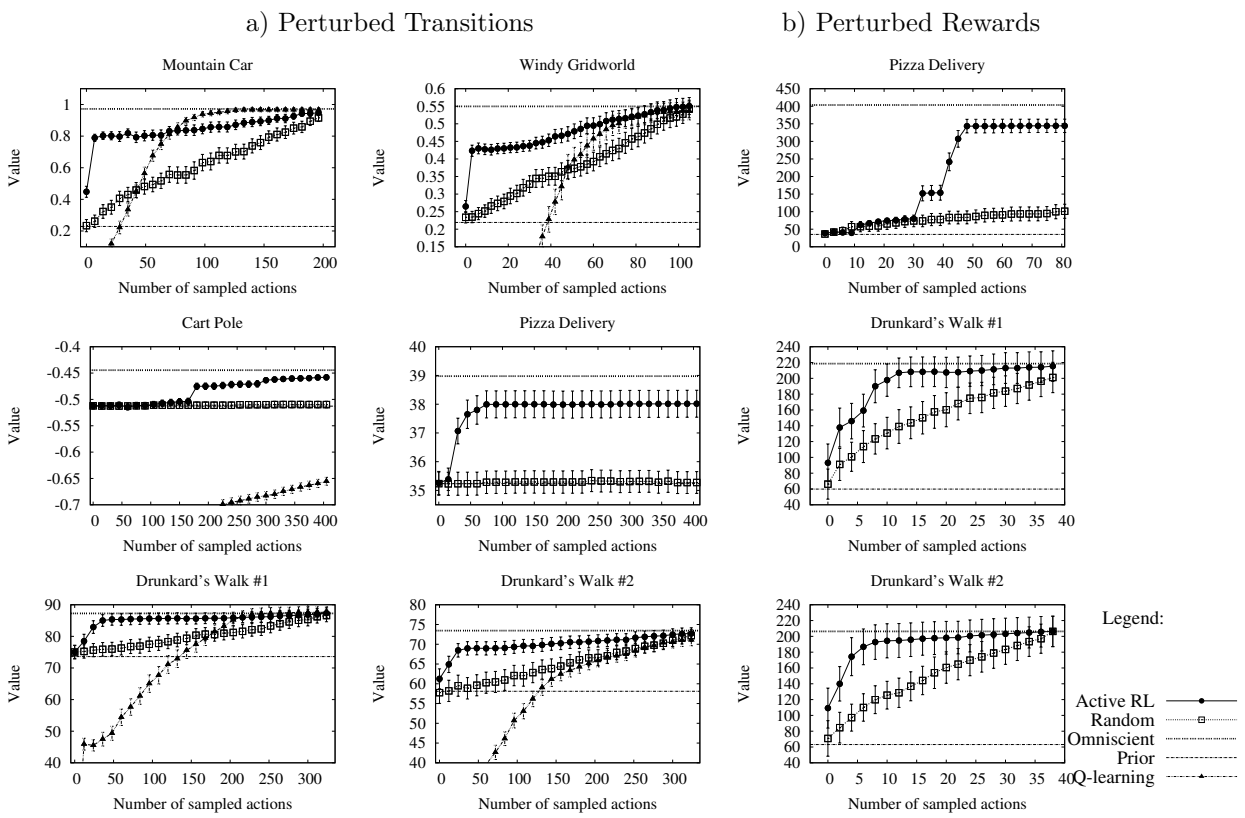

Figure 3. Evaluation of exploration strategies on perturbed MDPs. Error bars are based on 95% confidence intervals.

transition probabilities for all the possible next states for that action - this model was used to make the comparison between the Q-learning agent and the Active RL agent fair). The utility of the policy of each of these five agents appears in the plots in Figure 3-(a) as a function of the number of actions tested. The results are averaged over 100 different randomly generated actual worlds[4]. In each domain, the active RL agent outperforms the random sampling agent. The prior agent which relies solely on the expert's specification performs poorly, indicating the need for exploration. As expected, the Q-learning agent performs poorly initially since it has no prior knowledge, but improves with experience. It rarely catches up with the Active RL agent because Q-learning is forced to explore without resets. These experiments indicate that integrating Active RL with Q-learning may result in improvement in the Q-learning agent's performance. This is an important future extension of our work.

In the next experiment, the random worlds were generated by perturbing the rewards rather than transition probabilities of the MDP[5]. Performance of the four exploration strategies on the three domains with non-trivial reward structure appear in Figure 3-(b). Once again, the active RL agent significantly outperforms the random sampling agent.

Finally, we experimented with approximate active RL in the sailboat simulation, in which the agent must navigate a whirlpool of water current to reach the finish line. The whirlpool was modeled by ten concentric bands based on the distance from the center of the vertex, and the magnitude of the current varied proportionally to this distance. The expert-specified world reflected uncertainty about the direction of the whirlpool current: the direction of the current was counterclockwise with probability 0.1, clockwise with probability 0.1, and there was no current with prob-

[4]The test worlds were generated by perturbing transition probabilities of each action uniformly in the probability simplex within a radius of 0.6 around the expert-specified values T_0. A random variable $T \in \mathbb{R}^n$ uniformly distributed on the n-dimensional probability simplex can be generated from $n-1$ random variables $X_1, .., X_{n-1} \sim Uniform(0,1)$ by sorting them into $X_{(0)} \triangleq 0, X_{(1)}, .., X_{(n-1)}, X_{(n)} \triangleq 1$, and letting $T_i = X_{(i)} - X_{(i-1)}$ (Devroye, 1986). Rejection sampling is then used to ensure that $\|T - T_0\| \leq 0.6$.

[5]The test worlds were generated by perturbing all the nonzero rewards uniformly in the interval $[-70, 70]$ around the expert-specified values.

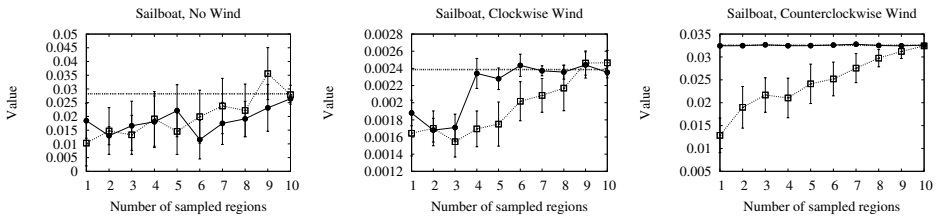

Figure 4. Evaluation of exploration strategies in the approximation architecture. The legend is the same as in figure 3, but with Prior strategy not shown (its value is too low to appear on the plots). Error bars are based on 95% confidence intervals.

ability 0.8. In each iteration of the active RL algorithm, local policy search was performed from each of the seven policies shown in Figure 2, and the best policy was selected. Approximate Active RL was tested in three actual worlds: one with a deterministic clockwise current, one with a deterministic counterclockwise current, and one with no current. The results appear in Figure 4. In the two worlds with current, the algorithm which samples bands according to the active RL-prescribed order outperforms the algorithm which samples bands according to a random order. In the world with no current, the performance of the two algorithms is similar.

9. Conclusions

In this paper, we presented a new algorithm for combining exploration with prior knowledge in reinforcement learning. We demonstrated that our algorithm can be implemented efficiently using policy iteration and a standard SOCP solver. We also introduced an approximate version of active RL to be applied in domains with large state spaces. In addition to being useful for exploration, the active RL algorithm can be used by an MDP designer to determine which regions of the state space require most precision in specifying transition probabilities and rewards. An important future extension of this work is designing a policy which explores the sensitive regions of the state space without resets.

Training Structural SVMs when Exact Inference is Intractable

Thomas Finley TOMF@CS.CORNELL.EDU
Thorsten Joachims TJ@CS.CORNELL.EDU
Cornell University, Department of Computer Science, Upson Hall, Ithaca, NY 14853 USA

Abstract

While discriminative training (e.g., CRF, structural SVM) holds much promise for machine translation, image segmentation, and clustering, the complex inference these applications require make exact training intractable. This leads to a need for approximate training methods. Unfortunately, knowledge about how to perform efficient and effective approximate training is limited. Focusing on structural SVMs, we provide and explore algorithms for two different classes of approximate training algorithms, which we call undergenerating (e.g., greedy) and overgenerating (e.g., relaxations) algorithms. We provide a theoretical and empirical analysis of both types of approximate trained structural SVMs, focusing on fully connected pairwise Markov random fields. We find that models trained with overgenerating methods have theoretic advantages over undergenerating methods, are empirically robust relative to their undergenerating brethren, and relaxed trained models favor non-fractional predictions from relaxed predictors.

1. Introduction

Discriminative training methods like conditional random fields (Lafferty et al., 2001), maximum-margin Markov networks (Taskar et al., 2003), and structural SVMs (Tsochantaridis et al., 2005) have substantially improved prediction performance on a variety of structured prediction problems, including part-of-speech tagging (Altun et al., 2003), natural language parsing (Tsochantaridis et al., 2005), sequence alignment (Yu et al., 2007), and classification under multivariate loss functions (Joachims, 2005). In the context of structural SVMs, in all these problems, both the inference problem (i.e., computing a prediction) and the separation oracle required in the cutting-plane training algorithm can be solved exactly. This leads to theoretical guarantees of training procedure convergence and solution quality.

However, in many important problems (e.g., clustering (Culotta et al., 2007; Finley & Joachims, 2005), multi-label classification, image segmentation, machine translation) exact inference and the separation oracle are computationally intractable. Unfortunately, use of approximations in these settings abandons many of the existing theoretical guarantees of structural SVM training, and relatively little is known about discriminative training using approximations.

This paper explores training structural SVMs on problems where exact inference is intractable. A pairwise fully connected Markov random field (MRF) serves as a representative class of intractable models. This class includes natural formulations of models for multi-label classification, image segmentation, and clustering. We identify two classes of approximation algorithms for the separation oracle in the structural SVM cutting-plane training algorithm, namely undergenerating and overgenerating algorithms, and we adapt loopy belief propagation (LBP), greedy search, and linear-programming and graph-cut relaxations to this problem. We provide a theoretical and empirical analysis of using these algorithms with structural SVMs.

We find substantial differences between different approximate algorithms in training and inference. In particular, much of the existing theory can be extended to overgenerating though not undergenerating methods. In experimental results, intriguingly, our structural SVM formulations using the overgenerating linear-programming and graph-cut relaxations successfully learn models in which relaxed inference is "easy" (i.e., the relaxed solution is mostly integral), leading to robust and accurate models. We conclude that the relaxation formulations are preferable over the formulations involving LBP and greedy search.

2. Structured Output Prediction

Several discriminative structural learners were proposed in recent years, including conditional random fields (CRFs) (Lafferty et al., 2001), Perceptron HMMs (Collins, 2002), max-margin Markov networks (M^3Ns) (Taskar et al., 2003), and structural SVMs (SSVMs) (Tsochantaridis et al., 2005). Notational differences aside, these methods all learn (kernelized) linear discriminant functions, but differ in how they choose model parameters.

2.1. Structural SVMs

Structural SVMs minimize a particular trade-off between model complexity and empirical risk. From a training set $\mathcal{S} = ((\mathbf{x}_1, \mathbf{y}_1), \ldots, (\mathbf{x}_n, \mathbf{y}_n))$, an SSVM learns a hypothesis $h : \mathcal{X} \rightarrow \mathcal{Y}$ to map inputs $\mathbf{x} \in \mathcal{X}$ to outputs $\mathbf{y} \in \mathcal{Y}$. Hypotheses take the form $h(\mathbf{x}) = \operatorname{argmax}_{\mathbf{y} \in \mathcal{Y}} f(\mathbf{x}, \mathbf{y})$ with discriminant function $f : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$, where $f(\mathbf{x}, \mathbf{y}) = \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y})$. The $\mathbf{\Psi}$ combined feature vector function relates inputs and outputs, and $\mathbf{w}$ are model parameters. The loss function $\Delta : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$ indicates how far $h(\mathbf{x}_i)$ is from true output $\mathbf{y}_i$. To find $\mathbf{w}$ balancing model complexity and empirical risk $R^{\Delta}_{\mathcal{S}}(h) = \frac{1}{n} \sum_{i=1}^{n} \Delta(\mathbf{y}_i, h(\mathbf{x}_i))$, SSVMs solve this quadratic program (QP) (Tsochantaridis et al., 2005):

Optimization Problem 1. (Structural SVM)

$$\min_{\mathbf{w}, \xi \geq \mathbf{0}} \frac{1}{2} \|\mathbf{w}\|^2 + \frac{C}{n} \sum_{i=1}^{n} \xi_i \quad (1)$$

$$\forall i, \forall \mathbf{y} \in \mathcal{Y} \setminus \mathbf{y}_i : \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}_i, \mathbf{y}_i) \geq \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}_i, \mathbf{y}) + \Delta(\mathbf{y}_i, \mathbf{y}) - \xi_i \quad (2)$$

Introducing a constraint for every wrong output is typically intractable. However, OP 1 can be solved by the cutting plane algorithm in Algorithm 1. This iteratively constructs a sufficient subset $\bigcup_i S_i$ of constraints and solves the QP only over this subset (line 10). The algorithm employs a separation oracle to find the next constraint to include (line 6). It finds the currently most violated constraint (or, a constraint that is violated by at least the desired precision ϵ). If a polynomial time separation oracle exists, OP 1 and Algorithm 1 have three theoretical guarantees (Tsochantaridis et al., 2005):

Polynomial Time Termination: Algorithm 1 terminates in a polynomial number of iterations, and thus overall polynomial time.

Correctness: Algorithm 1 solves OP 1 accurate to a desired precision ϵ, since Algorithm 1 terminates only when all constraints in OP 1 are respected within ϵ (lines 8 and 13).

Empirical Risk Bound: Since each ξ_i upper bounds training loss $\Delta(\mathbf{y}_i, h(\mathbf{x}_i))$, $\frac{1}{n} \sum_{i=1}^{n} \xi_i$ upper bounds empirical risk.

Unfortunately, proofs of these properties rely on the separation oracle (line 6) being exactly solvable, and do not necessarily hold with approximations. We will later analyze which properties are retained.

2.2. Markov Random Fields in SSVMs

A special case of structural SVM that we will examine throughout this paper is M^3N (Taskar et al., 2003). In this, $\mathbf{\Psi}(\mathbf{x}, \mathbf{y})$ is constructed from an MRF

$$f(\mathbf{x}, \mathbf{y}) = \sum_{k \in \text{cliques}(G)} \phi_k(y_{\{k\}}) \quad (3)$$

with graph structure $G = (V, E)$ and the loss function is restricted to be linearly decomposable in the cliques, i.e., $\Delta(\mathbf{y}, \hat{\mathbf{y}}) = \sum_{k \in \text{cliques}(G)} \delta_k(y_{\{k\}}, \hat{y}_{\{k\}})$. Here, $\mathbf{y}$ is the value assignment to variables, δ_k are sub-component local loss functions, and ϕ_k are potential functions representing the fitness of variable assignment $y_{\{k\}}$ to clique k. The network potential $f(\mathbf{x}, \mathbf{y})$ serves as a discriminant function representing the variable assignment $\mathbf{y}$ in the structural SVM, and $h(\mathbf{x}) = \operatorname{argmax}_{\mathbf{y} \in \mathcal{Y}} f(\mathbf{x}, \mathbf{y})$ serves as the maximum a posteriori (MAP) prediction.

OP 1 requires we express (3) in the form $f(\mathbf{x}, \mathbf{y}) = \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y})$. First express potentials as $\phi_k(y_{\{k\}}) = \mathbf{w}^T \psi(\mathbf{x}, y_{\{k\}})$. The feature vector functions ψ_k relate $\mathbf{x}$ and label assignments $y_{\{k\}}$. Then, $f(\mathbf{x}, \mathbf{y}) = \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y})$ where $\mathbf{\Psi}(\mathbf{x}, \mathbf{y}) = \sum_{k \in \text{cliques}(G)} \psi_k(\mathbf{x}, y_{\{k\}})$.

In the following, we use a particular linearly decomposable loss function that simply counts the percentage proportion of different labels in $\mathbf{y}$ and $\hat{\mathbf{y}}$, i.e.,

$\Delta(\mathbf{y}, \hat{\mathbf{y}}) = \|100 \cdot \mathbf{y} - \hat{\mathbf{y}}\|_0 / |V|$. Further, in our applications, labels are binary (i.e., each $y_u \in \mathbb{B} = \{0, 1\}$), and we allow only $\phi_u(1)$ and $\phi_{uv}(1, 1)$ potentials to be non-zero. This latter restriction may seem onerous, but any pairwise binary MRF with non-zero $\phi_u(0), \phi_{uv}(0, 0), \phi_{uv}(0, 1), \phi_{uv}(1, 0)$ has an equivalent MRF where these potentials are zero.

To use Algorithm 1 for MRF training and prediction, one must solve two argmax problems:

Prediction: $\text{argmax}_{\mathbf{y} \in \mathcal{Y}} \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y})$

Separation Oracle: $\text{argmax}_{\mathbf{y} \in \mathcal{Y}} \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y}) + \Delta(\mathbf{y}_i, \mathbf{y})$

The prediction problem is equivalent to MAP inference. Also, we can state the separation oracle as MAP inference. Taking the MRF we would use to solve $\text{argmax}_{\mathbf{y} \in \mathcal{Y}} \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y})$, we include $\Delta(\mathbf{y}_i, \mathbf{y})$ in the argmax by incrementing the node potential $\phi_u(y)$ by $\frac{100}{|V|}$ for each wrong value y of u, since each wrong variable assignment increases loss by $\frac{100}{|V|}$. Thus, we may express the separation oracle as MAP inference.

3. Approximate Inference

Unfortunately, MAP inference is $\#P$-complete for general MRFs. Fortunately, a variety of approximate inference methods exist. For prediction and the separation oracle, we explore two general classes of approximate inference methods, which we call undergenerating and overgenerating approximations.

3.1. Undergenerating Approximations

Undergenerating methods approximate $\text{argmax}_{\mathbf{y} \in \mathcal{Y}}$ by $\text{argmax}_{\mathbf{y} \in \underline{\mathcal{Y}}}$, where $\underline{\mathcal{Y}} \subseteq \mathcal{Y}$. We consider the following undergenerating methods in the context of MRFs:

Greedy iteratively changes the single variable value y_u that would increase network potential most.

LBP is loopy belief propagation (Pearl, 1988).

Combine picks the assignment $\mathbf{y}$ with the highest network potential from both greedy and LBP.

We now theoretically characterize undergenerating learning and prediction. All theorems generalize to any learning problem, not just MRFs. Due to space constraints, provided proofs are proof skeletons.

Since undergenerating approximations can be arbitrarily poor, we must restrict our consideration to a subclass of undergenerating approximations to make meaningful theoretical statements. This analysis focuses on ρ-approximation algorithms, with $\rho \in (0, 1]$. What is a ρ-approximation? In our case, for predictive inference, if $\mathbf{y}^* = \text{argmax}_{\mathbf{y}} \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y})$ is the true optimum and $\mathbf{y}'$ the ρ-approximation output, then

$$\rho \cdot \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y}^*) \leq \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y}') \tag{4}$$

Similarly, for our separation oracle, for $\mathbf{y}^* = \text{argmax}_{\mathbf{y}} \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y}) + \Delta(\mathbf{y}_i, \mathbf{y})$ as the true optimum, and if $\mathbf{y}'$ corresponds to the constraint found by our ρ-approximation, we know

$$\rho\big[\mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y}^*) + \Delta(\mathbf{y}_i, \mathbf{y}^*)\big] \leq \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}, \mathbf{y}') + \Delta(\mathbf{y}_i, \mathbf{y}') \tag{5}$$

For simplicity, this analysis supposes $\mathcal{S}$ contains exactly one training example $(\mathbf{x}_0, \mathbf{y}_0)$. To generalize, one may view n training examples as 1 example, where inference consists of n separate processes with combined outputs, etc. Combined ρ-approximation outputs may be viewed as a single ρ-approximation output.

Theorem 1. (Polynomial Time Termination) *If $\bar{R} = \max_{i, \mathbf{y} \in \mathcal{Y}} \|\Psi(\mathbf{x}_i, \mathbf{y})\|$, $\bar{\Delta} = \max_{i, \mathbf{y} \in \mathcal{Y}} \|\Delta(\mathbf{y}_i, \mathbf{y})\|$ are finite, an undergenerating learner terminates after adding at most $\epsilon^{-2}(C\bar{\Delta}^2\bar{R}^2 + n\bar{\Delta})$ constraints.*

Proof. The original proof holds as it does not depend upon separation oracle quality (Algorithm 1, l.6). □

Lemma 1. *After line 6 in Algorithm 1, let $\mathbf{w}$ be the current model, $\hat{\mathbf{y}}$ the constraint found with the ρ-approximation separation oracle, and $\hat{\xi} = H(\hat{\mathbf{y}})$ the slack associated with $\hat{\mathbf{y}}$. Then, $\mathbf{w}$ and slack $\hat{\xi} + \frac{1-\rho}{\rho}\left[\mathbf{w}^T \mathbf{\Psi}(\mathbf{x}_0, \hat{\mathbf{y}}) + \Delta(\mathbf{y}_0, \hat{\mathbf{y}})\right]$ is feasible in OP 1.*

Proof. If we knew the true most violated constraint $\mathbf{y}^*$, we would know the minimum ξ^* such that $\mathbf{w}, \xi^*$ was feasible in OP 1. The proof upper bounds ξ^*. □

Theorem 2. *When iteration ceases with the result $\mathbf{w}, \xi$, if $\hat{\mathbf{y}}$ was the last found most violated constraint, we know that the optimum objective function value v^* for OP 1 lies in the interval*

$$\tfrac{1}{2}\|\mathbf{w}\|^2 + C\xi \leq v^* \leq \tfrac{1}{2}\|\mathbf{w}\|^2 + C\Big[\tfrac{1}{\rho}\big[\mathbf{w}^T \mathbf{\Psi}(\mathbf{x}_0, \hat{\mathbf{y}}) + \Delta(\mathbf{y}_0, \hat{\mathbf{y}})\big] - \mathbf{w}^T \mathbf{\Psi}(\mathbf{x}_0, \mathbf{y}_0)\Big]$$

Proof. Lemma 1 applied to the last iteration. □

So, even with ρ-approximate separation oracles, one may bound how far off a final solution is from solving OP 1. Sensibly, the better the approximation, i.e., as ρ approaches 1, the tighter the solution bound.

The last result concerns empirical risk. The SVM margin attempts to ensure that high-loss outputs have a low discriminant function value, and ρ-approximations produce outputs within a certain factor of optimum.

Theorem 3. (ρ-Approximate Empirical Risk) *For $\mathbf{w}, \xi$ feasible in OP 1 from training with single example $(\mathbf{x}_0, \mathbf{y}_0)$, the empirical risk using ρ-approximate prediction has upper bound $(1-\rho)\mathbf{w}^T\mathbf{\Psi}(\mathbf{x}_0, \mathbf{y}_0) + \xi$.*

Proof. Take the $\mathbf{y}' = h(\mathbf{x}_0)$ associated constraint, then apply known bounds to its $\mathbf{w}^T\mathbf{\Psi}(\mathbf{x}_0, \mathbf{y}')$ term. □

If also using undergenerating ρ-approximate training, one may employ Theorem 2 to get a feasible ξ.

3.2. Overgenerating Approximations

Overgenerating methods approximate $\text{argmax}_{\mathbf{y}\in\mathcal{Y}}$ by $\text{argmax}_{\mathbf{y}\in\overline{\mathcal{Y}}}$, where $\overline{\mathcal{Y}} \supseteq \mathcal{Y}$. We consider the following overgenerating methods:

LProg is an expression of the inference problem as a relaxed integer linear program (Boros & Hammer, 2002). We first add $y_{uv} \in \mathbb{B}$ values indicating if $y_u = y_v = 1$ to linearize the program:

$$\max_{\mathbf{y}} \sum_{u\in\{1..|V|\}} y_u\phi_u(1) + \sum_{u,v\in\{1..|V|\}} y_{uv}\phi_{uv}(1,1) \quad (6)$$

$$\text{s.t.} \quad \forall u, v. \quad y_u \geq y_{uv} \qquad y_v \geq y_{uv} \quad (7)$$

$$y_u + y_v \leq 1 + y_{uv} \qquad y_u, y_{uv} \in \mathbb{B} \quad (8)$$

We relax $\mathbb{B}$ to $[0, 1]$ to admit fractional solutions. Importantly, there is always some optimal solution where all $y_u, y_{uv} \in \{0, \frac{1}{2}, 1\}$ (Hammer et al., 1984).

Cut is quadratic pseudo-Boolean optimization using a graph-cut (Kolmogorov & Rother, 2004). This is a different relaxation where, instead of $\mathbf{y} \in \mathbb{B}^{|V|}$, we have $\mathbf{y} \in \{0, 1, \varnothing\}^{|V|}$.

The LProg and Cut approximations share two important properties (Boros & Hammer, 2002; Hammer et al., 1984): *Equivalence* says that maximizing solutions of the Cut and LProg formulations are transmutable. One proof defines this transmutation procedure, where $\varnothing$ (in cuts optimization) and $\frac{1}{2}$ (in LP optimization) variable assignments are interchangeable (Boros & Hammer, 2002). The important practical implication of equivalence is both approximations return the same solutions. *Persistence* says unambiguous labels (i.e., not fractional or $\varnothing$) are optimal labels.

As a final detail, in the case of LProg, $\Delta(\mathbf{y}, \hat{\mathbf{y}}) = \frac{1}{|V|}\sum_{u\in\{1..|V|\}} |y_u - \hat{y}_u|$ and $\mathbf{\Psi}(\mathbf{x}, \mathbf{y}) = \sum_{u\in\{1..|V|\}} y_u\psi_u(1) + \sum_{u,v\in\{1..|V|\}} y_{uv}\psi_{uv}(1,1)$. Cut's functions have similar formulations.

Theorem 4. (Polynomial Time Termination) *If $\bar{R} = \max_{i,\mathbf{y}\in\overline{\mathcal{Y}}} \|\Psi(\mathbf{x}_i, \mathbf{y})\|$, $\bar{\Delta} = \max_{i,\mathbf{y}\in\overline{\mathcal{Y}}} \|\Delta(\mathbf{y}_i, \mathbf{y})\|$ are finite ($\overline{\mathcal{Y}}$ replacing $\mathcal{Y}$ in the overgenerating case), an overgenerating learner terminates after adding at most $\epsilon^{-2}(C\bar{\Delta}^2\bar{R}^2 + n\bar{\Delta})$ constraints.*

Proof. The original proof holds as an overgenerating learner is a straightforward structural learning problem on a modified output range $\overline{\mathcal{Y}}$. □

Theorem 5. (Correctness) *An overgenerating Algorithm 1 terminates with $\mathbf{w}, \xi$ feasible in OP 1.*

Proof. The learner considers a superset of outputs $\overline{\mathcal{Y}} \supseteq \mathcal{Y}$, so constraints in OP 1 are respected within ϵ. □

With these "extra" constraints from overgenerating inference, Algorithm 1's solution may be suboptimal w.r.t. the original OP 1. Further, for undergenerating methods correctness does not hold, as Algorithm 1 may not find violated constraints present in OP 1.

Theorem 6. (Empirical Risk Bound) *If prediction and the separation oracle use the same overgenerating algorithm, Algorithm 1 terminates with $\frac{1}{n}\sum_i \xi_i$ upper bounding empirical risk $R^{\Delta}_{\mathcal{S}}(h)$.*

Proof. Similar to the proof of Theorem 4.

3.3. Related Work

In prior work on discriminative training using approximate inference, structural SVMs have learned models for correlation clustering, utilizing both greedy and LP relaxed approximations (Finley & Joachims, 2005). For M^{3}Ns, Anguelov et al. (Anguelov et al., 2005) proposed to directly fold a linear relaxation into OP 1. This leads to a very large QP, and is inapplicable to other inference methods like LBP or cuts. Furthermore, we will see below that the linear-program relaxation is the slowest method. With CRFs, likelihood training requires computing the partition function in addition to MAP inference. Therefore, the partition function is approximated (Culotta et al., 2007; He et al., 2004; Kumar & Hebert, 2003; Vishwanathan et al., 2006), or the model is simplified to make the partition function tractable (Sutton & McCallum, 2005), or CRF max-likelihood training is replaced with Perceptron training (Roth & Yih, 2005).

The closest work to ours is a theoretical analysis of MRF structural learning with LBP and LP-relaxation approximations (Kulesza & Pereira, 2007). It defines the concepts *separable* (i.e., there exists $\mathbf{w}$ such that $\forall(\mathbf{x}_i, \mathbf{y}_i) \in \mathcal{S}, \mathbf{y} \in \mathcal{Y}, \mathbf{w}^T\mathbf{\Psi}(\mathbf{x}_i, \mathbf{y}_i) \geq \mathbf{w}^T\mathbf{\Psi}(\mathbf{x}_i, \mathbf{y})$), *algorithmically separable* (i.e., there exists $\mathbf{w}$ so that empirical risk under the inference algorithm is 0), and *learnable* (i.e., the learner using the inference method finds a separating $\mathbf{w}$). The paper illustrates that using

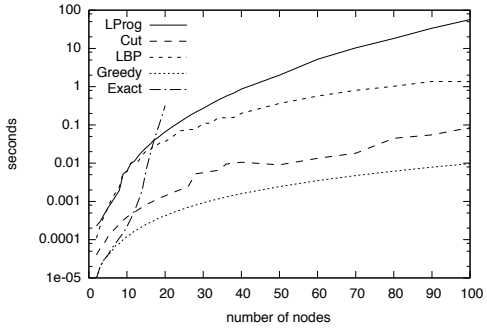

Figure 1. Runtime comparison. Average inference time for different methods on random problems of different sizes.

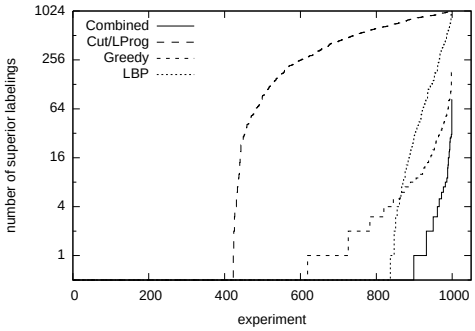

Figure 2. Quality comparison. Inference on 1000 random 18 label problems. Lower curves are better.

approximate inference, these concepts are not equivalent. Our work's major differences are our analysis handles non-zero training error, generalizes to any structural problem, uses structural SVMs, and we have an empirical analysis.

4. Experiments: Approximate Inference

Before we move into learning experiments, it helps to understand the runtime and quality performance characteristics of our MAP inference algorithms.

For runtime, Figure 1 illustrates each approximate inference method's average time to solve a single pairwise fully connected MRF with random potentials as the number of nodes increases.[1] Note that cuts are substantially faster than LBP, and several orders of magnitude faster than the linear relaxation while maintaining equivalence.

For evaluating solution quality, we generate 1000 random problems, ran the inference methods, and exhaustively count how many labelings with higher discriminant value exist. The resulting curve for 10-node MRFs is shown in Figure 2. For cut, $\varnothing$ labels are randomly assigned to 0 or 1. The lower the curve, the better the inference method. LBP finds "perfect" labelings more often than Greedy, but also tends to fall into horrible local maxima. Combined does much better than either alone; apparently the strengths of Greedy and LBP are complimentary.

Finally, note the apparent terrible performance of Cut, which is due to assigning many $\varnothing$ labels. At first glance, persistence is an attractive property since we *know* unambiguous labels are correct, but on the other hand, classifying only when it is certain leads it to leave many labels ambiguous.

[1]Implementation details: The methods were C-language Python extension modules. LProg was implemented in GLPK (see `http://www.gnu.org/software/glpk/glpk.html`). Cut was implemented with Maxflow software (Boykov & Kolmogorov, 2004). Other methods are home-spun. Experiments were run on a 2.6 GHz P4 Linux box.

5. Experiments: Approximate Learning

Our goal in the following experiments is to gain insight about how different approximate MRF inference methods perform in SSVM learning and classification. Our evaluation uses multi-label classification using pairwise fully connected MRFs as an example application.

Multi-label classification bears similarity to multi-class classification, except classes are not mutually exclusive, e.g., a news article may be about both "Iraq" and "oil." Often, incorporating inter-label dependencies into the model can improve performance (Cesa-Bianchi et al., 2006; Elisseeff & Weston, 2002).

How do we model this labeling procedure as an MRF? For each input $\mathbf{x}$, we construct an MRF with a vertex for each possible label, with values from $\mathbb{B} = \{0, 1\}$ (1 indicates $\mathbf{x}$ has the corresponding label), and an edge for each vertex pair (i.e., complete graph MRF).

What are our potential functions? In these problems, inputs $\mathbf{x} \in \mathbb{R}^m$ are feature vectors. Each of the ℓ possible labels u is associated with a weight vector $\mathbf{w}_u \in \mathbb{R}^m$. The resulting vertex potentials are $\phi_u(1) = {\mathbf{w}_u}^T\mathbf{x}$. Edge potentials $\phi_{uv}(1,1)$ come from individual values in $\mathbf{w}$, one for each label pair. Thus, the overall parameter vector $\mathbf{w} \in \mathbb{R}^{\ell m + \binom{\ell}{2}}$ has ℓm weights for the ℓ different $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_\ell$ sub-component weight vectors, and $\binom{\ell}{2}$ parameters for edge potentials. In terms of ψ functions, $\psi_u(\mathbf{x}, 1)$ vectors contain an offset version of $\mathbf{x}$ to "select out" $\mathbf{w}_u$ from $\mathbf{w}$, and $\psi_{uv}(\mathbf{x}, 1, 1)$ vectors have a single 1 entry to "select" the appropriate element from the end of $\mathbf{w}$.

5.1. Datasets and Model Training Details

We use six multi-label datasets to evaluate performance. Table 1 contains statistics on these datasets.

Table 1. Basic statistics for the datasets, including number of labels, training and test set sizes, number of features, and parameter vector **w** size, and performance on baseline trained methods and a default model.

Dataset	Labels	Train	Test	Feats.	**w** Size	Baseline	Default
Scene	6	1211	1196	294	1779	11.43±.29	18.10
Yeast	14	1500	917	103	1533	20.91±.55	25.09
Reuters	10	2916	2914	47236	472405	4.96±.09	15.80
Mediamill	10	29415	12168	120	1245	18.60±.14	25.37
Synth1	6	471	5045	6000	36015	8.99±.08	16.34
Synth2	10	1000	10000	40	445	9.80±.09	10.00

Four real datasets, **Scene** (Boutell et al., 2004), **Yeast** (Elisseeff & Weston, 2002), **Reuters** (the RCV1 subset 1 data set) (Lewis et al., 2004), and **Mediamill** (Snoek et al., 2006), came from the LIBSVM multi-label dataset collection (Chang & Lin, 2001). **Synth1** is a synthetic dataset of 6 labels. Labels follow a simple probabilistic pattern: label i is on half the time label $i-1$ is on and never otherwise, and label 1 is always on. Also, each label has 1000 related binary features (the learner does not know a priori which feature belong to each label): if i is on, a random 10 of its 1000 are set to 1. This hypothesis is learnable without edge potentials, but exploiting label dependency structure may result in better models. **Synth2** is a synthetic dataset of 10 labels. In this case, each example has exactly one label on. There are also 40 features. For an example, if label i is on, $4i$ randomly chosen features are set to 1. Only models with edge potentials can learn this concept.

We used 10-fold cross validation to choose C from 14 possible values $\{1{\cdot}10^{-2}, 3{\cdot}10^{-2}, 1{\cdot}10^{-1}, \ldots, 3{\cdot}10^{4}\}$. This C was then used when training a model on all training data. A separate C was chosen for each dataset and separation oracle.

5.2. Results and Analysis

Table 2 reports loss on the test set followed by standard error. For each dataset, we present losses for each combination of separation oracle used in learning (the rows) and of predictive inference procedure used in classification (the columns). This lets us distinguish badly learned models from bad inference procedures as explanations for inferior performance.

We also employ three additional methods as a point of comparison. Our **Baseline** is an MRF with no edge potentials, and our **Default** classifier always predicts the best-performing single labeling; results for these appear in Table 1. The **Exact** classifier is one which exhaustively searches for the argmax; to enable comparisons on Reuters and Mediamill, we pruned these datasets to the 10 most frequent labels.

Cut is omitted from Table 2. Its equivalence to LProg means the two are interchangeable and always produce the same results, excepting Cut's superior speed.

Table 3. Percentage of "ambiguous" labels in relaxed inference. Columns represent different data sets. Rows represent different methods used as separation oracles in training.

	Scene	Yeast	Reuters	Mediamill	Synth1	Synth2
Greedy	0.43%	17.02%	31.28%	20.81%	0.00%	31.17%
LBP	0.31%	0.00%	0.00%	0.00%	0.00%	0.00%
Combine	2.90%	91.42%	0.44%	4.27%	0.00%	29.11%
Exact	0.95%	84.30%	0.67%	65.58%	0.00%	27.92%
LProg	0.00%	0.43%	0.32%	1.30%	0.00%	1.48%

In all datasets, some edged model always exceeds the performance of the edgeless model. On Mediamill and Reuters, selecting only the 10 most frequent labels robs the dataset of many dependency relationships, which may explain the relatively lackluster performance.

5.2.1. The Sorry State of LBP, but Relax

Let's first examine the diagonal entries in Table 2. Models trained with LBP separation oracles yield generally poor performance. What causes this? LBP's tendency to fall into horrible local maxima (as seen in Section 4) misled Algorithm 1 to believe its most violated constraint was not violated, leading it to early termination, mirroring the result in (Kulesza & Pereira, 2007). The combined method remedies some of these problems; however, LProg still gives significantly better/worse performance on 3 vs. 1 datasets.

How does LProg training compare against exact training? Table 2 shows that both methods give similar performance. Exact-trained models significantly outperform relaxed-trained models on two datasets, but they also lose on two datasets.

5.2.2. Relaxation in Learning and Prediction

Observe that relaxation used *in prediction* performs well when applied to models trained with relaxation. However, on models trained with non-relaxed methods (i.e., models that do not constrain fractional solutions), relaxed inference often performs quite poorly. The most ludicrous examples appear in Yeast, Reuters, Mediamill, and Synth2. Table 3 suggests an explanation for this effect. The table lists the percentage of ambiguous labels from the relaxed classifier (fractional in LProg, $\varnothing$ in Cut). Ignoring degenerate LBP-trained models, the relaxed predictor *always* has the fewest ambiguous judgments. Apparently, SSVMs with relaxed separation oracles produce models that disfavor non-integer solutions. In retrospect this is unsurprising: ambiguous labels always incur loss during training. Minimizing loss during training therefore not only reduces training error, but also encourages parameterizations that favor integral (i.e., exact) solutions.

Table 2. Multi-labeling loss on six datasets. Results are grouped by dataset. Rows indicate separation oracle method. Columns indicate classification inference method.

	Greedy	LBP	Combine	Exact	LProg	Greedy	LBP	Combine	Exact	LProg
	Scene Dataset					Mediamill Dataset

LProg	20.47±.54	20.45±.54	20.47±.54	20.48±.54	20.49±.54	8.94±.08	8.94±.08	8.94±.08	8.94±.08	8.94±.08
	Reuters Dataset					Synth2 Dataset				
Greedy	5.32±.09	13.38±.21	5.06±.09	5.42±.09	16.98±.26	7.27±.07	27.92±.20	7.27±.07	7.28±.07	19.03±.15
LBP	15.80±.25	15.80±.25	15.80±.25	15.80±.25	15.80±.25	10.00±.09	10.00±.09	10.00±.09	10.00±.09	10.00±.09
Combine	4.90±.09	4.57±.08	4.53±.08	4.49±.08	4.55±.08	7.90±.07	26.39±.19	7.90±.07	7.90±.07	18.11±.15
Exact	6.36±.11	5.54±.10	5.67±.10	5.59±.10	5.62±.10	7.04±.07	25.71±.19	7.04±.07	7.04±.07	17.80±.15
LProg	6.73±.12	6.41±.11	6.38±.11	6.38±.11	6.38±.11	5.83±.05	6.63±.06	5.83±.05	5.83±.05	6.29±.06

Undergenerating and exact training do not control for this, leading to relaxed inference yielding many ambiguous labelings.

On the other hand, observe that models trained with the relaxed separation oracle have relatively consistent performance, irrespective of the classification inference procedure; even LBP never shows the catastrophic failure it does with other training approximations and even exact training (e.g., Mediamill, Synth2). Why might this occur? Recall the persistence property from Section 3: unambiguous labels are optimal labels. In some respects this property is attractive, but Section 4 revealed its dark side: relaxation predictors are very conservative, delivering unambiguous labels only when they are *certain*. By making things "obvious" for the relaxed predictors (which are the most conservative w.r.t. what they label), it appears they simultaneously make things obvious for all predictors, explaining the consistent performance of relaxed-trained models regardless of prediction method.

SSVM's ability to train models to "adapt" to the weakness of overgenerating predictors is an interesting complement with Searn structural learning (Daumé III et al., 2006), which trains models to adapt to the weaknesses of undergenerating search based predictors.

5.2.3. Known Approximations

How robust is SSVM training to an increasingly poor approximate separation oracle? To evaluate this, we built an artificial ρ-approximation separation oracle: for example $(\mathbf{x}_i, \mathbf{y}_i)$ we exhaustively find the optimal $\mathbf{y}^* = \text{argmax}_{\mathbf{y}\in\mathcal{Y}} w^T\mathbf{\Psi}(\mathbf{x}_i, \mathbf{y}) + \Delta(\mathbf{y}_i, \mathbf{y})$, but we return the labeling $\hat{\mathbf{y}}$ such that $f(\mathbf{x}, \hat{\mathbf{y}}) \approx \rho f(\mathbf{x}, \mathbf{y}^*)$. In this way, we build an approximate undergenerating MRF inference method with known quality.

Table 4 details these results. The first column indicates the approximation factor used in training each model for each dataset. The remaining columns show train and test performance using exact inference.

What is promising is that test performance does not drop precipitously as we use increasingly worse approximations. For most problems, the performance remains reasonable even for $\rho = 0.9$.

6. Conclusion

This paper theoretically and empirically analyzed two classes of methods for training structural SVMs on models where exact inference is intractable. Focusing on completely connected Markov random fields, we explored how greedy search, loopy belief propagation, a linear-programming relaxation, and graph-cuts can be used as approximate separation oracles in structural SVM training. In addition to a theoretical comparison of the resulting algorithms, we empirically compared performance on multi-label classification problems. Relaxation approximations distinguish themselves as preserving key theoretical properties of structural SVMs, as well as learning robust predictive models. Most significantly, structural SVMs appear to train models to avoid relaxed inference methods' tendency to yield fractional, ambiguous solutions.

Abstract

The hierarchical Dirichlet process hidden Markov model (HDP-HMM) is a flexible, nonparametric model which allows state spaces of unknown size to be learned from data. We demonstrate some limitations of the original HDP-HMM formulation (Teh et al., 2006), and propose a *sticky* extension which allows more robust learning of smoothly varying dynamics. Using DP mixtures, this formulation also allows learning of more complex, multimodal emission distributions. We further develop a sampling algorithm that employs a truncated approximation of the DP to jointly resample the full state sequence, greatly improving mixing rates. Via extensive experiments with synthetic data and the NIST speaker diarization database, we demonstrate the advantages of our sticky extension, and the utility of the HDP-HMM in real-world applications.

1. Introduction

Hidden Markov models (HMMs) have been a major success story in many applied fields; they provide core statistical inference procedures in areas as diverse as speech recognition, genomics, structural biology, machine translation, cryptanalysis and finance. Even after four decades of work on HMMs, however, significant problems remain. One lingering issue is the choice of the hidden state space's cardinality. While standard parametric model selection methods can be adapted to the HMM, there is little understanding of the strengths and weaknesses of such methods in this setting.

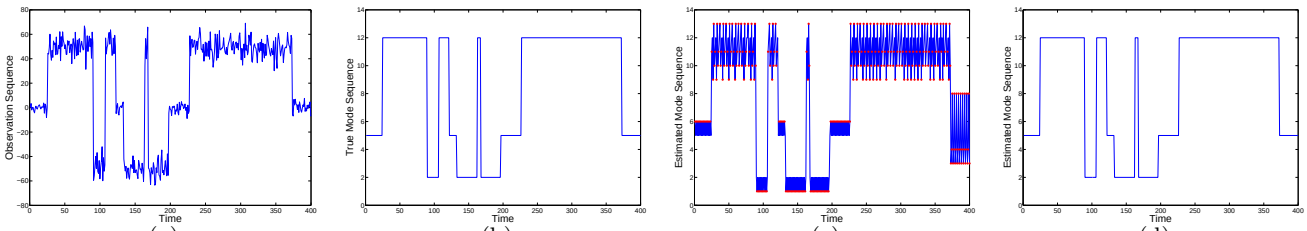
Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Recently, Teh et al. (2006) presented a nonparametric Bayesian approach to HMMs in which a stochastic process, the *hierarchical Dirichlet process* (HDP), defines a prior distribution on transition matrices over countably infinite state spaces. The resulting *HDP-HMM* leads to data–driven learning algorithms which infer posterior distributions over the number of states. This posterior uncertainty can be integrated out when making predictions, effectively averaging over models of varying complexity. The HDP-HMM has shown promise in a variety of applications, including visual scene recognition (Kivinen et al., 2007) and the modeling of genetic recombination (Xing & Sohn, 2007).

One serious limitation of the standard HDP-HMM is that it inadequately models the temporal persistence of states. This problem arises in classical finite HMMs as well, where semi-Markovian models are often proposed as solutions. However, the problem is exacerbated in the nonparametric setting, where the Bayesian bias towards simpler models is insufficient to prevent the HDP-HMM from learning models with unrealistically rapid dynamics, as demonstrated in Fig. 1.

To illustrate the seriousness of this issue, let us consider a challenging application that we revisit in Sec. 5. The problem of *speaker diarization* involves segmenting an audio recording into time intervals associated with individual speakers. This application seems like a natural fit for the HDP-HMM, as the number of true speakers is typically unknown, and may grow as more data is observed. However, this is not a setting in which model averaging is the goal; rather, it is critical to infer the number of speakers as well as the transitions among speakers. As we show in Sec. 5, the HDP-HMM's tendency to rapidly switch among redundant states leads to poor speaker diarization performance.

In contrast, the methods that we develop in this paper yield a state-of-the-art speaker diarization method, as



(a) (b) (c) (d)

Figure 1. Sensitivity of the HDP-HMM to within-state variations in the observations. (a) Observation sequence; (b) true state sequence; estimated state sequence after 100 Gibbs iterations for the (c) original and (d) sticky HDP-HMM, with errors indicated in red. Without an extra self–transition bias, the HDP-HMM rapidly transitions among redundant states.

well as a general solution to the problem of state persistence in HDP-HMMs. The approach is easily stated—we simply augment the HDP-HMM to include a parameter for self-transition bias, and place a separate prior on this parameter. The challenge is to consistently execute this idea in a nonparametric Bayesian framework. Earlier papers have also proposed self-transition parameters for HMMs with infinite state spaces (Beal et al., 2002; Xing & Sohn, 2007), but did not formulate general solutions that integrate fully with nonparametric Bayesian inference.

While the HDP-HMM treats the state transition distribution nonparametrically, it is also desirable to allow more flexible, nonparametric emission distributions. In classical applications of HMMs, finite Gaussian mixtures are often used to model multimodal observations. Dirichlet process (DP) mixtures provide an appealing alternative which avoids fixing the number of observation modes. Such emission distributions are not identifiable for the standard HDP-HMM, due to the tendency to rapidly switch between redundant states. With an additional self-transition bias, however, we show that a fully nonparametric HMM leads to effective learning algorithms. In particular, we develop a blocked Gibbs sampler which leverages forward–backward recursions to jointly resample the state and emission assignments for all observations.

In Sec. 2, we begin by presenting background material on the HDP. Sec. 3 then links these nonparametric methods with HMMs, and extends them to account for state persistence. We further augment the model with multimodal emission distributions in Sec. 4, and present results using synthetic data and the NIST speaker diarization database in Sec. 5.

2. Background: Dirichlet Processes

A Dirichlet process (DP), denoted by $\mathrm{DP}(\gamma, H)$, is a distribution over countably infinite random measures

$$G_0(\theta) = \sum_{k=1}^{\infty} \beta_k \delta(\theta - \theta_k) \qquad \theta_k \sim H \tag{1}$$

on a parameter space Θ. The weights are sampled via a *stick-breaking construction* (Sethuraman, 1994):

$$\beta_k = \beta'_k \prod_{\ell=1}^{k-1} (1 - \beta'_\ell) \qquad \beta'_k \sim \mathrm{Beta}(1, \gamma) \tag{2}$$

We denote this distribution by $\beta \sim \mathrm{GEM}(\gamma)$.

The DP is commonly used as a prior on the parameters of a mixture model of unknown complexity, resulting in a *DPMM* (see Fig. 2(a)). To generate observations, we choose $\bar{\theta}_i \sim G_0$ and $y_i \sim F(\bar{\theta}_i)$. This sampling process is often described via a discrete variable $z_i \sim \beta$ indicating which component generates $y_i \sim F(\theta_{z_i})$.

The *hierarchical Dirichlet process* (HDP) (Teh et al., 2006) extends the DP to cases in which groups of data are produced by related, yet unique, generative processes. Taking a hierarchical Bayesian approach, the HDP places a global Dirichlet process prior $\mathrm{DP}(\alpha, G_0)$ on Θ, and then draws group specific distributions $G_j \sim \mathrm{DP}(\alpha, G_0)$. Here, the base measure G_0 acts as an "average" distribution ($E[G_j] = G_0$) encoding the frequency of each shared, global parameter:

$$G_j(\theta) = \sum_{t=1}^{\infty} \tilde{\pi}_{jt} \delta(\theta - \tilde{\theta}_{jt}) \qquad \tilde{\pi}_j \sim \mathrm{GEM}(\alpha) \tag{3}$$

$$= \sum_{k=1}^{\infty} \pi_{jk} \delta(\theta - \theta_k) \qquad \pi_j \sim \mathrm{DP}(\alpha, \beta) \tag{4}$$

Because G_0 is discrete, multiple $\tilde{\theta}_{jt} \sim G_0$ may take identical values θ_k. Eq. (4) aggregates these probabilities, allowing an observation y_{ji} to be directly associated with the unique global parameters via an indicator random variable $z_{ji} \sim \pi_j$. See Fig. 2(b).

We can alternatively represent this generative process via indicator variables $t_{ji} \sim \tilde{\pi}_j$ and $k_{jt} \sim \beta$, as in Fig. 2(c). The stick-breaking priors on these mixture weights can be analytically marginalized, yielding simple forms for the predictive distributions of assignments. The resulting distribution on partitions is sometimes described using the metaphor of a *Chinese restaurant franchise* (CRF). There are J restaurants (groups), each with infinitely many tables (clusters) at

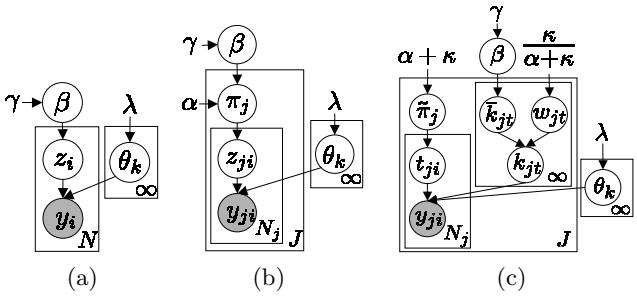


Figure 2. (a) DPMM in which $\beta \sim \text{GEM}(\gamma)$, $\theta_k \sim H(\lambda)$, $z_i \sim \beta$, and $y_i \sim f(y \mid \theta_{z_i})$. (b) HDP mixture model with $\beta \sim \text{GEM}(\gamma)$, $\pi_j \sim \text{DP}(\alpha, \beta)$, $\theta_k \sim H(\lambda)$, $z_{ji} \sim \pi_j$, and $y_{ji} \sim f(y \mid \theta_{z_{ji}})$. (c) CRF with loyal customers. Customers y_{ji} sit at table $t_{ji} \sim \tilde{\pi}_j$ which *considers* dish $\bar{k}_{jt} \sim \beta$, but override variables $w_{jt} \sim \text{Ber}(\kappa/\alpha + \kappa)$ can force the *served* dish k_{jt} to be j. The original CRF, as described in Sec. 2, has $\kappa = 0$ so that $k_{jt} = \bar{k}_{jt}$.

which customers (observations) sit. Upon entering the j^{th} restaurant, customer y_{ji} sits at currently occupied tables t_{ji} with probability proportional to the number of currently seated customers, or starts a new table $\tilde{t}$ with probability proportional to α. Each table chooses a dish (parameter) $\tilde{\theta}_{jt} = \theta_{k_{jt}}$ with probability proportional to the number of other tables in the franchise that ordered that dish, or orders a new dish $\theta_{\tilde{k}}$ with probability proportional to γ. Observation y_{ji} is then generated by global parameter $\theta_{z_{ji}} = \tilde{\theta}_{jt_{ji}} = \theta_{k_{jt_{ji}}}$.

An alternative, non–constructive characterization of samples $G_0 \sim \text{DP}(\gamma, H)$ from a Dirichlet process states that for every finite partition $\{A_1, \ldots, A_K\}$ of Θ,

$$(G_0(A_1), \ldots, G_0(A_K)) \sim \text{Dir}(\gamma H(A_1), \ldots, \gamma H(A_K)). \quad (5)$$

Using this expression, it can be shown that the following finite, hierarchical mixture model converges in distribution to the HDP as $L \to \infty$ (Ishwaran & Zarepour, 2002; Teh et al., 2006):

$$\begin{aligned} \beta &\sim \text{Dir}(\gamma/L, \ldots, \gamma/L) \\ \pi_j &\sim \text{Dir}(\alpha\beta_1, \ldots, \alpha\beta_L). \end{aligned} \quad (6)$$

Later sections use this *weak limit* approximation to develop efficient, blocked sampling algorithms.

3. The Sticky HDP-HMM

The HDP can be used to develop an HMM with an unknown, potentially infinite state space (Teh et al., 2006). For this HDP-HMM, each HDP group-specific distribution, π_j, is a state-specific transition distribution and, due to the infinite state space, there are infinitely many groups. Let z_t denote the state of the Markov chain at time t. For Markov chains $z_t \sim \pi_{z_{t-1}}$, so that z_{t-1} indexes the group to which y_t is assigned. The current HMM state z_t then indexes the parameter θ_{z_t} used to generate observation y_t (see Fig. 3).

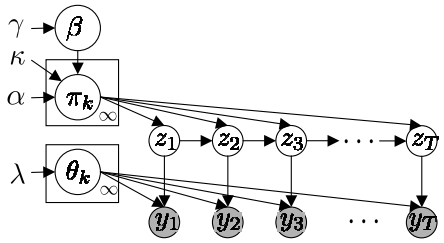

Figure 3. Graph of the sticky HDP-HMM. The state evolves as $z_{t+1} \sim \pi_{z_t}$, where $\pi_k \sim \text{DP}(\alpha + \kappa, (\alpha\beta + \kappa\delta_k)/(\alpha + \kappa))$ and $\beta \sim \text{GEM}(\gamma)$, and observations are generated as $y_t \sim F(\theta_{z_t})$. The original HDP-HMM has $\kappa = 0$.

By sampling $\pi_j \sim \text{DP}(\alpha, \beta)$, the HDP prior encourages states to have similar transition distributions ($E[\pi_{jk}] = \beta_k$). However, it does not differentiate self–transitions from moves between states. When modeling systems with state persistence, the flexible nature of the HDP-HMM prior allows for state sequences with unrealistically fast dynamics to have large posterior probability. For example, with Gaussian emissions, as in Fig. 1, a good explanation of the data is to divide an observation block into two small–variance states with slightly different means, and then rapidly switch between them (see Fig. 1). In such cases, many models with redundant states may have large posterior probability, thus impeding our ability to identify a single dynamical model which best explains the observations. The problem is compounded by the fact that once this alternating pattern has been instantiated by the sampler, its persistence is then reinforced by the properties of the Chinese restaurant franchise, thus slowing mixing rates. Furthermore, when observations are high-dimensional, this fragmentation of data into redundant states may reduce predictive performance. In many applications, one would thus like to be able to incorporate prior knowledge that slow, smoothly varying dynamics are more likely.

To address these issues, we propose to instead sample transition distributions π_j as follows:

$$\pi_j \sim \text{DP}\left(\alpha + \kappa, \frac{\alpha\beta + \kappa\delta_j}{\alpha + \kappa}\right). \quad (7)$$

Here, $(\alpha\beta + \kappa\delta_j)$ indicates that an amount $\kappa > 0$ is added to the j^{th} component of $\alpha\beta$. The measure of π_j over a finite partition $(Z_1, \ldots, Z_K)$ of the positive integers $\mathbb{Z}_+$, as described by Eq. (5), adds an amount κ only to the arbitrarily small partition containing j, corresponding to a self-transition. When $\kappa = 0$ the original HDP-HMM is recovered. Because positive κ values increase the prior probability $E[\pi_{jj}]$ of self–transitions, we refer to this extension as the *sticky* HDP-HMM.

In some ways, this κ parameter is reminiscent of the infinite HMM's self-transition bias (Beal et al., 2002).

However, that paper relied on a heuristic, approximate Gibbs sampler. The full connection between the infinite HMM and an underlying nonparametric Bayesian prior, as well as the development of a globally consistent inference algorithm, was made in Teh et al. (2006), but without a treatment of a self-transition parameter.

3.1. A CRF with Loyal Customers

We further abuse the Chinese restaurant metaphor by extending it to the sticky HDP-HMM, where our franchise now has restaurants with loyal customers. Each restaurant has a specialty dish with the same index as that of the restaurant. Although this dish is served elsewhere, it is more popular in the dish's namesake restaurant. We see this increased popularity from the fact that a table's dish is now drawn as

$$k_{jt} \sim \frac{\alpha\beta + \kappa\delta_j}{\alpha + \kappa}. \tag{8}$$

We will refer to z_t as the parent and z_{t+1} as the child. The parent enters a restaurant j determined by its parent (the grandparent), $z_{t-1} = j$. We assume there is a bijective mapping of indices $f : t \to ji$. The parent then chooses a table $t_{ji} \sim \tilde{\pi}_j$ and that table is served a dish indexed by $k_{jt_{ji}}$. Noting that $z_t = z_{ji} = k_{jt_{ji}}$, the increased popularity of the house specialty dish implies that children are more likely to eat in the same restaurant as their parent and, in turn, more likely to eat the restaurant's specialty dish. This develops family loyalty to a given restaurant in the franchise. However, if the parent chooses a dish other than the house specialty, the child will then go to the restaurant where this dish is the specialty and will in turn be more likely to eat this dish, too. One might say that for the sticky HDP-HMM, children have similar tastebuds to their parents and will always go the restaurant that prepares their parent's dish best. Often, this keeps many generations eating in the same restaurant.

The inference algorithm is simplified if we introduce a set of auxiliary random variables $\bar{k}_{jt}$ and w_{jt} as follows:

$$\bar{k}_{jt} \sim \beta, \qquad w_{jt} \sim \text{Ber}\left(\frac{\kappa}{\alpha+\kappa}\right), \qquad k_{jt} = \begin{cases} \bar{k}_{jt}, & w_{jt} = 0; \\ j, & w_{jt} = 1, \end{cases} \tag{9}$$

where $\text{Ber}(p)$ represents the Bernoulli distribution. The table first chooses a dish $\bar{k}_{jt}$ without taking the restaurant's specialty into consideration (i.e., the original CRF.) With some probability, this *considered* dish is overridden (perhaps by a waiter's suggestion) and the table is served the specialty dish j. Thus, k_{jt} represents the *served* dish. We refer to w_{jt} as the *override* variable. For the original HDP-HMM, when $\kappa = 0$, the considered dish is always the served dish since $w_{jt} = 0$ for all tables. See Fig. 2(c).

3.2. Sampling via Direct Assignments

In this section we describe a modified version of the direct assignment Rao-Blackwellized Gibbs sampler of Teh et al. (2006) which circumvents the complicated bookkeeping of the CRF by sampling indicator random variables directly. Throughout this section, we refer to the variables in the graph of Fig. 3. For this sampler, a set of auxiliary variables m_{jk}, $\bar{m}_{jk}$, and w_{jt} must be added (as illustrated in Fig. 2(c)).

Sampling z_t The posterior distribution factors as:

$$p(z_t = k \mid z_{\setminus t}, y_{1:T}, \beta, \alpha, \kappa, \lambda) \propto p(z_t = k \mid z_{\setminus t}, \beta, \alpha, \kappa) p(y_t \mid y_{\setminus t}, z_t = k, z_{\setminus t}, \lambda). \tag{10}$$

The properties of the Dirichlet process dictate that on the finite partition $\{1, \ldots, K, \tilde{k}\}$ we have the following form for the group-specific transition distributions:

$$\pi_j \sim \text{Dir}(\alpha\beta_1, \ldots, \alpha\beta_j + \kappa, \ldots, \alpha\beta_K, \alpha\beta_{\tilde{k}}). \tag{11}$$

We use the above definition of π_j and the Dirichlet distribution's conjugacy to the multinomial observations z_t to marginalize π_j and derive the following conditional distribution over the states assignments:

$$p(z_t = k \mid z_{\setminus t}, \beta, \alpha, \kappa) \propto (\alpha\beta_k + n^{-t}_{z_{t-1}k} + \kappa\delta(z_{t-1}, k)) \left(\frac{\alpha\beta_{z_{t+1}} + n^{-t}_{kz_{t+1}} + \kappa\delta(k, z_{t+1}) + \delta(z_{t-1}, k)\delta(k, z_{t+1})}{\alpha + n^{-t}_{k\cdot} + \kappa + \delta(z_{t-1}, k)} \right). \tag{12}$$

This formula is more complex than that of the standard HDP sampler due to potential dependencies in the marginalization of $\pi_{z_{t-1}}$ and π_{z_t}. For a detailed derivation, see Fox et al. (2007). The notation n_{jk} represents the number of Markov chain transitions from state j to k, $n_{j\cdot} = \sum_k n_{jk}$, and n^{-t}_{jk} the number of transitions from state j to k not counting the transition z_{t-1} to z_t or z_t to z_{t+1}. Intuitively, this expression chooses a state k with probability depending on how many times we have seen other z_{t-1} to k and k to z_{t+1} transitions. Note that there is a dependency on whether either or both of these transitions correspond to a self-transition, which is strongest when $\kappa > 0$.

As in Teh et al. (2006), by placing a conjugate prior on the parameter space, there is a closed analytic form for the likelihood component $p(y_t \mid y_{\setminus t}, z_t = k, z_{\setminus t}, \lambda)$.

Sampling β Assume there are currently $\bar{K}$ unique dishes being *considered* and take a finite partition $\{\theta_1, \theta_2, \ldots, \theta_{\bar{K}}, \theta_{\tilde{k}}\}$ of Θ, where $\theta_{\tilde{k}} = \Theta \setminus \bigcup_{k=1}^{\bar{K}} \{\theta_k\}$. Since $\tilde{\theta}_{jt} \sim G_0$ and $\bar{m}_{\cdot k}$ tables are considering dish θ_k, the properties of the Dirichlet distribution dictate:

$$p((\beta_1, \ldots, \beta_{\bar{K}}, \beta_{\tilde{k}}) \mid \bar{\boldsymbol{k}}, \gamma) \propto \text{Dir}(\bar{m}_{\cdot 1}, \ldots, \bar{m}_{\cdot \bar{K}}, \gamma). \tag{13}$$

From the above, we see that $\{\bar{m}_{\cdot k}\}_{k=1}^{\bar{K}}$ is a set of sufficient statistics for resampling β on this partition.

However, this requires sampling two additional variables, m_{jk} and w_{jt}, corresponding to the number of tables in restaurant j *served* dish k and the corresponding overwrite variables. We jointly sample from

$$p(\boldsymbol{m}, \boldsymbol{w}, \bar{\boldsymbol{m}} \mid z_{1:T}, \beta, \alpha, \kappa) = p(\bar{\boldsymbol{m}} \mid \boldsymbol{m}, \boldsymbol{w}, z_{1:T}, \beta, \alpha, \kappa) \\ p(\boldsymbol{w} \mid \boldsymbol{m}, z_{1:T}, \beta, \alpha, \kappa) p(\boldsymbol{m} \mid z_{1:T}, \beta, \alpha, \kappa). \quad (14)$$

We start by examining $p(\boldsymbol{m} \mid z_{1:T}, \beta, \alpha, \kappa)$. Having the state index assignments $z_{1:T}$ effectively partitions the data (customers) into both restaurants and dishes, though the table assignments are unknown since multiple tables can be served the same dish. Thus, sampling m_{jk} is in effect equivalent to sampling table assignments for each customer *after* knowing the dish assignment. This conditional distribution is given by:

$$p(t_{ji} = t \mid k_{jt} = k, \boldsymbol{t}^{-ji}, \boldsymbol{k}^{-jt}, y_{1:T}, \beta, \alpha, \kappa) \\ \propto \begin{cases} \tilde{n}_{jt}^{-ji}, & t \in \{1, \ldots, T_j\}; \\ \alpha\beta_k + \kappa\delta(k, j), & t = \tilde{t}_j, \end{cases} \quad (15)$$

where $\tilde{n}_{jt}^{-ji}$ is the number of customers at table t in restaurant j, not counting y_{ji}. The form of Eq. (15) implies that a customer's table assignment conditioned on a dish assignment k follows a DP with concentration parameter $\alpha\beta_k + \kappa\delta(k, j)$ and may be sampled by simulating the associated Chinese restaurant process.

We now derive the conditional distribution for the override variables w_{jt}. The table counts provide that m_{jk} tables are serving dish k in restaurant j. If $k \neq j$, we automatically have m_{jk} tables with $w_{jt} = 0$ since the served dish is not the house specialty. Otherwise,

$$p(w_{jt} \mid k_{jt} = j, \beta, \rho) \propto \begin{cases} \beta_j(1-\rho), & w_{jt} = 0; \\ \rho, & w_{jt} = 1, \end{cases} \quad (16)$$

where $\rho = \frac{\kappa}{\alpha+\kappa}$ is the prior probability that $w_{jt} = 1$. Observing served dish $k_{jt} = j$ makes it more likely that the considered dish $\bar{k}_{jt}$ was overridden than the prior suggests. We draw m_{jj} samples of w_{jt} from Eq. (16).

Given m_{jk} for all j and k and w_{jt} for each of these instantiated tables, we can now deterministically compute $\bar{m}_{jk}$. Any table that was overridden is an uninformative observation for the posterior of $\bar{m}_{jk}$ so that

$$\bar{m}_{jk} = \begin{cases} m_{jk}, & j \neq k; \\ m_{jj} - w_{j\cdot}, & j = k. \end{cases} \quad (17)$$

Sampling Hyperparameters Rather than fixing the sticky HDP-HMM's hyperparameters, we place vague gamma priors on γ and $(\alpha + \kappa)$, and a beta prior on $\kappa/(\alpha+\kappa)$. As detailed in Fox et al. (2007), the auxiliary variables introduced in the preceding section then allow tractable resampling of these hyperparameters. This allows the number of occupied states, and the degree of self–transition bias, to be strongly influenced by the statistics of observed data, as desired.

3.3. Blocked Sampling of State Sequences

The HDP-HMM direct assignment sampler can exhibit slow mixing rates since global state sequence changes are forced to occur coordinate by coordinate. This is explored in Scott (2002) for the finite HMM. Although the sticky HDP-HMM reduces the posterior uncertainty caused by fast state-switching explanations of the data, the self-transition bias can cause two continuous and temporally separated sets of observations of a given state to be grouped into two states. If this occurs, the high probability of self-transition makes it challenging for the sequential sampler to group those two examples into a single state.

A variant of the HMM forward-backward procedure (Rabiner, 1989) allows us to harness the Markov structure and jointly sample the state sequence $z_{1:T}$ given the observations $y_{1:T}$, transitions probabilities π_j, and model parameters θ_k. To take advantage of this procedure, we now must sample the previously marginalized transition distributions and model parameters. In practice, this requires approximating the theoretically countably infinite transition distributions. One approach is the degree L *weak limit approximation* to the DP (Ishwaran & Zarepour, 2002),

$$\mathrm{GEM}_L(\alpha) \triangleq \mathrm{Dir}(\alpha/L, \ldots, \alpha/L), \quad (18)$$

where L is a number that exceeds the total number of expected HMM states. This approximation encourages the learning of models with fewer than L components while allowing the generation of new components, upper bounded by L, as new data are observed.

The posterior distributions of β and π_j are given by:

$$\beta \sim \mathrm{Dir}(\gamma/L + \bar{m}_{\cdot 1}, \ldots, \gamma/L + \bar{m}_{\cdot L}) \quad (19)$$
$$\pi_j \sim \mathrm{Dir}(\alpha\beta_1 + n_{j1}, \ldots, \alpha\beta_j + \kappa + n_{jj}, \ldots, \alpha\beta_L + n_{jL}).$$

Depending on the form of the emission distribution and base measure on the parameter space Θ, we sample parameters for each of the currently instantiated states from the updated posterior distribution:

$$\theta_j \sim p(\theta \mid \{y_t \mid z_t = j\}, \lambda). \quad (20)$$

Now that we are sampling θ_j directly, we can use a non-conjugate base measure.

We block sample $z_{1:T}$ by first computing backward messages $m_{t,t-1}(z_{t-1}) \propto p(y_{t:T} | z_{t-1}, \boldsymbol{\pi}, \boldsymbol{\theta})$ and then recursively sampling each z_t conditioned on z_{t-1} from

$$p(z_t \mid z_{t-1}, y_{1:T}, \boldsymbol{\pi}, \boldsymbol{\theta}) \propto \\ p(z_t \mid \pi_{z_{t-1}}) p(y_t \mid \theta_{z_t}) m_{t+1,t}(z_t). \quad (21)$$

A similar sampler has been used for learning HDP hidden Markov trees (Kivinen et al., 2007). However, this work did not consider the complications introduced by multimodal emissions, as we explore next.

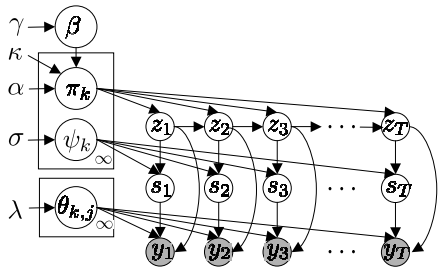

Figure 4. Sticky HDP-HMM with DP emissions, where s_t indexes the state-specific mixture component generating observation y_t. The DP prior dictates that $s_t \sim \psi_{z_t}$ for $\psi_k \sim \text{GEM}(\sigma)$. The j^{th} Gaussian component of the k^{th} mixture density is parameterized by $\theta_{k,j}$ so $y_t \sim F(\theta_{z_t,s_t})$.

4. Multimodal Emission Distributions

For many application domains, the data associated with each hidden state may have a complex, multimodal distribution. We propose to approximate such emission distributions nonparametrically, using an infinite DP mixture of Gaussians. This formulation is related to the nested DP (Rodriguez et al., 2006). The bias towards self-transitions allow us to distinguish between the underlying HDP-HMM states. If the model were free to both rapidly switch between HDP-HMM states and associate multiple Gaussians per state, there would be considerable posterior uncertainty. Thus, it is only with the sticky HDP-HMM that we can effectively learn such models.

We augment the HDP-HMM state z_t with a term s_t indexing the mixture component of the z_t^{th} emission density. For each HDP-HMM state, there is a unique stick-breaking distribution $\psi_k \sim \text{GEM}(\sigma)$ defining the mixture weights of the k^{th} emission density so that $s_t \sim \psi_{z_t}$. The observation y_t is generated by the Gaussian component with parameter θ_{z_t,s_t}. See Fig. 4.

To implement blocked resampling of $(z_{1:T}, s_{1:T})$, we use weak limit approximations to both the HDP-HMM and Dirichlet process emissions, approximated to levels L and L', respectively. The posterior distributions of β and π_k remain unchanged; that of ψ_k is given by:

$$\psi_k \sim \text{Dir}(\sigma/L' + n'_{k1}, \ldots, \sigma/L' + n'_{kL'}), \qquad (22)$$

where n'_{kl} are the number of observations assigned to the l^{th} mixture component of the k^{th} HMM state. The posterior distribution for each Gaussian's mean and covariance, $\theta_{k,j}$, is determined by the observations assigned to this component, namely,

$$\theta_{k,j} \sim p(\theta \mid \{y_t \mid (z_t = k, s_t = j)\}, \lambda). \qquad (23)$$

The augmented state (z_t, s_t) is sampled from

$$p(z_t, s_t \mid z_{t-1}, y_{1:T}, \boldsymbol{\pi}, \boldsymbol{\psi}, \boldsymbol{\theta}) \propto$$
$$p(z_t \mid \pi_{z_{t-1}}) p(s_t \mid \psi_{z_t}) p(y_t \mid \theta_{z_t,s_t}) m_{t+1,t}(z_t). \qquad (24)$$

Since the Markov structure is only on the z_t component of the augmented state, the backward message $m_{t,t-1}(z_{t-1})$ from (z_t, s_t) to (z_{t-1}, s_{t-1}) is solely a function of z_{t-1}. These messages are given by:

$$m_{t,t-1}(z_{t-1}) \propto \sum_{z_t} \sum_{s_t} p(z_t \mid \pi_{z_{t-1}}) p(s_t \mid \psi_{z_t})$$
$$p(y_t \mid \theta_{z_t,s_t}) m_{t+1,t}(z_t). \qquad (25)$$

5. Results

Synthetic Data We generated test data from a three-state Gaussian emission HMM with: 0.97 probability of self-transition; means 50, 0, and -50; and variances 50, 10, and 50 (see Fig. 1(a).) For the blocked sampler, we used a truncation level of $L = 15$.

Fig. 5 shows the clear advantage of considering a sticky HDP-HMM with blocked sampling. The Hamming distance error is calculated by greedily mapping the indices of the estimated state sequence to those maximizing overlap with the true sequence. The apparent slow convergence of the sticky HDP-HMM direct assignment sampler (Fig. 5(b)) can be attributed to the sampler splitting temporally separated segments of a true state into multiple, redundant states. Although not depicted due to space constraints, both sticky HDP-HMM samplers result in estimated models with significantly larger likelihoods of the true state sequence than those of the original HDP-HMM.

To test the model of Sec. 4, we generated data from a two-state HMM, where each state had a two-Gaussian mixture emission distribution with equally weighted components defined by means $(0, 10)$ and $(-7, 7)$, and variances of 10. The probability of self-transition was set to 0.98. The resulting observation and true state sequences are shown in Fig. 6(a) and (b).

Fig. 6(e)-(h) compares the performance of the sticky and original HDP-HMM with single and infinite Gaussian mixture emissions. All results are for the blocked sampler with truncation levels $L = L' = 15$. Intuitively, when constrained to single Gaussian emissions, the best explanation of the data is to associate each true mixture component with a separate state and then quickly switch between these states, resulting in the large Hamming distances of Fig. 6(g)-(h). Although not the desired effect in this scenario, this behavior, as depicted in Fig. 6(c), demonstrates the flexibility of the sticky HDP-HMM: if the best explanation of the data according to the model is fast state-switching, the sticky HDP-HMM still allows for this by learning a small bias towards self-transitions. The sticky HDP-HMM occasionally has more accurate state sequence estimates by grouping a true state's Gaussian mixture components into a single Gaussian with large variance. By far the best performance is

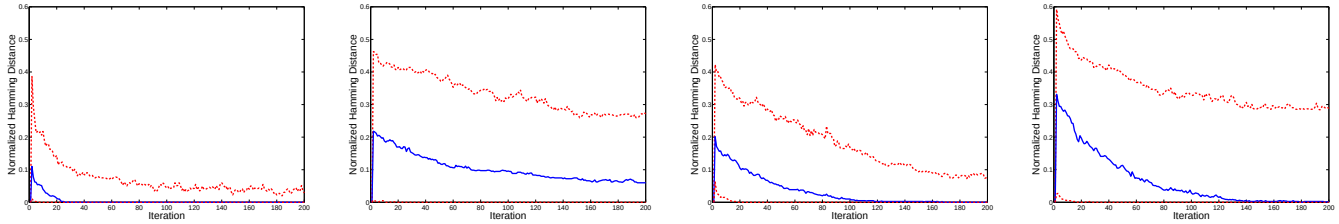

Figure 5. Hamming distance between true and estimated state sequences over 100 iterations for the sticky HDP-HMM (a) blocked and (b) direct assignment samplers and the original HDP-HMM (c) blocked and (d) direct assignment samplers. These plots show the median (solid blue) and 10^{th} and 90^{th} quantiles (dashed red) from 200 initializations.

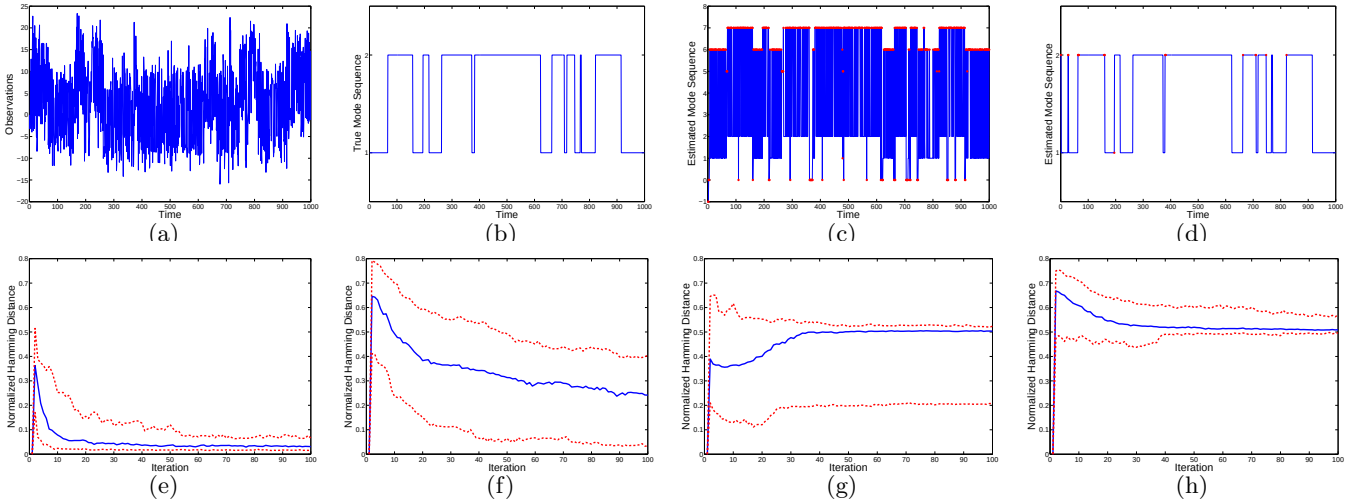

Figure 6. Performance of inference on data generated by an HMM with Gaussian mixture emissions. (a) Observation sequence; (b) true HMM state sequence; estimated HMM state sequence using the sticky HDP-HMM model with (c) single and (d) infinite Gaussian mixture emissions. Errors are indicated by red markers. The bottom row contains Hamming distance plots, as in Fig. 5, for infinite Gaussian mixture emissions and the (e) sticky HDP-HMM and (f) original HDP-HMM, and single Gaussian emissions for the (g) sticky HDP-HMM and (h) original HDP-HMM.

achieved by the sticky HDP-HMM with infinite Gaussian mixture emissions (see Fig. 6(e) and (d)); comparing to Fig. 6(f), we see that the gain can be attributed to modeling rather than just improved mixing rates.

Speaker Diarization Data The *speaker diarization* task involves segmenting an audio recording into speaker-homogeneous regions, while simultaneously identifying the number of speakers. We tested the utility of the sticky HDP-HMM for this task on the data distributed by NIST as part of the Rich Transcription 2004-2007 meeting recognition evaluations (NIST, 2007). We use the first 19 Mel Frequency Cepstral Coefficients (MFCCs), computed over a 30ms window every 10ms, as our feature vector. When working with this dataset, we discovered that: (1) the high frequency content of these features contained little discriminative information, and (2) without a minimum speaker duration, the sticky HDP-HMM learned within speaker dynamics in addition to global speaker changes. To jointly address these issues, we instead model feature averages computed over 250ms, non–overlapping blocks. A minimum speaker duration of 500ms is set by associating two average features with each hidden state. We also tie the covariances of within–state mixture components. We found single–Gaussian emission distributions to be less effective.

For each of 21 meetings, we compare 10 initializations of the original and sticky HDP-HMM blocked samplers. In Fig. 8(a), we report the official NIST diarization error rate (DER) of the run with the largest observation sequence likelihood, given parameters estimated at the 1000th Gibbs iteration. The sticky HDP-HMM's temporal smoothing provides substantial performance gains. Fig 8(b) plots the estimated versus true number of speakers who talk for more than 10% of the meeting time, and shows our model's ability to adapt to a varying number of speakers. As a further comparison, the ICSI team's algorithm (Wooters & Huijbregts, 2007), by far the best performer at the 2007 competition, has an overall DER of 18.37%, simi-

lar to our 19.04%. Our best and worst DER are 1.26% and 31.42%, respectively, compared to their 4.39% and 32.23%. We use the same non-speech pre-processing, so that the differences are due to changes in the identified speakers. As depicted in Fig. 7, a significant proportion of our errors can be attributed to splitting or merging speakers. The ICSI team's algorithm uses agglomerative clustering, and requires significant tuning of parameters on representative training data. In contrast, our hyperparameters are automatically set meeting-by-meeting, so that each component's expected mean and covariance are that of the entire feature sequence. Note that the selected runs plotted in Fig. 8 are not necessarily those with the smallest DER. For example, the run depicted in Fig. 7(d) had 24.06% DER, while another run on the same meeting had 4.37% (versus ICSI's 22.00%.) There is inherent posterior uncertainty in this task, and our sampler has the advantage of giving several interpretations. When considering the best per-meeting DER for the five most likely samples, our overall DER drops to 15.14%; we hope to explore automated ways of combining multiple samples in future work. Regardless, our results demonstrate that the sticky HDP-HMM provides an elegant and empirically effective speaker diarization method.

6. Discussion

We have demonstrated the considerable benefits of an extended HDP-HMM in which a separate parameter captures state persistence. We have also shown that this sticky HDP-HMM allows a fully nonparametric treatment of multimodal emissions, disambiguated by its bias towards self-transitions, and presented efficient sampling techniques with mixing rates that improve on the state-of-the-art. Results on synthetic data, and a challenging speaker diarization task, clearly demonstrate the practical importance of our extensions.

Acknowledgments

We thank O. Vinyals, G. Friedland, and N. Morgan for helpful discussions about the NIST dataset. This research was supported in part by DARPA contract NBCHD030010, and MURIs funded through ARO Grant W911NF-06-1-0076 and AFOSR Grant FA9550-06-1-0324. E.B.F. was partially funded by an NDSEG fellowship.

Optimized Cutting Plane Algorithm for Support Vector Machines

Vojtěch Franc VOJTECH.FRANC@FIRST.FRAUNHOFER.DE

Fraunhofer Institute FIRST, Kekulestr. 7, 12489 Berlin, Germany

Abstract

We have developed a new Linear Support Vector Machine (SVM) training algorithm called OCAS. Its computational effort scales linearly with the sample size. In an extensive empirical evaluation OCAS significantly outperforms current state of the art SVM solvers, like SVM$^{\text{light}}$, SVM$^{\text{perf}}$ and BMRM, achieving speedups of over 1,000 on some datasets over SVM$^{\text{light}}$ and 20 over SVM$^{\text{perf}}$, while obtaining the same precise Support Vector solution. OCAS even in the early optimization steps shows often faster convergence than the so far in this domain prevailing approximative methods SGD and Pegasos. Effectively parallelizing OCAS we were able to train on a dataset of size 15 million examples (itself about 32GB in size) in just 671 seconds — a competing string kernel SVM required 97,484 seconds to train on 10 million examples subsampled from this dataset.

1. Introduction

Many applications in e.g. Bioinformatics, IT-Security and Text-Classification come with *huge* amounts (e.g. millions) of data points, which are indeed *needed* to obtain state-of-the-art results. They therefore require computationally extremely efficient methods capable of dealing with ever growing data sizes. Support Vector Machines (SVM) e.g. (Cortes & Vapnik, 1995; Cristianini & Shwawe-Taylor, 2000) have proven to be powerful tools for a wide range of different data analysis problems. Given labeled training examples $\{(\boldsymbol{x}_1, y_1), \dots (\boldsymbol{x}_m, y_m)\} \in (\mathbb{R}^n \times \{-1, +1\})^m$ and a regularization constant $C > 0$ they learn a linear classification rule $h(\boldsymbol{x}) = \text{sgn}(\langle \boldsymbol{w}^*, \boldsymbol{x} \rangle + b^*)$ by solving the quadratic SVM primal optimization problem (P) or its dual formulation (D) allowing the use of *kernels*.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

$$(\mathbf{P}) \quad \min_{\boldsymbol{w},\boldsymbol{\xi},b} \quad \frac{1}{2}\|\boldsymbol{w}\|_2^2 + \frac{C}{m}\sum_{i=1}^{m}\xi_i, \text{for } \boldsymbol{w} \in \mathbb{R}^n, \boldsymbol{\xi} \in \mathbb{R}_+^m, b \in \mathbb{R}$$
$$\text{s.t.} \quad y_i\left(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b\right) \geq 1 - \xi_i, \quad i = 1, \dots, m$$

$$(\mathbf{D}) \max_{\boldsymbol{\alpha} \in \mathbb{R}^m} \quad \sum_{i=1}^m \alpha_i - \frac{1}{2}\sum_{i=1}^m \sum_{j=1}^m \alpha_i \alpha_j y_i y_j \langle \boldsymbol{x}_i, \boldsymbol{x}_j \rangle$$
$$\text{s.t.}: \ \sum_{i=1}^m \alpha_i y_i = 0, \ 0 \leq \alpha_i \leq \frac{C}{m}, \ i = 1 \dots m$$

Due to the central importance of SVMs, many techniques have been proposed to solve the SVM problem. As in practice only limited precision solutions to (P) and (D) can be obtained they may be categorized into *approximative* and *accurate*.

Approximative Solvers make use of heuristics (e.g. learning rate, number of iterations) to obtain (often crude) approximations to the QP-solution. They have very low per-iteration cost and low total training time. Especially for large scale problems, they are claimed to be sufficiently precise while delivering the best performance vs. training time trade-off (Bottou & Bousquet, 2008), which may be attributed to the robust nature of *large margin* SVM solutions. However while they are fast in the beginning they often fail to achieve precise solution. Among the to-date most efficient solvers are Pegasos (Shwartz et al., 2007) and SGD (Bottou & Bousquet, 2008), which are based on stochastic (sub-)gradient descent.

Accurate Solvers In contrast to approximative solvers, accurate methods solve a QP up to a given precision ε, where ε commonly denotes the violation of the relaxed KKT conditions (Joachims, 1999) or the (relative) duality gap. Accurate methods often have good asymptotic convergence properties, and thus for small ε converge to very precise solutions being limited only by numerical precision. Classical examples are off-the-shelf optimizers (e.g. MINOS, CPLEX, LOQO). However it is usually infeasible to use standard optimization tools for solving the SVM training problems (D) on datasets containing more than a few thousand examples. So-called decomposition techniques as chunking (e.g. used in (Joachims, 1999)), or SMO (used in

(Chang & Lin, 2001)) overcome this limitation by exploiting the special structure of the SVM problem. The key idea of decomposition is to freeze all but a small number of optimization variables (*working set*) and to solve a sequence of constant-size problems (subproblems of the SVM dual). While decomposition based solvers are very flexible as they are working in the dual and thus allow the use of kernels they become computationally intractable with a few hundred thousand examples. This limitation can be explained as follows: Decomposition methods exploit the fact that the optimal solution of (P) does not change if inactive constraints at the optimum are removed, they are therefore only efficient if the number of active constraints is reasonably small. Unfortunately, the number of active constraints is lower bound by the portion of misclassified examples, which is proportional to the number of examples m. Thus decomposition methods are computationally prohibitive for large-scale problems (empirically about 10%-30% of the training points become active constraints).

This poses a challenging task for even current state-of-the-art SVM solvers such as SVM$^{\text{light}}$ (Joachims, 1999), Gradient Projection-based Decomposition Technique-SVM (GPDT-SVM) (Zanni et al., 2006), LibSVM (Chang & Lin, 2001). As improving training times using the dual formulation is hard, the research focus has shifted back to the original SVM primal problem. The importance of being able to efficiently solve the primal problem for large datasets is documented by a number of very recently developed methods, e.g. SVMLin (Sindhwani & Keerthi, 2007; Chapelle, 2007), LibLinear (Lin et al., 2007), SVM$^{\text{perf}}$ (Joachims, 2006) and BMRM (Teo et al., 2007).

In the following we will focus on finding *accurate* solutions of the unconstrained linear SVM primal problem[1]

$$\boldsymbol{w}^* = \operatorname*{argmin}_{\boldsymbol{w}} F(\boldsymbol{w}) := \left[\tfrac{1}{2}\|\boldsymbol{w}\|^2 + CR(\boldsymbol{w})\right], \quad (1)$$

$$\text{where} \quad R(\boldsymbol{w}) = \tfrac{1}{m}\sum_{i=1}^{m} \max\{0, 1 - y_i\langle \boldsymbol{w}, \boldsymbol{x}_i\rangle\} \quad (2)$$

is a convex risk approximating the training error.

Among the up to date most efficient *accurate* SVM primal problem (1) solvers are the Cutting Plane Algorithm (CPA) based methods put forward in (Joachims, 2006; Teo et al., 2007) and implemented in SVM$^{\text{perf}}$ and BMRM. The idea of CPAs is to approximate the risk R by a piece-wise linear function defined as the maximum over a set of linear underestimators, in CPA terminology called *cutting planes*. In (Joachims, 2006; Teo et al., 2007) it was shown that their number does not depend on the number of training examples m and that very few such cutting planes are needed in practice to sufficiently approximate (1).

[1]Note that we focus on the linear rule without a bias. The bias can be included by adding a constant feature to each training example $\boldsymbol{x}_i$.

In this work we propose a new method, called the Optimized Cutting Plane Algorithm for SVMs (OCAS). We empirically show that OCAS converges on a wide variety of large-scale datasets even considerably faster than SVM$^{\text{perf}}$, BMRM and SVM$^{\text{light}}$, achieving speedups of several orders of magnitude on some problems. We also demonstrate that OCAS even in the early optimization steps shows faster convergence than the so far in this domain dominating approximative methods. Finally we critically analyze all solvers w.r.t. classification performance in an extensive model selection study.

The report is organized as follows. CPA is described in Section 2. In Section 3, we point out a source of inefficiency of CPA and propose a new method, OCAS, to alleviate the problem and prove linear convergence. An extensive empirical evaluation is given in Section 4 and concludes the paper.

2. Cutting Plane Algorithm

Recently, the Cutting Plane Algorithm (CPA) based large-scale solvers, SVM$^{\text{perf}}$ (Joachims, 2006) and BMRM (Teo et al., 2007), have been proposed. SVM$^{\text{perf}}$ implements CPA specifically for the linear SVM problem (1). Decoupling regularizer and loss function, BMRM generalizes SVM$^{\text{perf}}$ to a wide range of losses and regularizers making it applicable to many machine learning problems, like classification, regression, structure learning etc. It should be noted that BMRM using the two norm regularizer $\|.\|_2$ and hinge loss (i.e. SVM problem (1)) coincides with SVM$^{\text{perf}}$. It was shown that SVM$^{\text{perf}}$ and BMRM by far outperform the decomposition methods like SVM$^{\text{light}}$ on large-scale problems. The rest of this section describes the idea behind CPA for the standard SVM setting (1) in more detail.

In CPA terminology, the original problem (1) is called the master problem. Using the approach of (Teo et al., 2007) one may define a reduced problem of (1) which reads

$$\boldsymbol{w}_t = \operatorname*{argmin}_{\boldsymbol{w}} F_t(\boldsymbol{w}) := \left[\frac{1}{2}\|\boldsymbol{w}\|^2 + CR_t(\boldsymbol{w})\right]. \quad (3)$$

Problem (3) is obtained from the master problem (1) by substituting a piece-wise linear approximation R_t for the risk R while leaving the regularization term unchanged, i.e. only the complex part of the objective F is approximated. The approximation R_t is derived as follows. Since the risk R is a convex function, it can be approximated at any point $\boldsymbol{w}'$ by a linear under estimator

$$R(\boldsymbol{w}) \geq R(\boldsymbol{w}') + \langle \boldsymbol{a}', \boldsymbol{w} - \boldsymbol{w}'\rangle, \qquad \forall \boldsymbol{w} \in \mathbb{R}^n, \quad (4)$$

where $\boldsymbol{a}'$ is any subgradient of R at the point $\boldsymbol{w}'$. We will use a shortcut $b' = R(\boldsymbol{w}') - \langle \boldsymbol{a}', \boldsymbol{w}'\rangle$ to abbreviate (4) as $R(\boldsymbol{w}) \geq \langle \boldsymbol{a}', \boldsymbol{w}\rangle + b'$. In CPA terminology, $\langle \boldsymbol{a}', \boldsymbol{w}\rangle + b' = 0$

is called a cutting plane. A subgradient $\boldsymbol{a}'$ of R at the point $\boldsymbol{w}'$ can be obtained as

$$\boldsymbol{a}' = -\frac{1}{m}\sum_{i=1}^{m}\pi_i y_i \boldsymbol{x}_i, \quad \pi_i = \begin{cases} 1 & \text{if} \quad y_i\langle \boldsymbol{w}', \boldsymbol{x}_i\rangle \leq 1\,, \\ 0 & \text{if} \quad y_i\langle \boldsymbol{w}', \boldsymbol{x}_i\rangle > 1\,. \end{cases} \tag{5}$$

To get a better approximation of the risk R than a single cutting plane, one may use a collection of cutting planes $\{\langle \boldsymbol{a}_i, \boldsymbol{w}\rangle + b_i = 0 \mid i = 1, \ldots, t\}$ at t distinct points $\{\boldsymbol{w}_1, \ldots, \boldsymbol{w}_t\}$ and take their point-wise maximum

$$R_t(\boldsymbol{w}) = \max\left\{0, \max_{i=1,\ldots,t}\left(\langle \boldsymbol{a}_i, \boldsymbol{w}\rangle + b_i\right)\right\}. \tag{6}$$

The zero cutting plane is added to the maximization as the risk R is always greater or equal to zero. It follows directly from (4) that the approximation R_t lower bounds R and thus also F_t lower bounds F.

To select the cutting planes, CPA starts from $t = 0$ (no cutting plane) and then it iterates two steps:

1. Compute $\boldsymbol{w}_t$ by solving the reduced problem (3), which can be cast as a standard QP with t variables.
2. Add a new cutting plane $(\boldsymbol{a}_{t+1}, b_{t+1})$ to approximate the risk R at the current solution $\boldsymbol{w}_t$.

A natural stopping condition for CPA is based on evaluating the ε-optimality condition $F(\boldsymbol{w}_t) - F_t(\boldsymbol{w}_t) \leq \varepsilon$ which, if satisfied, guarantees that $F(\boldsymbol{w}_t) - F(\boldsymbol{w}^*) \leq \varepsilon$ holds. [2] (Joachims, 2006) proved that for arbitrary $\varepsilon > 0$ CPA converges to the ε-optimal solution after $\mathcal{O}(\frac{1}{\varepsilon^2})$ iterations, i.e. it does not depend on the number of examples m. An improved analysis of the CPA published recently (Teo et al., 2007) shows that the number of iterations scales only with $\mathcal{O}(\frac{1}{\varepsilon})$. More important, in practice CPA usually requires only tens of iterations to reach a sufficiently precise solution.

3. Optimized Cutting Plane Algorithm for SVMs (OCAS)

We first point out a source of inefficiency appearing in CPA and then propose a new method to alleviate the problem.

CPA selects a new cutting plane such that the reduced problem objective function $F_t(\boldsymbol{w}_t)$ monotonically increases with w.r.t. the number of iterations t. However, there is no such guarantee for the master problem objective $F(\boldsymbol{w}_t)$. Even though it will ultimately converge to the minimum $F(\boldsymbol{w}^*)$, its value can heavily fluctuate between iterations. The reason for these fluctuations is the following. CPA selects at each iteration t the cutting plane which perfectly approximates the master objective F *at the current solution* $\boldsymbol{w}_t$. However, there is no guarantee that such cutting plane will be an active constraint in the vicinity of the optimum $\boldsymbol{w}^*$, nor must the new solution $\boldsymbol{w}_{t+1}$ of the reduced problem improve the master objective. In fact it often occurs that $F(\boldsymbol{w}_{t+1}) > F(\boldsymbol{w}_t)$.

To speed up the convergence of CPA, we propose a new method which we call the Optimized Cutting Plane Algorithm for SVMs (OCAS). Unlike standard CPA, OCAS aims at simultaneously optimizing the master and reduced problem's objective functions F and F_t, respectively. In addition, OCAS tries to select such cutting planes that have higher chance to actively contribute to the approximation of the master objective function F around the optimum $\boldsymbol{w}^*$. In particular, we propose the following three changes to CPA.

Change 1 We maintain the best so far solution $\boldsymbol{w}_t^{\mathrm{b}}$ obtained during the first t iterations, i.e. $F(\boldsymbol{w}_1^{\mathrm{b}}), \ldots, F(\boldsymbol{w}_t^{\mathrm{b}})$ forms a monotonically decreasing sequence.

Change 2 The new best so far solution $\boldsymbol{w}_t^{\mathrm{b}}$ is found by searching along a line starting at the previous best solution $\boldsymbol{w}_{t-1}^{\mathrm{b}}$ crossing the reduced problem's solution $\boldsymbol{w}_t$, i.e. ,

$$\boldsymbol{w}_t^{\mathrm{b}} = \min_{k\geq 0} F(\boldsymbol{w}_{t-1}^{\mathrm{b}}(1-k) + \boldsymbol{w}_t k)\,, \tag{7}$$

which can be solved exactly in $\mathcal{O}(m \log m)$ time (see Appendix A).

Change 3 The new cutting plane is selected to approximate the master objective F at a point $\boldsymbol{w}_t^{\mathrm{c}}$ which lies in a vicinity of the best so far solution $\boldsymbol{w}_t^{\mathrm{b}}$. In particular, the point $\boldsymbol{w}_t^{c}$ is computed as

$$\boldsymbol{w}_t^{c} = \boldsymbol{w}_t^{\mathrm{b}}(1-\lambda) + \boldsymbol{w}_t\lambda\,, \tag{8}$$

where $\lambda \in (0, 1]$ is a prescribed parameter. Having the point $\boldsymbol{w}_c$, the new cutting plane is computed using Equation (5) such that $F(\boldsymbol{w}_t^{\mathrm{c}}) = F_{t+1}(\boldsymbol{w}_t^{\mathrm{c}})$. Note that although the theoretical bound on the number of iterations (see Theorem 1) does not depend on λ its value has impact on the convergence speed in practice. We found that the value $\lambda = 0.1$ works consistently well in all experiments.

Algorithm 1 describes the proposed OCAS. Figure 1 shows the impact of the proposed changes to the convergence. OCAS generates a monotonically decreasing sequence of master objective values $F(\boldsymbol{w}_1^{\mathrm{b}}), \ldots, F(\boldsymbol{w}_t^{\mathrm{b}})$ and a monotonically strictly increasing sequence of reduced objective values $F_1(\boldsymbol{w}_1), \ldots, F_t(\boldsymbol{w}_t)$. Similar to CPA, a natural stopping condition for OCAS reads

$$F(\boldsymbol{w}_t^{\mathrm{b}}) - F_t(\boldsymbol{w}_t) \leq \varepsilon\,, \tag{9}$$

where $\varepsilon > 0$ is a prescribed precision parameter. Satisfying the condition (9) guarantees that $F(\boldsymbol{w}_t^{\mathrm{b}}) - F(\boldsymbol{w}^*) \leq \varepsilon$ holds.

[2] An alternative stopping condition advocated in (Joachims, 2006) halts the algorithm when $R(\boldsymbol{w}_t) - R_t(\boldsymbol{w}_t) \leq \hat{\varepsilon}$. It can be seen that both the stopping conditions become equivalent if we set $\varepsilon = C\hat{\varepsilon}$.

Algorithm 1 Optimized Cutting Plane Algorithm

1: Set $t = 0$ (i.e. there is no cutting plane at the beginning) and $\boldsymbol{w}_0^{\mathrm{b}} = \mathbf{0}$.
2: **repeat**
3: Compute $\boldsymbol{w}_t$ by solving the reduced problem (3).
4: Compute a new best so far solution $\boldsymbol{w}_t^{\mathrm{b}}$ using the line-search (7).
5: Add a new cutting plane which approximates the risk R at the point $\boldsymbol{w}_t^{\mathrm{c}}$ given by (8), i.e. ,

$$\begin{aligned} \boldsymbol{a}_{t+1} &= -\tfrac{1}{m}\textstyle\sum_{i=1}^{m} \pi_i y_i \boldsymbol{x}_i \,, \\ b_{t+1} &= R(\boldsymbol{w}_t^{\mathrm{c}}) - \langle \boldsymbol{a}_{t+1}, \boldsymbol{w}_t^{\mathrm{c}} \rangle \,, \\ \text{where} \qquad \pi_i &= \begin{cases} 1 & \text{if} \quad y_i \langle \boldsymbol{w}_t^{\mathrm{c}}, \boldsymbol{x}_i \rangle \leq 1 \,, \\ 0 & \text{if} \quad y_i \langle \boldsymbol{w}_t^{\mathrm{c}}, \boldsymbol{x}_i \rangle > 1 \,. \end{cases} \end{aligned}$$

6: $t := t + 1$
7: **until** a stopping condition is satisfied

Theorem 1 *For any $\varepsilon > 0$, $C > 0$, $\lambda \in (0, 1]$, and any training set $\{(\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_m, y_m)\}$, Algorithm 1 satisfies the stopping condition (9) after at most*

$$\max\left\{\frac{2C}{\varepsilon}, \frac{8C^3Q^2}{\varepsilon^2}\right\}, \tag{10}$$

iterations where $Q = \max_{i=1,\ldots,m} \|\boldsymbol{x}_i\|$.

Proof The proof is along the lines of the convergence analysis of the standard CPA (Joachims, 2006). First, it can be shown that violated condition (9) guarantees that adding a new cutting plane $(\boldsymbol{a}_t, b_t)$ leads to an improvement of the reduced objective $\Delta_t = F_{t+1}(\boldsymbol{w}_{t+1}) - F_t(\boldsymbol{w}_t)$ which is not less than $\min\left\{\frac{\varepsilon}{2}, \frac{\varepsilon^2}{8Q^2}\right\}$. Second, by exploiting that $0 \leq F_t(\boldsymbol{w}_t) \leq F(\boldsymbol{w}^*)$ and $F(\boldsymbol{w}^*) \leq F(\mathbf{0}) = C$ one can conclude that the sum of improvements $\sum_{i=0}^{t} \Delta_t$ cannot be greater than C. Combining these two results gives immediately the bound (10). For more details we refer to our technical report (Franc & Sonnenburg, 2007).

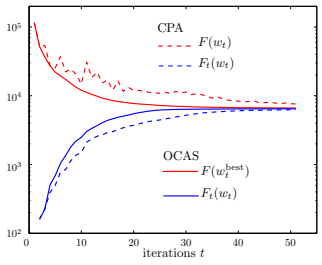

Figure 1. Convergence behaviour of the standard CPA vs. OCAS.

The bound on the maximal number of iterations of OCAS coincides with the bound for CPA given in (Joachims, 2006). Despite the same theoretical bounds, in practice OCAS converges significantly faster compared to CPA (cf. Table 2 in the experiments section).

3.1. Time Complexity and Parallelization

By Theorem 1 the number of iterations of OCAS does not depend on the number of examples m. Hence the overall time complexity is given by the effort required per iteration which is $\mathcal{O}(mn + m \log m) \approx \mathcal{O}(mn)$ (in practice $\log(m) \ll n$, where n is the dimensionality of the data). The per-iteration complexity of the subtasks and the way how they can be effectively parallelized is detailed below:

Output computation involves computation of the dot products $\langle \boldsymbol{w}_t, \boldsymbol{x}_i \rangle$, $i = 1, \ldots, m$, which requires $\mathcal{O}(s)$ time, where s equals the number of non-zero elements in the training examples. Distributing the computation equally to p processor leads to $\mathcal{O}(\frac{s}{p})$ time.

Line-search The dominant part is sorting $|K|$ numbers ($K \leq m$, see Appendix A for details) which can be done in $\mathcal{O}(|K| \log |K|)$. A speedup can be achieved by parallelizing the sorting function to using p processors, reducing complexity to $\mathcal{O}\big(\frac{|K| \log |K|}{p}\big)$. Note that our implementation of OCAS uses quicksort, whose worst case complexity is $\mathcal{O}(|K|^2)$, although its *expected* run-time is $\mathcal{O}(|K| \log |K|)$.

Cutting plane computation The dominant part requires computing the sum $-\frac{1}{m}\sum_{i=1}^{m} \pi_i y_i \boldsymbol{x}_i$ which can be done in $\mathcal{O}(s_\pi)$, where s_π is the number of non-zero elements in the training examples for which π_i is non-zero. Using p processors leads to $\mathcal{O}(\frac{s_\pi}{p})$ time.

Reduced problem The size of the reduced problem (3) is upper bound by the number of iterations which is invariant against the dataset size, hence it requires $\mathcal{O}(1)$ time. Though solving the reduced problem cannot be easily parallelized, it does not constitute the bottleneck as the number of iterations required in practice is small (cf. Table 2).

4. Experiments

We now compare current state-of-the-art SVM solvers (SGD, Pegasos, SVM$^{\text{light}}$, SVM$^{\text{perf}}$, BMRM[3] on a variety of datasets with the proposed method (OCAS) using 5 carefully crafted experiments measuring:

1. Training time and objective for optimal C
2. Speed of convergence (time vs. objective)
3. Time to perform a full model selection
4. Scalability w.r.t. dataset size
5. Effects of parallelization

To this end we implemented OCAS and the standard CPA[4] in C. We use the very general compressed sparse column

[3] SGD version 1.1 (svmsgd2) `http://leon.bottou.org/projects/sgd`, SVM$^{\text{light}}$ 6.01 and SVM$^{\text{perf}}$ 2.1 `http://svmlight.joachims.org`, pegasos `http://ttic.uchicago.edu/~shai/code/`, BMRM version 0.01 `http://users.rsise.anu.edu.au/~chteo/BMRM.html`.

[4] To not measure implementation specific effects (solver, dot-product computation) etc.

(CSC) representation to store the data. Here each element is represented by an index and a value (each 64bit). To solve the reduced problem (3), we use our implementation of improved SMO (Fan et al., 2005).

4.1. Experimental Setup

The datasets used throughout the experiments are summarized in Table 1. We augmented the Cov1, CCAT, Astro datasets from (Joachims, 2006) by the MNIST, a artificial dense and two larger bioinformatics splice datasets for worm and human. The artificial dataset was generated

Dataset	Examples	Dim	Sp	Split
MNIST	70,000	784	19	77/09/14
Astro	99,757	62,369	0.08	43/05/52
Artificial	150,000	500	100	33/33/33
Cov1	581,012	54	22	81/09/10
CCAT	804,414	47,236	0.16	87/10/03
Worm	1,026,036	804	25	80/05/15
Human	15,028,326	564	25	

Table 1. Datasets used in the experimental evaluation. Sp denotes the average number of non-zero elements of a dataset in percent. Split describes the size of the train/validation/test sets in percent. Datasets are available from the following urls: MNIST `http://yann.lecun.com/exdb/mnist/`, Cov1 `http://kdd.ics.uci.edu/databases/covertype/covertype.html`, CCAT `http://www.daviddlewis.com/resources/testcollections/rcv1/`, Worm and Human `http://www.fml.tuebingen.mpg.de/raetsch/projects/lsmkl`

from two Gaussians with different diagonal covarience matrices of multiple scale. If not otherwise stated experiments were performed on a 2.4GHz AMD Opteron Linux machine. We disabled the bias term in the comparison. As stopping conditions we use the defaults: $\varepsilon_{light} = \varepsilon_{gpdt} = 0.001$, $\varepsilon_{perf} = 0.1$ and $\varepsilon_{bmrm} = 0.001$. For OCAS we used the same stopping condition which is implemented in SVM$^{\text{perf}}$, i.e., $\frac{F(\boldsymbol{w})-F_t(\boldsymbol{w})}{C} \leq \frac{\varepsilon_{perf}}{100} = 10^{-3}$. Note that these ε have a very different meaning denoting the maximum KKT violation for SVM$^{\text{light}}$, the maximum tolerated violation of constraints for SVM$^{\text{perf}}$ and for the BMRM the relative duality gap. For SGD we fix the number of iterations to 10 and for Pegasos we use $100/\lambda$, as suggested in (Shwartz et al., 2007). For the regularization parameter C and λ we use the following relations: $\lambda = 1/C$, $C_{perf} = C/100$, $C_{bmrm} = C$ and $C_{light} = Cm$. Throughout experiments we use C as a shortcut for C_{light}.[5]

[5]The exact cmdlines are: `svm_perf_learn -l 2 -m 0 -t 0 --b 0 -e 0.1 -c` C_{perf}, `pegasos -lambda` λ `-iter` $100/\lambda$ `-k 1`, `svm_learn -m 0 -t 0 -b 0 -e 1e-3 -c` C_{light}, `bmrm-train -r 1 -m 10000 -i 999999 -e 1e-3 -c` C_{bmrm}, `svmsgd2 -lambda` λ `-epochs 10`

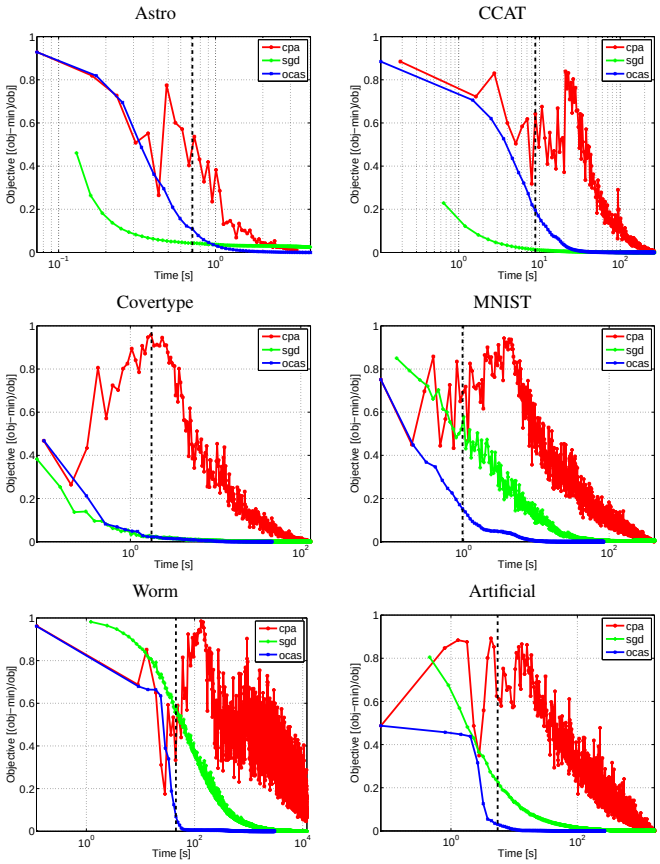

Figure 2. Objective value vs. Training time of CPA (red), SGD (green) and OCAS (blue) measured for a different number of training examples.The dashed line shows the time required to run SGD for 10 iterations. OCAS was stopped when the precision fell below 10^{-6} or the training time for CPA was achieved. In all cases OCAS achieves the minimal objective value and is even on half of the datasets already in the beginning outperforming all other methods including SGD.

4.2. Evaluation

In the following paragraphs we run and evaluate the aforementioned experiments 1–5.

Training time and objective for optimal C We trained all methods on all except the human splice dataset using the training data and measured training time (in seconds) and computed the unconstrained objective value $F(\boldsymbol{w})$

The obtained results are displayed in Table 2. The proposed method – OCAS – consistently outperforms all its competitors of the *accurate solver* category on all benchmark datasets in terms of training time while obtaining a comparable (often the best) objective value. BMRM and SVM$^{\text{perf}}$ implement the same CPA algorithm but due to implementation specific details results can be different. Our implementation of CPA gives very similar results (not shown).[6] Note that for SGD, Pegasos (and SVM$^{perf2.0}$ –

Table 2. Comparison of OCAS against other SVM solvers. "-" means not converged, blank not attempted. Shown in bold is the unconstrained SVM objective value Eq. (1). The two numbers below the objective value denote the number of iterations (left) and the training time in seconds (right). Lower timing and objective values mean "better." All methods solve the unbiased problem. As convergence criteria the standard settings described in Section 4.1 are used. On MNIST pegasos ran into numerical problems. OCAS clearly outperforms all of its competitors in the *accurate solver* category by a large margin achieving similar and often lowest objective value. The objective value obtained by SGD and Pegasos is often far away from the optimal solution, cf. text for a further discussion.

not shown) the objective value sometimes deviates significantly from the true objective. As a result the learned classifier may differ substantially from the optimal parameter $\boldsymbol{w}^*$. However as training times for SGD are significantly below all others it remains unclear whether SGD achieves the same precision using less time when run for further iterations. An answer to this question is given in the next paragraph.

Speed of convergence (time vs. objective) To address this problem we re-ran the best methods CPA, OCAS and SGD, recording *intermediate* progress, i.e. while optimization record time and objective for several time points. The results are shown in Figure 2. Ocas was stopped when reaching the maximum time or a precision of $1 - F(\boldsymbol{w}^*)/F(\boldsymbol{w}) \leq 10^{-6}$ and was in all cases achieving the minimum objective. In three of the six datasets OCAS not only as expected at a later time point achieves the best objective but already from the very beginning. Further analysis made clear that OCAS wins over SGD in cases where *large* C were used and thus the optimization problem is more difficult. Still plain SGD outcompetes even CPA. One may argue that practically the true objective is not the unconstrained SVM-primal value (1), but the performance on a validation set, i.e. optimization is stopped when the validation error won't change.

One should however note that one in this case does not obtain an SVM but *some classifier* instead. Then a comparison should not be limited to SVM solvers but should be open to any other large scale approach, like on-line algorithms (e.g. perceptrons) too. We argue that to compare *SVM solvers* in a fair way one needs to compare objective values. As it is still interesting to see how the methods perform w.r.t. classification performance we analyze them under this criterion in the next paragraph.

Time to perform a full model selection When using SVMs in practice, their C parameter needs to be tuned in model selection. We therefore train all methods using different settings[7] for C on the training part of all datasets, evaluate them on the validation set and choose the best model to do predictions on the test set. As performance measure we use the area under the receiver operator characteristic curve (auROC) (Fawcett, 2003). Again among the *accurate methods* OCAS outperforms its competitors by a large margin, followed by SVM$^{\text{perf}}$. Note that for all *accurate methods* the performance is very similar and has little variance. Except for the artificial dataset plain SGD is clearly fastest while achieving a similar accuracy. However the optimal parameter settings for accurate SVMs and SGD are different. Accurate SVM solvers use a larger C constant than SGD. For lower C the objective function is dominated by the regularization term $\|w\|$. A potential explanation is that SGDs update rule puts more emphasize on the regularization term and SGD when not run for a large number of iterations does imply early stopping.

Scalability w.r.t. Dataset Size In this section, we investigate how computational time of OCAS, CPA and SGD scales with the number of examples on the worm splice dataset, for sizes 100 to $1,026,036$. We again use our implementation of CPA that shares essential sub-routines with OCAS. Results are shown and discussed in Figure 3.

CPA did not converge for large C on worm even after 5000 iterations. Most likely the core solver of SVM$^{\text{perf}}$ is more robust.

[7] For Worm and Artificial we used $C = 0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1, 5,$ for CCAT, Astro, Cov1 $C = 0.1, 0.5, 1, 5, 10$ and for MNIST $C = 1, 5, 10, 50, 100$.

Table 3. Comparison of OCAS against other SVM solvers. "-" means not converged, blank not attempted. Shown in bold is the area under the receiver operator characteristic curve (auROC) obtained for the best model obtained via model selection over a wide range of regularization constants C. In each cell, numbers on the left denote the optimal C, numbers on the right the training time in seconds to perform the whole model selection. As there is little variance, for accurate SVM solvers only the mean and standard deviation of the auROC are shown. SGD is clearly fastest achieving similar performance for all except for the artificial dataset. However often a smaller C than the ones chosen by accurate SVMs is selected — an indication that the learned decision function is only remotely SVM-like. Among the accurate solvers OCAS clearly outperforms its competitors. It should be noted that training times for all accurate methods are dominated by training for large C (see Table 2 for training times for the optimal C). For further discussion see the text.

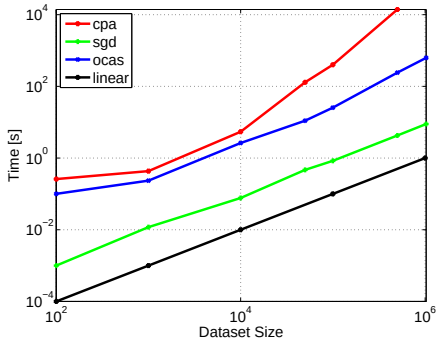

Figure 3. This figure displays how the methods scale with dataset size on the worm splice dataset. The slope of the "lines" in this figure denotes the exponent e in $\mathcal{O}(m^e)$, where the black line denotes linear effort $\mathcal{O}(m)$. Both OCAS and SGD scale about linearly. Note that SGD is much faster (as it runs for a fixed number of iterations and thus does early stopping).

Effects of Parallelization As OCAS training times are very low on the above datasets, we also apply OCAS to the 15 million human splice dataset. Using a 2.4GHz 16-Core AMD Opteron Linux machine we run OCAS using $C = 0.0001$ on 1 to 16 CPUs and show the accumulated times for each of the subtasks, the total training time and the achieved speedup w.r.t. the single CPU algorithm in Table 4. Also shown is the time accumulated for each of the threads. As can be seen — except for the line search — computations distribute nicely. Using 8 CPU cores the speedup saturates at a factor of 4.5, most likely as memory access becomes the bottleneck (for 8 CPUs output computation creates a load of 28GB/s just on memory reads).

5. Conclusions

We have developed a new Linear SVM solver called OCAS, which outperforms current state of the art SVM solvers by several orders of magnitude. OCAS even in the early optimization steps shows often faster convergence than the so far in this domain dominating approximative methods. By parallelizing the subtasks of the algorithm, OCAS gained additional speedups of factors up to 4.6 on a multi-core multiprocessor machine. Using OCAS we were able to train on a dataset of size 15 million examples (itself about 32GB in size) in just 671 seconds. As extensions to one and multi-class are straight forward, we plan to implement them in the near future. Furthermore OCAS can be extended to work with a bias term. Finally it will be future work to investigate how the kernel framework can be incorporated into OCAS and how the $\mathcal{O}(\frac{1}{\varepsilon})$ result of (Teo et al., 2007) can be applied to OCAS. An implementation of OCAS is available within the shogun toolbox `http://www.shogun-toolbox.org` and as a separate library from `http://ida.first.fraunhofer.de/~franc/ocas`.

CPUs	1	2	4	8	16
speedup	1	1.77	3.09	4.5	4.6
line search (s)	238	184	178	139	117
$\boldsymbol{a}_t$ (s)	270	155	80	49	45
output (s)	2476	1300	640	397	410
total (s)	3087	1742	998	684	671

Table 4. Speedups due to parallelizing OCAS achieved on 15 million human splice dataset.

A. Computing Line-search efficiently

The line-search (7) is an essential procedure of OCAS which is called at every iteration. We show that the line-search can be solved exactly in $\mathcal{O}(m \log m)$ time. First, we introduce a more compact notation for the objective function of the line-search problem (7) $F(\boldsymbol{w}_{t-1}^{\mathrm{b}}(1-k) + \boldsymbol{w}_t k)$ by $G(k) = g_0(k) + \sum_{i=1}^m g_i(k)$ where $g_0(k) = \frac{1}{2}k^2 A_0 + kB_0 + C_0$, $g_i(k) = \max\{0, kB_i + C_i\}$, $A_0 = \|\boldsymbol{w}_{t-1}^{\mathrm{b}} - \boldsymbol{w}_t\|^2$, $B_0 = \langle \boldsymbol{w}_{t-1}^{\mathrm{b}}, \boldsymbol{w}_t - \boldsymbol{w}_{t-1}^{\mathrm{b}} \rangle$, $C_0 = \frac{1}{2}\|\boldsymbol{w}_{t-1}^{\mathrm{b}}\|^2$, $B_i = \frac{C}{m} y_i \langle \boldsymbol{x}_i, \boldsymbol{w}_{t-1}^{\mathrm{b}} - \boldsymbol{w}_t \rangle$ and $C_i = \frac{C}{m}(1 - y_i \langle \boldsymbol{x}_i, \boldsymbol{w}_{t-1}^{\mathrm{b}} \rangle)$. Hence the line-search (7) involves solving $k^* = \operatorname{argmin}_{k \geq 0} G(k)$ and computing $\boldsymbol{w}_t^{\mathrm{b}} = \boldsymbol{w}_{t-1}^{\mathrm{b}}(1 - k^*) + \boldsymbol{w}_t k^*$. As function G is convex the unconstrained minimum of G is attained at the point k^* at which the subdifferential $\partial G(k)$ contains zero, i.e. $0 \in \partial G(k^*)$. The subdifferential of G is $\partial G(k) = kA_0 + B_0 + \sum_{i=1}^m \partial g_i(k)$,

$$\partial g_i(k) = \begin{cases} 0 & \text{if} \quad kB_i + C_i < 0\,, \\ B_i & \text{if} \quad kB_i + C_i > 0\,, \\ [0, B_i] & \text{if} \quad kB_i + C_i = 0\,. \end{cases}$$

Note that the subdifferential is not a function as there ex-

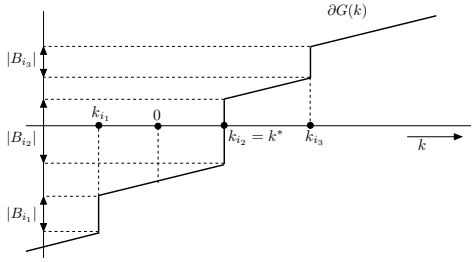

Figure 4. Illustration of the subgradient $\partial G(k)$ of the objective function $G(k)$ minimized in the line-search.

ist k for which $\partial G(k)$ is an interval. The first term of the subdifferential $\partial G(k)$ is an ascending linear function $kA_0 + B_0$ since A_0 must be greater than zero (A_0 is zero only if the algorithm has converged but then the line-search is not invoked). The term $\partial g_i(k)$ is either constantly zero, if $B_i = 0$, or it is a step-like jump whose value changes at the point $k_i = -\frac{C_i}{B_i}$. The value of $\partial g_i(k)$ w.r.t. k is summarized in Table 5. Hence the subdifferential $\partial G(k)$ is a

	$k < k_i$	$k = k_i$	$k > k_i$
$B_i = 0$	0	0	0
$B_i < 0$	B_i	$[B_i, 0]$	0
$B_i > 0$	0	$[0, B_i]$	B_i

Table 5. The value of $\partial g_i(k)$ with respect to k.

monotonically increasing function as is illustrated in Figure 4. To solve $k^* = \operatorname{argmin}_{k \geq 0} G(k)$ we proceed as follows: If $\max(\partial G(0))$ is strictly greater than zero then the unconstrained minimum $\operatorname{argmin}_k G(k)$ is at a point less or equal to 0. Thus the constrained minimum is attained at the point $k^* = 0$.

If $\max(\partial G(0))$ is less then zero then the optimum k^* corresponds to the unconstrained optimum $\operatorname{argmin}_k G(k)$ attained at the intersection between the graph of $\partial G(k)$ and the x-axis. This point can be found efficiently by sorting $K = \{k_i \mid k_i > 0, i = 1, \ldots, m\}$ and checking the condition $0 \in G(k)$ for $k \in K$ and for k in the intervals which split the domain $(0, \infty)$ in the points K. These computation are dominated by sorting the numbers K which takes $\mathcal{O}(|K| \log |K|)$.

Stopping Conditions for Exact Computation of Leave-One-Out Error in Support Vector Machines

Abstract

We propose a new stopping condition for a Support Vector Machine (SVM) solver which precisely reflects the objective of the Leave-One-Out error computation. The stopping condition guarantees that the output on an intermediate SVM solution is identical to the output of the optimal SVM solution with one data point excluded from the training set. A simple augmentation of a general SVM training algorithm allows one to use a stopping criterion equivalent to the proposed sufficient condition. A comprehensive experimental evaluation of our method shows consistent speedup of the exact LOO computation by our method, up to the factor of 13 for the linear kernel. The new algorithm can be seen as an example of constructive guidance of an optimization algorithm towards achieving the best attainable expected risk at optimal computational cost.

1. Introduction

The interrelation between a computational complexity and a generalization ability of learning algorithms has seldom been considered in machine learning. Since the solutions to a majority of learning problems are obtained by iterative optimization algorithms, solution accuracy plays an important role in the estimation of expected risk (Bartlett & Mendelson, 2006). In practice, the available computational resources necessitate a tradeoff between approximation accuracy determined by the choice of a class of functions, estimation error determined by a finite set of examples, and an optimization error determined by the accuracy of a solver attainable within a given time budget (Bottou & Bousquet, 2008).

The asymptotic analysis in (Bottou & Bousquet, 2008) provides upper bounds on the time required to reach a certain expected risk by a given algorithm. From the practical point of view, it is desirable to have *constructive* influence over a learning algorithms, by choosing its parameters, such as e.g. learning rate or stopping conditions, to reach the best attainable expected risk. The present contribution provides an example of such a constructive mechanism by developing optimal stopping conditions for SVM training using a particular estimator of an expected risk – the leave-one-out (LOO) error. Although exact computation of a LOO error is hardly used for large-scale learning due to its computational burden, our method is feasible for "small-scale" learning with "expensive" data (e.g. in bioinformatics or finance), especially when accurate estimation of expected risk is required.

The LOO is known to provide an unbiased estimator of the generalization error (Lunts & Brailovskiy, 1967). The naive computation of the LOO error, i.e. by explicit relearning after exclusion of each single example, is in all but the simplest cases impractical. The problem of speeding up a computation of a LOO error has received significant attention. The following approaches exist:

- LOO bounds provide an estimate of the LOO error given an optimal solution of the SVM training problem ((Joachims, 2000; Vapnik & Chapelle, 2000; Jaakkola & Haussler, 1999; Zhang, 2001)). These bounds are computationally efficient but imprecise. In practice, if an accurate estimate of the classification accuracy is needed, exact computation of the LOO error is unavoidable.
- Incremental SVM (Cauwenberghs & Poggio, 2000) allows one to exactly determine for each candidate

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

training point – *after* obtaining the optimal SVM solution – whether or not it will be a LOO error. This approach avoids explicit re-training, but incremental unlearning of points is complicated and requires special organization of matrix operations (Laskov et al., 2007).

- Loose stopping conditions based on the ε-KKT allow one to speed up the LOO computation *before* obtaining an optimal solution. Such methods, (e.g. (Lee & Lin, 2000; Martin et al., 2004)) use fairly simple heuristics, but lack theoretical justification that would connect the ε to a precision of the LOO computation. As it is illustrated in the examples in Section 2, these methods can also be imprecise.

In this contribution we propose a new stopping condition for an SVM solver which *precisely reflects* the objective of the LOO error computation. Our main result, given in Theorem 1, provides a sufficient condition for which the output on an intermediate SVM solution is identical to the output of the optimal SVM solution with one data point excluded from the training set. Although this sufficient condition cannot be computed in practice, we propose a simple augmentation of a general SVM training algorithm which allows one to use a stopping criterion equivalent to the proposed sufficient condition.

2. Leave-One-Out Error Estimate For Support Vector Machines Classifier

Let $\mathcal{X}$ be a set of inputs and $\mathcal{Y} = \{-1, +1\}$ a set of labels of an analyzed object. Let further $\mathcal{T}_{XY} = \{(x_1, y_1), \ldots, (x_m, y_m)\} \in (\mathcal{X} \times \mathcal{Y})^m$ be a finite training set i.i.d. sampled from unknown $P(x, y)$. The goal is to learn a classifier $f\colon \mathcal{X} \to \mathcal{Y}$ minimizing the probability of misclassification $R[f] = \int V(y, f(x))dP(x, y)$ where $V(y, y') = 1$ for $y \neq y'$ and $V(y, y') = 0$ otherwise.

The SVMs represent the input states in the Reproducing Kernel Hilbert Space (RKHS) via a map $\mathbf{\Phi}\colon \mathcal{X} \to \mathcal{H}$ which is implicitly defined by a kernel function $k\colon \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ (Schölkopf & Smola, 2002). The classifier is assumed to be linear, i.e., $f(x; \boldsymbol{w}, b) = \langle \boldsymbol{w}, \mathbf{\Phi}(x) \rangle + b$, where $\boldsymbol{w} \in \mathcal{H}$, $b \in \mathbb{R}$ are unknown parameters and $\langle \cdot, \cdot \rangle$ denotes an inner product in RKHS. Because $R[f]$ cannot be minimized directly due to the unknown $P(x, y)$, the SVMs replace $R[f]$ by a regularized risk its minimization leads to

$$(\boldsymbol{w}^*, b^*) = \operatorname*{argmin}_{\boldsymbol{w} \in \mathcal{H}, b \in \mathbb{R}} \left(\frac{1}{2} \|\boldsymbol{w}\|^2_{\mathcal{H}} + C \sum_{i \in \mathcal{I}} \hat{V}(y_i, f(x_i; \boldsymbol{w}, b)) \right) \tag{1}$$

where $C \in \mathbb{R}^+$ is a regularization constant, $\hat{V}(y_i, f(x_i; \boldsymbol{w},)) = \max(0, 1 - y_i f(x_i; \boldsymbol{w}, b))$ is a convex piece-wise linear approximation of $V(y_i, f(x_i; \boldsymbol{w}, b))$ and $\mathcal{I} = \{1, \ldots, m\}$. By the Representer theorem (Schölkopf & Smola, 2002), the optimal SVM classifier $f(x; \boldsymbol{w}^*, b^*)$ can be expressed in the form

$$f(x; \boldsymbol{\alpha}, b) = \begin{cases} +1 & \text{if} \quad \sum\limits_{i \in \mathcal{I}} \alpha_i y_i k(x, x_i) + b \geq 0 \,, \\ -1 & \text{if} \quad \sum\limits_{i \in \mathcal{I}} \alpha_i y_i k(x, x_i) + b < 0 \,, \end{cases} \tag{2}$$

where $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_m)^T \in \mathbb{R}^m$, $b \in \mathbb{R}$. Substituting (2) to (1) allows to find the optimal SVM classifier by solving a convex QP task

$$(\boldsymbol{\alpha}^*, b^*, \boldsymbol{\xi}^*) = \operatorname*{argmin}_{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \in \mathcal{A}} F(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \tag{3}$$

where the convex objective function reads

$$F(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) = \frac{1}{2} \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{I}} \alpha_i \alpha_j y_i y_j k(x_i, x_j) + C \sum_{i \in \mathcal{I}} \xi_i \,,$$

and the convex feasible set $\mathcal{A}$ contains all $(\boldsymbol{\alpha} \in \mathbb{R}^m, b \in \mathbb{R}, \boldsymbol{\xi} \in \mathbb{R}^m)$ satisfying

$$\begin{aligned} y_i \left(\sum_{j \in \mathcal{I}} \alpha_j y_j k(x_i, x_j) + b \right) &\geq 1 - \xi_i \,, \quad i \in \mathcal{I} \,, \\ \xi_i &\geq 0 \,, \quad i \in \mathcal{I} \,. \end{aligned}$$

Minimizing the regularized risk (1) (or QP task (3) respectively) allows to find parameters $(\boldsymbol{\alpha}, b)$ of the SVM classifier provided the hyper-parameters, i.e., the kernel function k and the regularization constant C, are known. This is not the case in practice and the hyper-parameters (C, k) must be optimized as well. A common approach is to select the best (C, k) from a given finite set Θ by minimizing some performance measure. The set Θ is usually created by reasonably discretizing the hyper-parameters space. As the performance measure, the LOO error $R_{LOO}[f]$ is a common choice.

Let $(\boldsymbol{\alpha}^*(r), b^*(r), \boldsymbol{\xi}^*(r))$ denote the optimal solution of the primal QP task (3) with r-th example removed from the training set which is equivalent to solving the task

$$(\boldsymbol{\alpha}^*(r), b^*(r), \boldsymbol{\xi}^*(r)) = \operatorname*{argmin}_{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \in \mathcal{A}(r)} F(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \,, \tag{4}$$

where $\mathcal{A}(r) = \mathcal{A} \cap \{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \mid \alpha_r = 0\}$, i.e., $\mathcal{A}(r)$ denotes the original feasible set $\mathcal{A}$ enriched by an additional constraint $\alpha_r = 0$. The LOO error estimator is defined as

$$R_{LOO}[f(\cdot; \boldsymbol{\alpha}^*, b^*)] = \frac{1}{m} \sum_{r \in \mathcal{I}} V(y_r, f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))) \,. \tag{5}$$

The major practical disadvantage of the LOO error is its high computational cost. A naive approach to compute LOO requires solving m different QP tasks (4). In some

cases, however, the value $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ can be immediately derived from the optimal solution $(\boldsymbol{\alpha}^*, b^*, \boldsymbol{\xi}^*)$ computed from the entire training set. Table 1 summarizes the known sufficiency checks; the implication 1 is generally known and the implications 2, 3 are due to (Joachims, 2000).

1. If $\alpha_r^* = 0$ then $y_r = f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$.
2. If $y_r \neq f(x_r; \boldsymbol{\alpha}^*, b^*)$ then $y_r \neq f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$.
3. Let R^2 be an upper bound on $k(x,x) - k(x,x')$, $\forall x, x' \in \mathcal{X}$, and let $(\boldsymbol{\alpha}^*, b^*, \boldsymbol{\xi}^*)$ be a stable solution which means that there exist at least one $i \in \mathcal{I}$ such that $0 < \alpha_i^* < C$. In this case, if $2\alpha_r^* R^2 + \xi_r^* < 1$ then $y_r = f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$.

Table 1. Sufficiency checks for computing $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ directly from $(\boldsymbol{\alpha}^*, b^*, \boldsymbol{\xi}^*)$.

A portion of the training examples for which the sufficiency checks apply depends on the problem at hand (for empirical study see (Martin et al., 2004)). (Joachims, 2000) proposed using the sufficiency checks to compute an upper bound on the LOO error called $\xi\alpha$-estimator. It has been empirically shown, that in general the $\xi\alpha$-estimator is not sufficiently precise for the hyper-parameter tuning (Duan et al., 2003). Algorithm 1 shows a standard procedure of computing the LOO error exactly with the use of the sufficiency checks to reduced the number of cases when the solution of the QP task (4) is required.

Algorithm 1 Computation of the LOO Error

1: Solve the QP task (3) to obtain $(\boldsymbol{\alpha}^*, b^*, \boldsymbol{\xi}^*)$.
2: Apply the sufficiency checks from Table 1 to compute $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ from $(\boldsymbol{\alpha}^*, b^*, \boldsymbol{\xi}^*)$.
3: For examples unresolved in Step 2 solve the QP task (4) to obtain $(\boldsymbol{\alpha}^*(r), b^*(r))$.
4: Compute the LOO error by (5) using $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$, $r \in \mathcal{I}$ obtained in Steps 2 and 3.

Algorithm 1 requires the use of an optimization method solving the QP tasks (3) and (4) exactly, i.e., producing the optimal solutions. Although such optimization methods exist, they are applicable only for very small problems. In practice, the QP tasks are solved only approximately via their dual representation which is more suitable for optimization due to a simpler feasible set. In particular, the minimizer $\boldsymbol{\alpha}^*$ of the primal QP task (3) can be equivalently computed by solving the dual QP task

$$\boldsymbol{\alpha}^* = \operatorname*{argmax}_{\boldsymbol{\alpha} \in \mathcal{B}} \left(\sum_{i \in \mathcal{I}} \alpha_i - \frac{1}{2} \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{I}} \alpha_i \alpha_j y_i y_j k(x_i, x_j) \right), \tag{6}$$

where $\mathcal{B}$ is a convex feasible set which contains all $\boldsymbol{\alpha} \in \mathbb{R}^m$ satisfying

$$\sum_{i \in \mathcal{I}} \alpha_i y_i = 0\,, \quad \text{and} \quad 0 \leq \alpha_i \leq C\,, i \in \mathcal{I}\,.$$

We will use $G(\boldsymbol{\alpha})$ to denote the objective function of (6). Having $\boldsymbol{\alpha}^*$ computed, the remaining primal variables $(b^*, \boldsymbol{\xi}^*)$ can be obtained easily from the Karush-Kuhn-Tucker (KKT) optimality conditions (e.g., (Boyd & Vandenberghe, 2004)). Similarly, the minimizer $\boldsymbol{\alpha}^*(r)$ of the QP task (4) is obtained by solving the dual

$$\boldsymbol{\alpha}^*(r) = \operatorname*{argmax}_{\boldsymbol{\alpha} \in \mathcal{B}(r)} G(\boldsymbol{\alpha})\,, \tag{7}$$

where $\mathcal{B}(r) = \mathcal{B} \cap \{\boldsymbol{\alpha} \mid \alpha_r = 0\}$ and the primal variables $(b^*(r), \boldsymbol{\xi}^*(r))$ can be again obtained by the KKT conditions. From the optimization point of view, the QP tasks (6) and (7) are equivalent since the latter can be converted to the former simply by excluding the r-th variable. Thus we now concentrate only on the optimization of the QP task (6).

Algorithm 2 Commonly used iterative QP solver

1: Initialize $t := 0$ and $\boldsymbol{\alpha}^{(t)} \in \mathcal{B}$.
2: $t := t + 1$.
3: Update $\boldsymbol{\alpha}^{(t-1)} \rightarrow \boldsymbol{\alpha}^{(t)}$, i.e., find $\boldsymbol{\alpha}^{(t)} \in \mathcal{B}$ such that $G(\boldsymbol{\alpha}^{(t-1)}) < G(\boldsymbol{\alpha}^{(t)})$.
4: If $\boldsymbol{\alpha}^{(t)}$ satisfies the ε-KKT conditions (8) halt otherwise go to 2.

A framework of a commonly used QP solver optimizing (6) describes Algorithm 2. Among the most popular methods which fit to the framework of Algorithm 2 belong the Sequential Minimal Optimizer (SMO) (Platt, 1998), SVM ^{light} (Joachims, 1998) and other decomposition methods (e.g. (Vapnik, 1995; Osuna et al., 1997)). All these solvers iteratively increase the dual criterion $G(\boldsymbol{\alpha})$ until the solution satisfies stopping conditions. A relaxed version of the KKT optimality conditions is the most frequently used stopping criterion: let $\varepsilon \geq 0$ be a prescribed number and $\nabla_i(\boldsymbol{\alpha}) = 1 - y_i \sum_{j \in \mathcal{I}} \alpha_j y_j k(x_i, x_j)$; then a vector $\boldsymbol{\alpha} \in \mathcal{B}$ satisfies the relaxed KKT conditions (e.g. (Keerthi et al., 2001)) if there exist $b \in \mathbb{R}$ such that

$$\begin{array}{rcll} \nabla_i(\boldsymbol{\alpha}) + by_i & \leq & \varepsilon\,, & \text{if} \quad \alpha_i = 0\,, \\ -\nabla_i(\boldsymbol{\alpha}) + by_i & \leq & \varepsilon\,, & \text{if} \quad \alpha_i = C\,, \\ |\, -\nabla_i(\boldsymbol{\alpha}) + by_i \,| & \leq & \varepsilon\,, & \text{if} \quad 0 < \alpha_i < C\,. \end{array} \tag{8}$$

The tightness of the stopping conditions (8) is controlled by $\varepsilon \geq 0$; hereafter we will refer to (8) as the ε-KKT conditions. An advantage of the ε-KKT is their simplicity and a low computational overhead: $O(m)$ operations since $\nabla_i(\boldsymbol{\alpha})$ is usually available during the course of the

QP solver. A disadvantage of the ε-KKT conditions is a tricky choice of ε. Provided $\varepsilon = 0$, the solution $\boldsymbol{\alpha}$ satisfying the ε-KKT conditions is guaranteed to be optimal. The practically applicable QP solvers, however, are guaranteed to halt in a finite number of iterations only for $\varepsilon > 0$. A typically used value is $\varepsilon = 0.001$, e.g., in software packages SVM^{light} ((Joachims, 1998)) or `svmlib` ((Chang & Lin, 2001)). To our knowledge, there is no theoretical result connecting $\varepsilon > 0$ to the value of $R_{LOO}[f(\cdot; \boldsymbol{\alpha}^*, b^*)]$ which is the only desired outcome of the entire computation.

We will illustrate the impact of ε when the LOO error estimator is used for a model selection. Let Θ be a given finite set of hyper-parameters $\boldsymbol{\theta} = (C, k)$. Let $R_{LOO}(\boldsymbol{\theta}, \varepsilon)$ denote the LOO error estimate computed for given $\boldsymbol{\theta}$ using Algorithm 1 with a QP solver in Algorithm 2. Thus the estimated LOO error $R_{LOO}(\theta, \varepsilon)$ is a function of both the hyper-parameters $\boldsymbol{\theta}$ and ε. For a fixed value $\varepsilon > 0$, the model selection produces the hyper-parameters

$$\boldsymbol{\theta}(\varepsilon) = \operatorname*{argmin}_{\boldsymbol{\theta} \in \Theta} R_{LOO}(\boldsymbol{\theta}, \varepsilon) \; . \tag{9}$$

Figure 1 plots the behavior of $R_{LOO}(\boldsymbol{\theta}(\varepsilon), \varepsilon)$ and $R_{LOO}(\boldsymbol{\theta}(10^{-4}), \varepsilon)$, as well as the cost of the LOO error computation as a function of ε for three datasets selected from the IDA repository (cf. Section 5).

The "golden truth" expected risk is given by the left-most plots in the graphs (using $\varepsilon = 10^{-4}$ for both model selection and risk estimation). The dashed line representing $R_{LOO}(\boldsymbol{\theta}(10^{-4}), \varepsilon)$ shows that the expected risk is slightly overestimated provided we use high accuracy for model selection and variable accuracy for risk estimation. The solid line representing $R_{LOO}(\boldsymbol{\theta}(\varepsilon), \varepsilon)$ shows that a low-accuracy LOO computation used in model selection eventually results in overfitting, as a model is selected that grossly underestimates the expected risk. Interestingly, both plots coincide until a certain breakdown point beyond which the low-accuracy LOO estimation runs aground. The breakdown point varies between 0.001 and 0.1 depending on a dataset. This suggests that a commonly used $\varepsilon = 0.001$ is a reasonable setting to obtain an accurate estimate. It is, however, clear from the timing plots that knowing the right accuracy could significantly lower the computational cost.

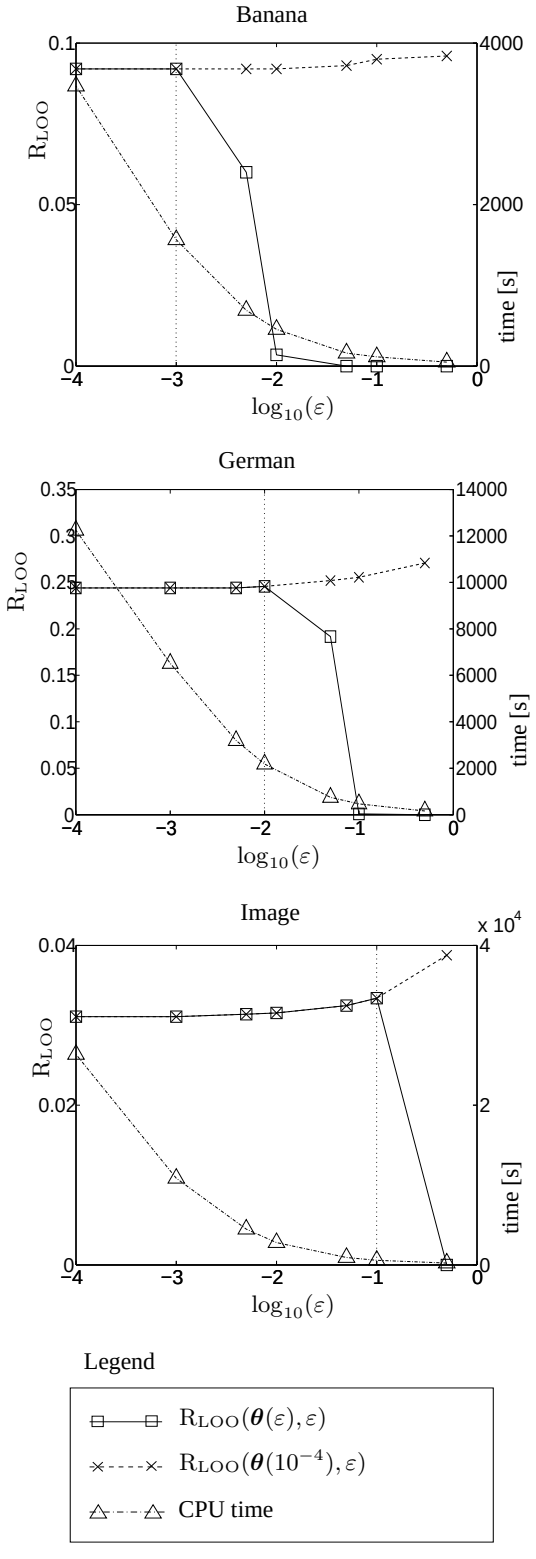

Figure 1. Influence of the parameter ε of the ε-KKT conditions on the LOO error estimate and the required computational time for three data sets (Banana, German and Image) selected from IDA repository.

3. Exact Computation of the LOO Error

In this section we show that a response of the optimal classifier $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$, required when the LOO error is being computed, can be obtained without the need to solve the QP task (4) (or its dual (7)) optimally. Let us define

three convex sets

$$\mathcal{A}_+(r) = \mathcal{A}(r) \cap \Big\{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \mid \sum_{i\in\mathcal{I}} \alpha_i y_i k(x_i, x_r) + b > 0\Big\},$$
$$\mathcal{A}_0(r) = \mathcal{A}(r) \cap \Big\{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \mid \sum_{i\in\mathcal{I}} \alpha_i y_i k(x_i, x_r) + b = 0\Big\},$$
$$\mathcal{A}_-(r) = \mathcal{A}(r) \cap \Big\{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \mid \sum_{i\in\mathcal{I}} \alpha_i y_i k(x_i, x_r) + b < 0\Big\}. \tag{10}$$

Notice, that to compute $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ we do not necessarily need to know the optimal $(\boldsymbol{\alpha}^*(r), b^*(r), \boldsymbol{\xi}^*(r))$ but it suffices to determine whether $(\boldsymbol{\alpha}^*(r), b^*(r), \boldsymbol{\xi}^*(r))$ belongs to $\mathcal{A}_+(r) \cup \mathcal{A}_0(r)$ or to $\mathcal{A}_-(r)$. Our method is based on a simple observation which can be formally stated by the following theorem:

Theorem 1 *For any $(\hat{\boldsymbol{\alpha}}, \hat{b}, \hat{\boldsymbol{\xi}}) \in \mathcal{A}(r)$ which satisfy*

$$F(\hat{\boldsymbol{\alpha}}, \hat{b}, \hat{\boldsymbol{\xi}}) < \min_{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \in \mathcal{A}_0(r)} F(\boldsymbol{\alpha}, b, \boldsymbol{\xi})\,, \tag{11}$$

the equation $f(x_r; \hat{\boldsymbol{\alpha}}, \hat{b}) = f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ holds.

Proof 1 *We proof Theorem 1 by transposition: we show that $f(x_r; \hat{\boldsymbol{\alpha}}, \hat{b}) \neq f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ implies the assumption (11) is violated. Without loss of generality let $f(x_r; \hat{\boldsymbol{\alpha}}, \hat{b}) = +1$ and $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r)) = -1$. Let us define three vectors*

$$\hat{\boldsymbol{\theta}} = \begin{pmatrix} \hat{\boldsymbol{\alpha}} \\ \hat{b} \\ \hat{\boldsymbol{\xi}} \end{pmatrix}, \quad \boldsymbol{\theta}^*(r) = \begin{pmatrix} \boldsymbol{\alpha}^*(r) \\ b^*(r) \\ \boldsymbol{\xi}^*(r) \end{pmatrix}, \quad \boldsymbol{\theta}_0 = \begin{pmatrix} \boldsymbol{\alpha}_0 \\ b_0 \\ \boldsymbol{\xi}_0 \end{pmatrix}.$$

With a slight abuse of notation, we will handle F as a function of a single argument $\boldsymbol{\theta} \in \mathbb{R}^{2m+1}$. Then the assumptions $f(x_r; \hat{\boldsymbol{\alpha}}, \hat{b}) = +1$ and $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r)) = -1$ is equivalent to $\hat{\boldsymbol{\theta}} \in \mathcal{A}_+(r) \cup \mathcal{A}_0(r)$ and $\boldsymbol{\theta}^*(r) \in \mathcal{A}_-(r)$. From (10) it follows that for any $\hat{\boldsymbol{\theta}} \in \mathcal{A}_+(r) \cup \mathcal{A}_0(r)$ and $\boldsymbol{\theta}^*(r) \in \mathcal{A}_-(r)$ there exists $\tau \in [0, 1]$ such that $\boldsymbol{\theta}_0 = ((1-\tau)\hat{\boldsymbol{\theta}} + \tau\boldsymbol{\theta}^*(r)) \in \mathcal{A}_0(r)$. Since F is convex, $\tau \in [0, 1]$ and $F(\boldsymbol{\theta}^*) \leq F(\hat{\boldsymbol{\theta}})$ we can write

$$\begin{aligned} F(\boldsymbol{\theta}_0) &\leq (1-\tau)F(\hat{\boldsymbol{\theta}}) + \tau F(\boldsymbol{\theta}^*(r)) \\ &\leq \max\big\{F(\hat{\boldsymbol{\theta}}), F(\boldsymbol{\theta}^*(r))\big\} = F(\hat{\boldsymbol{\theta}})\,, \end{aligned}$$

which shows that there exist $\boldsymbol{\theta}_0 \in \mathcal{A}_0(r)$ such that $F(\boldsymbol{\theta}_0) \leq F(\hat{\boldsymbol{\theta}})$. Using the original notation, this is equivalent to $F(\boldsymbol{\alpha}_0, b_0, \boldsymbol{\xi}_0) \leq F(\hat{\boldsymbol{\alpha}}, \hat{b}, \hat{\boldsymbol{\xi}})$. However, this contradicts the assumption (11) which was to be shown.

By Theorem 1, any triplet $(\hat{\boldsymbol{\alpha}}, \hat{b}, \hat{\boldsymbol{\xi}}) \in \mathcal{A}(r)$ satisfying the condition (11) determines a classifier $f(x; \hat{\boldsymbol{\alpha}}, \hat{b})$ which has the same response on the input x_r as the optimal classifier $f(x; \boldsymbol{\alpha}^*(r), b^*(r))$. From a practical point of view, this result cannot be used directly due to the unknown value of the right hand side of the inequality (11), i.e.,

$$\min_{(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \in \mathcal{A}_0(r)} F(\boldsymbol{\alpha}, b, \boldsymbol{\xi})\,. \tag{12}$$

The problem (12) is a convex QP task its dual reads

$$\boldsymbol{\beta}^*(r) = \max_{\boldsymbol{\beta} \in \mathcal{B}_0(r)} \left(\sum_{i\in\mathcal{I}} \beta_i - \frac{1}{2} \sum_{i\in\mathcal{I}} \sum_{j\in\mathcal{I}} \beta_i \beta_j y_i y_i k'(x_i, x_j) \right), \tag{13}$$

where $k'(x_i, x_j) = k(x_i, x_j) - k(x_r, x_i) - k(x_r, x_j) - k(x_r, x_r)$ and $\mathcal{B}_0(r)$ is a convex feasible set which contains all $\boldsymbol{\beta} \in \mathbb{R}^m$ satisfying

$$0 \leq \beta_i \leq C\,, i \in \mathcal{I} \setminus \{r\}\,, \quad \text{and} \quad \beta_r = 0\,.$$

We will use $H(\boldsymbol{\beta})$ to denote the objective function of (13). By the weak duality theorem, the inequality $F(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \geq H(\boldsymbol{\beta})$ holds for any $(\boldsymbol{\alpha}, b, \boldsymbol{\xi}) \in \mathcal{A}_0(r)$ and $\boldsymbol{\beta} \in \mathcal{B}_0(r)$. This allows us to derive the following useful corollary:

Corollary 1 *For any $(\hat{\boldsymbol{\alpha}}, \hat{b}, \hat{\boldsymbol{\xi}}) \in \mathcal{A}_0(r)$ and $\boldsymbol{\beta} \in \mathcal{B}_0(r)$ which satisfy*

$$F(\hat{\boldsymbol{\alpha}}, \hat{b}, \hat{\boldsymbol{\xi}}) < H(\hat{\boldsymbol{\beta}})\,, \tag{14}$$

the equation $f(x_r; \hat{\boldsymbol{\alpha}}, \hat{b}) = f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ holds.

Notice, that the condition (14) is satisfiable except for a very rare degenerate cases. It is easy to show, that if the condition (14) is not satisfiable then the error estimate $V(y_r; f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ is unstable anyway since there exists an optimal classifier $f(x; \boldsymbol{\alpha}^*(r), b^*(r))$ its separating hyperplane passes through the tested point x_r.

4. Algorithm

A direct application of Corollary 1 would require solving a mixed set of one quadratic and many linear inequalities. We are not aware of any simple and efficient algorithm to solve such task. Instead, we show how to use Corollary 1 to derive a novel stopping condition for a standard iterative QP solver (cf. Algorithm 2).

Algorithm 3 Proposed QP solver

1: Initialize $t := 0$, $\boldsymbol{\alpha}^{(t)} \in \mathcal{B}(r)$ and $\boldsymbol{\beta}^{(t)} \in \mathcal{B}_0(r)$.
2: $t := t + 1$.
3: Update $\boldsymbol{\alpha}^{(t-1)} \rightarrow \boldsymbol{\alpha}^{(t)}$, i.e., find $\boldsymbol{\alpha}^{(t)} \in \mathcal{A}(r)$ such that $G(\boldsymbol{\alpha}^{(t-1)}) < G(\boldsymbol{\alpha}^{(t)})$.
4: If $\boldsymbol{\alpha}^{(t)}$ satisfies the ε-KKT conditions then halt otherwise continue to Step 5.
5: For fixed $\boldsymbol{\alpha}^{(t)}$ compute feasible $b^{(t)}$ and $\boldsymbol{\xi}^{(t)}$ minimizing $F(\boldsymbol{\alpha}^{(t)}, b, \boldsymbol{\xi})$.
6: Update $\boldsymbol{\beta}^{(t-1)} \rightarrow \boldsymbol{\beta}^{(t)}$, i.e., find $\boldsymbol{\beta}^{(t)} \in \mathcal{B}_0(r)$ such that $H(\boldsymbol{\beta}^{(t-1)}) < H(\boldsymbol{\beta}^{(t)})$.
7: If $F(\boldsymbol{\alpha}^{(t)}, b^{(t)}, \boldsymbol{\xi}^{(t)}) < H(\boldsymbol{\beta}^{(t)})$ holds then halt otherwise go to Step 2.

The proposed method is described by Algorithm 3 which, compared to a standard QP solver, involves three additional Steps 5, 6 and 7. In Step 5, the algorithm computes the

primal variables $(\boldsymbol{\xi}^{(t)}, b^{(t)})$ minimizing $F(\boldsymbol{\alpha}^{(t)}, b^{(t)}, \boldsymbol{\xi}^{(t)})$ which amounts to a simple optimization problem since $\boldsymbol{\alpha}^{(t)}$ is known. In Step 6, the algorithm maximizes the auxiliary criterion $H(\boldsymbol{\beta}^{(t)})$ w.r.t. $\boldsymbol{\beta}^{(t)}$. Finally, in Step 7, the algorithm checks whether $H(\boldsymbol{\beta}^{(t)})$ has become greater than $F(\boldsymbol{\alpha}^{(t)}, b^{(t)}, \boldsymbol{\xi}^{(t)})$; as soon as this occurs the algorithm halts since $f(x_r; \boldsymbol{\alpha}^{(t)}, b^{(t)}) = f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$ is guaranteed according to Corollary 1. The ε-KKT conditions are retained in Step 3 of Algorithm 3 since the condition (14) need not be satisfiable in general.

The proposed Algorithm 3 is intended to be used for computation of $f(x_r; \boldsymbol{\alpha}^*(r), b^*(r))$, i.e., it is called in Step 4 of Algorithm 1 calculating the LOO error, as a replacement for the standard QP solver. In terms of accuracy of computing the LOO error, the proposed algorithm cannot perform worse than the standard one. If the ε-KKT conditions are satisfied earlier than the proposed stopping condition then both the solvers find an identical classifier. In the opposite case, however, the response of the classifier found by the proposed algorithm is guaranteed to be optimal. Albeit the proposed algorithm provides a theoretical guarantee for the found solution to be optimal, from the practical point of view both the algorithms will produce an identical LOO error estimate for a sufficiently low ε. We will empirically show, however, that the proposed algorithm is numerically more efficient though it optimizes two QP tasks simultaneously compared to the standard approach. The higher efficiency is achieved by the proposed stopping condition which is often satisfied earlier than the ε-KKT condition.

To increase the numerical performance we also implemented the following simple efficiency test. The proposed algorithm is not applied on a single example but rather on a set of examples which cannot be resolved by the sufficiency checks. We experimentally observed, that the efficiency of the proposed algorithm can be reliably estimated from a few examples. This allows us to switch to using the standard QP solver when the efficiency of the proposed algorithm is low. The efficiency test, implemented in Step 4 of Algorithm 1, works as follows: We apply the proposed Algorithm 3 on the first M examples. Let M_{Prec} denote the number of examples for which Algorithm 3 halt in Step 7 (i.e., the proposed stopping condition was applied). If $M_{Prec}/M < 0.5$ we switch from using Algorithm 3 to using the standard Algorithm 2. We empirically found $M = 10$ to be a good choice number in all our experiments.

5. Experiments

In this section, we experimentally evaluate the proposed method for computing the LOO error compared to the standard approach on the datasets from the IDA benchmark repository [1].

The standard approach computes the LOO error using the procedure described by Algorithm 1. An iterative QP solver with the ε-KKT conditions (Algorithm 2) is called whenever the solution of the QP task is required. In particular, we used the Improved SMO algorithm (Keerthi et al., 2001) to implement the QP solver. In addition, we implemented α-seeding approach (DeCoste & Wagstaff, 2000) which re-uses the solution $\boldsymbol{\alpha}^*$ (obtained in Step 1 of Algorithm 1) to efficiently set up the initial solution of the QP solver (initialization of $\boldsymbol{\alpha}^{(0)}$ in Step 1 of Algorithm 2).

The proposed approach uses the same procedure for computing the LOO error except for a different QP solver used in Step 4 of Algorithm 1. As the QP solver, we applied the proposed Algorithm 3 which involves optimization of the QP tasks $G(\boldsymbol{\alpha}^{(t)})$ w.r.t. $\boldsymbol{\alpha}^{(t)} \in \mathcal{B}(r)$ and $H(\boldsymbol{\beta}^{(t)})$ w.r.t. $\boldsymbol{\beta}^{(t)} \in \mathcal{B}_0(r)$ required in Step 3 and Step 6, respectively. We again used the Improved SMO algorithm to optimize $G(\boldsymbol{\alpha}^{(t)})$ w.r.t. $\boldsymbol{\alpha}^{(t)} \in \mathcal{B}(r)$ and its straightforward modification to optimize $H(\boldsymbol{\beta}^{(t)})$ w.r.t. $\boldsymbol{\beta}^{(t)} \in \mathcal{B}_0(r)$ ($\mathcal{B}_0(r)$ does not contain the equality constraint thus a single variable can be updated).

The experiments were carried out in Matlab 6 environment runnig on the Linux machine with the AMD K8 2.2GHz processor. Algorithms 1,2 and 3 were implemented in C.

The IDA repository consists of 13 artificial and real-world binary classification problems collected from UCI, DELVE and STATLOG repositories (c.f. (Rätsch et al., 2001)). For each dataset, there are 100 random realizations of training and testing set (except for Image and Splice sets, where it is 20). The training parts of the first 5 realizations are used for model selection. The best hyper-parameters (C, k) were selected from a finite set Θ by minimizing an average LOO error $\hat{R}_{LOO}$. The average LOO error $\hat{R}_{LOO}$ is computed over the 5 realizations.

We considered two separate model selection problems for the linear and the RBF kernel. In the case of the liner kernel, the model was select from $\Theta = \{C \mid C = 10^i, i = -2, \ldots, 2\} \times \{k \mid k(x, x') = \langle x, x' \rangle\}$ and, in the case of the RBF kernel $\Theta = \{C \mid C = 10^{\frac{i}{7}\log(500)}, i = 0, \ldots, 7\} \times \{k \mid k(x, x') = \exp(-2^{\frac{i}{7}11}\|x - x'\|^2), i = 0, \ldots, 7\}$. Having the model selected, the classifier is trained for all 100 realizations of the training sets and the testing error is computed on the corresponding testing set. The reported testing errors $\hat{R}_{TST}$ are averages accompanied with the standard deviations computed over the 100 realizations.

Table 2 shows the average LOO errors $\hat{R}_{LOO}$ and the testing errors $\hat{R}_{TST}$ for the best selected models. We experimentally verified, that both the standard and the proposed

[1] http://ida.first.fraunhofer.de/projects/bench/benchmarks.htm

approach yielded identical LOO errors since a low value of $\varepsilon = 0.001$ was used in the ε-KKT conditions. Therefore the errors listed in Table 2 apply for both the approaches. We also found that the classification errors for the RBF kernel are very similar to the errors reported in (Rätsch et al., 2001) for the SVM classifier with the RBF kernel tuned by the 5-fold cross-validation. Interestingly, the linear kernel achieves in some cases comparable performance as the more complex RBF kernel. We can also observe, that the average LOO errors $\hat{R}_{LOO}$ for the linear kernel are very good estimators of the testing errors $\hat{R}_{TST}$.

Table 3 summarizes the numerical efficiency of the proposed approach and the standard one. The efficiency was measured in terms of the computational time and the number of kernel evaluations. The reported $Time$ is the overall computational time spent by a given algorithm to calculate all the LOO errors needed for the model selection. E.g., in the case of the RBF kernel it was necessary to compute $5 \times 64 = 320$ LOO error estimates (5 stands for the number of the training set realizations and 64 is the cardinality of Θ). Similarly, the number of kernel evaluations $KerEval$ is the overall value normalized to the number of training data m, i.e., $KerEval$ is the number of columns of the kernel matrix. In the case of the standard approach, we listed the absolute values of $Time$ and $KerEval$. In the case of the proposed approach, we listed the gained speed up computed as the ratio $Standard/Proposed$. The last column of Table 3 contains the value $Prec$ being the percentage of the cases when the proposed stopping condition was satisfied earlier then the ε-KKT conditions, i.e., in $Prec$ cases the computed LOO error is theoretically guaranteed to be optimal.

It can be seen, that the proposed method was never slower (up to the rounding error in computing the speed up) than the standard algorithm both in terms of the computational time and the kernel evaluations. A higher performance was achieved for the linear kernel compared to the RBF kernel. For the linear kernel, the proposed approach was on average 4 times faster than the standard approach. The best performance was achieved for the Image dataset when the speed up was nearly 13. For RBF kernel, the average speed up was slightly higher than 2, and, in the best case the speed up was 5 for the Banana dataset. It shows that while the efficiency gained for the RBF kernel is only moderate, in the case of the linear kernel it is much appealing.

6. Conclusions

The new stopping conditions for an SVM solver proposed in this contribution allow to determine an optimal solution accuracy needed for exact computation of a LOO error. Our new algorithm allows one to significantly reduce complexity of the LOO error computation without a risk of overfitting due to imprecise optimization. Our experiments on 13 datasets from the IDA repository achieved the average speedup of 2 to 4 times and the maximal speedup of up to the factor of 13.

These results demonstrate the importance of investigating relationships between the optimization accuracy and the expected risk estimation in machine learning, as suggessed by recent work (Bartlett & Mendelson, 2006; Bottou & Bousquet, 2008). To our knowledge, the new algorithm is the first theoretically justified constructive instrument to guide an optimization algorithm – for the particular case of the SVM QP solver and the LOO error – towards achieving the best attainable expected risk at optimal computational cost. Future work should explore more general mechanisms of relating parameters of optimization algorithms deployed in machine learning with the estimation of expected risk.

Abstract

We consider the task of reinforcement learning in an environment in which rare significant events occur independently of the actions selected by the controlling agent. If these events are sampled according to their natural probability of occurring, convergence of conventional reinforcement learning algorithms is likely to be slow, and the learning algorithms may exhibit high variance. In this work, we assume that we have access to a simulator, in which the rare event probabilities can be artificially altered. Then, importance sampling can be used to learn with this simulation data. We introduce algorithms for policy evaluation, using both tabular and function approximation representations of the value function. We prove that in both cases, the reinforcement learning algorithms converge. In the tabular case, we also analyze the bias and variance of our approach compared to TD-learning. We evaluate empirically the performance of the algorithm on random Markov Decision Processes, as well as on a large network planning task.

1. Introduction

We consider a practically important class of control tasks, in which rare (potentially catastrophic) events might take place. For example, in a computer network, links and nodes can fail, causing traffic to be undelivered and large penalties to be incurred. A robot exploring a rugged terrain may be caught by a sudden gust of wind which rolls it over. An investment agent may be faced with a market that is in turmoil due to a sudden unforeseen event. In such cases, the rare events occur *independently* of the actions of the agent, with some small probability. However, such rare events can have a disproportionate effect on the agent's utility. If such events are sampled on-line, as is the case in most reinforcement learning (RL) applications, they may not occur often enough to obtain an accurate estimate of the value function.

In this paper, we formalize this problem and propose solution algorithms. We assume that learning will be done in a simulation environment in which the probability of the rare event can be set to desired levels. In most safety-critical applications, training in a simulated environment is a common approach. In this case, we can sample rare events more often, and use importance sampling corrections similar to (Precup et al. 2000, 2001) to evaluate a given policy. However, importance sampling can cause high variance in the learning updates. We propose to use an adaptive algorithm in which the sampling rate for the rare event is adjusted in such a way as to minimize variance. For the case in which the value function is represented as a table, we show that the algorithm converges and provide a bias-variance analysis, based on (Mannor et al., 2007) . For the case of linear function approximation, we prove convergence. We note that a bias-variance analysis for this case is not even available for TD-learning without importance sampling. We illustrate the performance of our approach on two domains: random Markov Decision Processes (MDPs), and a large network planning task. Our approach proves quite successful when compared to on-line TD-learning.

The literature on simulation of rare events is vast; see (Bucklew, 2004; Asmussen & Glynn, 2007) for comprehensive reviews. There are many Markov (or Markov-like) models that have been studied in the simulation community including queues, inventory control problems, call centers, communication systems, etc. The main objective of these works is to estimate the probability of a rare event by simulating the system under an alternative probability mea-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

sure, and then use importance sampling to unbias the results. The search for the optimal change of measure can be done in several ways, including the cross-entropy method (Rubinstein & Kroese, 2004) and stochastic approximation. Variance reduction has also been studied within the RL community. In particular, (Baxter & Bartlett, 2001) considered adaptive control-variates for policy gradient algorithms.

The explicit modeling of rare events in reinforcement learning-style algorithms was studied in (Bhatnagar et al., 2006). Their objective is to find an optimal control policy conditioned on the occurrence of a rare event. A model that closely resembles our approach is presented in (Ahamed et al., 2006). However, they assume that the model of the transition probabilities is known, and can be arbitrarily modified. We make a less restrictive assumption: the only parameter of the simulator that can be modified is the rate at which the rare events occur. Also, the bias-variance analysis and discussion of the function approximation case are novel.

The rest of the paper is organized as follows. In Section 2 we provide the essential background on RL and MDPs. In Section 3 we formally describe the rare events model used in this paper. We review RL algorithms that use importance sampling in Section 4. The learning algorithm we propose is described in Section 5. In Section 6 we present bias-variance results for learning in MDPs with rare events. Section 7 presents a learning algorithm with function approximation and a proof of convergence in this case. The empirical results of our approach are presented in Section 8. Finally, Section 9 presents conclusions and avenues for future work.

2. Background

We use the standard RL framework (Sutton & Barto, 1998) in which an agent interacts with its environment at discrete time steps $t = 0, 1, 2, \ldots$. At time t, the agent finds itself in a state $s_t \in S$, chooses an available action $a_t \in A_{s_t}$, and then receives a numerical reward, $r_{t+1} \in \mathbb{R}$ and observes the next state s_{t+1}. We denote $A = \bigcup_{s \in S} A_s$. If the environment is modeled as an MDP, its dynamics are characterized by the stationary transition probability distribution:

$$p(s'|s,a) = \Pr\{s_{t+1} = s' | s_t = s, a_t = a\},$$

and a bounded, real-valued reward function $r(s,a,s')$ with $|r(s,a,s')| \leq R_{\max} < \infty, \forall s, s' \in S, a \in A$.

We are concerned with the problem of policy evaluation in discounted infinite horizon problems with discount factor $\gamma \in (0,1)$. The agent chooses its actions according to a stationary policy $\pi(s,a) = \Pr\{a_t = a | s_t = s\}$. We are interested in computing the state-value function $V^\pi : S \to \mathbb{R}$ for the given policy π. This value function is the solution to the well-known Bellman equations

$$V^\pi(s) = \sum_{a \in A} \pi(s,a) \sum_{s' \in S} p(s'|s,a)[r(s,a,s') + \gamma V^\pi(s')]. \quad (1)$$

In RL, this value function is often estimated on-line using the well-known TD-learning algorithm (Sutton, 1988). If the actions are chosen using the desired policy π, after observing transition (s,a,r,s'), the estimate of the value function, V, can be updated as:

$$V(s) \leftarrow V(s) + \alpha \left[r + \gamma V(s') - V(s) \right]. \quad (2)$$

In control tasks, the objective is to find the policy that maximizes $V^\pi(s)$ at all states s.

3. Rare Events

We are concerned with problems involving rare, significant events that occur as a result of environmental factors, and which are independent of the current action taken by the agent. We model this using a mixture of two separate transition probability distributions: $f(s'|s,a)$, which captures the environment dynamics during "normal" operating conditions, and $g(s'|s)$, which is the "rare event" transition distribution. We assume that at every state $s \in S$, there is a small probability, $\varepsilon(s)$, that an unusual event might occur from this state. In this case, the transition to the next state is determined exclusively by g. If such an event does not occur, the next state is drawn according to f, and depends on both the current state and the agent's action. Hence, the transition probability in the environment can be re-written as:

$$p(s'|s,a) = (1 - \varepsilon(s)) f(s'|s,a) + \varepsilon(s) g(s'|s). \quad (3)$$

Without loss of generality, we will assume that the "normal" states (reachable by f) and the "rare event" states (reachable by g) are disjoint. Hence, the transition probability distribution can be re-written as:

$$p(s'|s,a) = \begin{cases} (1 - \varepsilon(s)) f(s'|s,a) & \text{if } s' \notin T, \\ \varepsilon(s) g(s'|s) & \text{if } s' \in T, \end{cases}$$

where $T \subseteq S$ is the set of "rare event" states.

We are concerned with rare events that have a significant impact on the state-value function for a given policy. Therefore we define the rare events state set as follows.

Definition 3.1. *A subset of states $T \subseteq S$ is called a* rare events state set *if the following three properties hold:*

1. *For all $s \in S$, $a \in A$, $s' \in T$, $f(s'|s,a) = 0$ (i.e., T is not reachable from any state s using the agent's actions).*

2. *There exists $s \in S$, $s' \in T$ such that $g(s'|s) > 0$ (i.e., T can be forced by the environment)*

3. *Let V_f^π denote the value function obtained by replacing p with f in (1). Then, for the given policy π,*

$$\exists s \in S \text{ s.t. } |V_f^\pi(s) - V^\pi(s)| \gg 0.$$

The last condition means that the states in the rare event state set must (collectively) have a large impact on the state-value function. We define *rare events* to be transitions into the rare event state set. For convenience, we will refer to the states that are not in the rare event state set, $S \setminus T$, as the normal states.

We note that we use the term "rare event" loosely from the point of view of the simulation community (Bucklew, 2004), because our definition is not based solely on the probability of the event. We deviate from the typical definition due to the fact that there may be events that occur infrequently but do not have a noticeable effect on our value function estimates, and we are not concerned with these events.

4. Importance Sampling for Reinforcement Learning

The TD update (2) is based on the idea that the right-hand side of the Bellman equations (1) can be approximated using samples of the next transition, $r(s,a,s') + \gamma V(s')$, where $a \sim \pi(s,\cdot)$ and $s' \sim p(\cdot|s,a)$. However, in an environment with rare events, if $\varepsilon(s)$ is very small, a very large number of samples will be needed in order for the rare events to be averaged properly in the value function estimates. Instead, we investigate a sampling distribution which allows these events to be sampled preferentially, and then we use importance sampling corrections to account for this in the TD updates.

Importance sampling is a variance-reduction technique commonly used in statistics, as well as in the simulation community (Bucklew, 2004). The main idea is that instead of obtaining samples from the true distribution p, they will be drawn from a different distribution q, called the *proposal distribution*, in which events of interest occur more frequently. If q is devised well, then using these samples will reduce the variance of the estimator. Precup, Sutton & Singh (2000) extended this approach to TD-learning. They studied the case in which a target policy π is evaluated based on data generated by a different behavior policy. In this case, they showed that a TD-learning algorithm can still be used, in which the TD targets are adjusted by using the appropriate importance sampling weights: $w(s,a,s')(r(s,a,s') + \gamma V(s'))$, where:

$$w(s,a,s') = \frac{p(s'|s,a)}{q(s'|s,a)}.$$

In their case, the change of measure is induced by the behavior policy, and the importance sampling weights are the likelihood ratios of the probabilities of action a under the two policies.

Ahamed, Borkar & Juneja (2004) use the same idea but with the goal of changing the next-state probabilities in a discrete-time finite-state Markov chain with positive costs. They assume that the transition probabilities are known and can be modified at will, and propose an adaptive importance sampling algorithm (ASA) which finds an alternative set of transition probabilities in order to minimize the variance of the value function estimator. They provide a convergence proof (assuming a tabular representation of the value function), a discussion of convergence rates, and simulation results.

5. Learning in the Presence of Rare Events

The ASA algorithm assumes that we have full knowledge of the transition model, and can completely control the transition probabilities, so all the transition probabilities can be tilted towards the zero-variance importance sampling distribution. In this paper, we relax this assumption because it is difficult to achieve in practical applications. We assume that the true rare event probability ε is known (e.g., as the mean of a Poisson process that generates failures in a network, or the weight of the tail of a distribution in which rare events occur). We assume that the system dynamics, f and g are unknown and cannot be modified, but that the probability with which rare events are generated can be changed as the simulation proceeds. In general, with only this parameter at our disposal, we cannot achieve the zero-variance importance sampling distribution; however, we can tilt the transition probability distribution p towards the zero-variance distribution, and therefore reduce the variance of our estimates.

We define $\hat{\varepsilon} : S \to [0,1]$ to be the probability of a rare event occurring from every state during the simulation. Hence, the next states will be sampled from a proposal distribution given by:

$$q(s'|s,a) = (1 - \hat{\varepsilon}(s)) f(s'|s,a) + \hat{\varepsilon}(s) g(s'|s), \qquad (4)$$

where f and g remain unchanged. By considering that the state space S is separated into disjoint normal and rare event subsets of states, we note that the importance sampling corrections $w(s,a,s')$ can be computed by:

$$w(s,a,s') = \begin{cases} \varepsilon(s)/\hat{\varepsilon}(s) & \text{if } s \in T, \\ (1-\varepsilon(s))/(1-\hat{\varepsilon}(s)) & \text{if } s \notin T. \end{cases} \qquad (5)$$

Following a similar argument as in the development of the ASA algorithm, we can determine the following optimal

form for the rare event sampling distribution:

$$\varepsilon^*(s) = \varepsilon(s) \frac{\sum_{s' \in T} g(s'|s)[(\sum_{a \in A} \pi(s,a) r(s,a,s')) + \gamma V^\pi(s')]}{V^\pi(s)}, \tag{6}$$

Fortunately, the values $\varepsilon^*(s)$ can be estimated on-line using samples.

Algorithm 1 is our proposed approach for learning in the presence of rare events. We call this algorithm rare events adaptive stochastic approximation (REASA). It is based on the observation that we can rewrite $\varepsilon^*(s)$ as follows:

$$\varepsilon^*(s) = \frac{T^*(s)}{T^*(s) + U^*(s)}, \text{ where}$$

$$T^*(s) = \varepsilon(s) \sum_{s' \in T} g(s'|s)[(\sum_{a \in A} \pi(s,a) r(s,a,s')) + \gamma V^\pi(s')]$$

is the contribution to the value of s by the rare event state set T, and

$$U^*(s) = (1 - \varepsilon(s)) \sum_{a \in A} \pi(s,a) \sum_{s' \notin T} f(s'|s,a)[r(s,a,s') + \gamma V^\pi(s')]$$

is the contribution to $V^\pi(s)$ from the normal states.

In the algorithm, $T(s)$ is an unbiased estimator of $T^*(s)$ and $U(s)$ is an unbiased estimator of $U^*(s)$. It follows that as $t \to \infty$, from Equation (6),

$$\hat{\varepsilon}(s) = \frac{T(s)}{T(s) + U(s)} \to \varepsilon^*(s),$$

for every state $s \in S$. Since we use importance sampling to calculate $\hat{V}^\pi(s)$, we also have that as $t \to \infty$, $\hat{V}^\pi(s) \to V^\pi(s)$ from standard stochastic approximation arguments under some mild assumptions on the MDP structure. We summarize the result in the following proposition.

Proposition 1. *Using Algorithm 1 and assuming that the MDP is unichain for* $\varepsilon = \delta$ [1] *we have that:*

$$\hat{V}^\pi(s) \to V^\pi(s) \text{ almost surely.}$$

Moreover, $\forall s$ *s.t.* $\varepsilon^*(s) \in (\delta, 1-\delta)$ *we have that* $\hat{\varepsilon}(s) \to \varepsilon^*(s)$ *almost surely.*

We note that we guarantee that we have enough persistent exploration by requiring that $\hat{\varepsilon}(s)$ is bounded from below by δ and from above by $1 - \delta$ (step 5h in Algorithm 1).

Although the treatment above is assuming positive rewards (for ease of notation), our algorithm is actually formulated for the general case in which rewards can be both positive and negative, which is an extension of the ASA algorithm.

[1] The unichain assumption is needed to invoke the stochastic approximation argument; see (Bertsekas & Tsitsiklis, 1996). Also note that if the MDP is unichain for one value of $\varepsilon \in (\delta, 1-\delta)$ it is unichain for all values.

Algorithm 1 Rare-event Adaptive Importance Sampling

Input: Rare event set $T \subset S$, true rare-event probabilities $\varepsilon(s)$, and parameter $\delta > 0$, used to keep the sampling distribution non-zero everywhere.

1. Initialize $\hat{V}^\pi$ arbitrarily.
2. Initialize the rare-event sampling distribution: $\hat{\varepsilon}(s) \leftarrow 1/2, \forall s$.
3. Initialize the variables $T(s)$, $U(s)$ (which measure the contribution of T and $S \setminus T$ to V^π) to 0.
4. Initialize eligibility traces: $e(s) = 0, \forall s$.
5. Select the initial state s_0.
6. Repeat for $t = 0, 1, \ldots$:
   (a) Update the eligibility trace of the current state
   $$e(s_t) = e(s_t) + 1.$$
   (b) Select an action $a_t \sim \pi(s_t, \cdot)$.
   (c) Select whether a rare event happens, according to $\hat{\varepsilon}(s_t)$, and sample s_{t+1} from f or g accordingly. Observe the reward r_{t+1}.
   (d) Compute the importance sampling weight w_t according to Equation (5).
   (e) Compute the importance-sampling TD-error:
   $$\Delta_t = w_t(r_{t+1} + \gamma \hat{V}^\pi(s_{t+1})) - \hat{V}^\pi(s_t).$$
   (f) Update the value estimates:
   $$\hat{V}^\pi(s) \leftarrow \hat{V}^\pi(s) + \alpha e(s) \Delta_t, \forall s,$$
   where $\alpha \in [0,1]$ is a learning rate.
   (g) If $s_{t+1} \in T$, then:
   $$T(s_t) \leftarrow (1 - \alpha_T) T(s_t) + \alpha_T \varepsilon(s_t)(r_{t+1} + \gamma \hat{V}^\pi(s_{t+1})),$$
   else
   $$U(s_t) \leftarrow (1 - \alpha_U) U(s_t) + \alpha_U (1 - \varepsilon(s_t))(r_{t+1} + \gamma \hat{V}^\pi(s_{t+1})),$$
   where $\alpha_T, \alpha_U \in (0,1)$ are learning rates. In the experiments, we use the inverse of the number of times a transition from s_t has been observed to T and $S \setminus T$ respectively.
   (h) Update the rare event probabilities:
   $$\hat{\varepsilon}(s_t) \leftarrow \min\left(\max\left(\delta, \frac{|T(s_t)|}{|T(s_t)| + |U(s_t)|}\right), 1 - \delta\right).$$
   (i) Update eligibility traces:
   $$e(s) \leftarrow \gamma \lambda w_t e(s), \forall s.$$

6. Bias and Variance of Reinforcement Learning with Rare Events

For simplicity, let us assume that $\varepsilon(s) = \varepsilon$ for all states $s \in S$ (all the analysis can be done without this assumption, but becomes more tedious). Let R^π denote the vector of immediate rewards for every state, with entries:

$$R^\pi_s = \sum_{a \in A} \sum_{s' \in S} \pi(s,a) p(s'|s,a) r(s,a,s'),$$

and P^π be an $|S| \times |S|$ transition matrix under π, with entries:

$$P^\pi_{ss'} = \sum_a \pi(s,a) p(s'|s,a).$$

From (3), we can re-write P^π as:

$$P^\pi = (1-\varepsilon) F^\pi + \varepsilon G,$$

where F^π is the transition matrix corresponding to staying in the normal states, and G is the matrix corresponding to transiting into the rare event states. Note that according to our assumptions, G does not depend on π. Similarly, the reward vector can be decomposed into two components, R^π_F and R^π_G. We use two sequences, $\{X_k\}_{k=1}^\infty$ and $\{Y_k\}_{k=1}^\infty$, of geometrically distributed random variables, with means $(1-\varepsilon)^{-1}$ and ε^{-1} respectively, to represent the amount of time between transitions from the normal states and the rare event states respectively. We also assume that the initial state is a normal state. Hence, the simulation starts in some normal state and stays in the set of normal states for X_1 time steps, at which point it transitions to a state in the rare event set, where it stays for Y_1 time steps, then transitions back to the normal set for X_2 time steps, etc. We make two further simplifications. First, we assume that after each excursion into the rare event state set, the system "jumps back" to the normal state in which it was before entering; that is, $(F^\pi)^i G^j (F^\pi)^k \approx (F^\pi)^{i+k}$. Second, we assume that the rewards for transitioning to states in the normal set are similar regardless of the origin, that is that $G R^\pi_F \approx F^\pi R^\pi_F$. The analysis can be done without these assumptions, but it becomes more tedious. These assumptions are reasonable because in general the rare events model failures in the system, such as a failed link in a network, and when the failure is no longer present, the system resumes from the state prior to the failure. We define $\tau(k) = \sum_{i=1}^{k-1} X_k$ and $\upsilon(k) = \sum_{i=1}^{k-1} Y_k$. The value function estimate, V^π, can be re-written as:

$$V^\pi \approx \mathbb{E}\left[\sum_{k=1}^{\infty} \gamma^{\tau(k)+\upsilon(k)} (F^\pi)^{\tau(k)-1} \cdot \left(\sum_{i=0}^{X_k-1} \gamma^i (F^\pi)^i R^\pi_F + \gamma^{X_k} (F^\pi)^{X_k-1} \sum_{i=0}^{Y_i-1} \gamma^i G^i R^\pi_G \right) \right].$$

When the value function is estimated from data using TD-learning, we can analyze the bias and variance of this estimate by considering that all the model component estimates are affected by noise components (Mannor et al., 2007). The estimate of the value function, $\hat{V}^\pi$ can be broken up into two components; the first component ignores rare events, and the second takes rare events into account. The first component is:

$$\mathbb{E}[\hat{V}^\pi_F] = \sum_{k=1}^{\infty} \mathbb{E}\left[\gamma^{\tau(k)+\upsilon(k)} (F^\pi + \tilde{F}^\pi)^{\tau(k)-1} \cdot \sum_{i=0}^{\infty} (1-\varepsilon)^i \varepsilon \gamma^i (F^\pi + \tilde{F}^\pi)^i (R^\pi_F + \tilde{R}^\pi_F) \right]$$

where $\tilde{R}^\pi_F$, $\tilde{F}^\pi$ represent the noise estimates in the normal part of the model. The bias and variance of this estimate can be derived directly as in (Mannor et al., 2007), noting that $\tau(k)$ and $\upsilon(k)$ are sums of independent geometrically distributed variables, and are therefore distributed according to a negative binomial distribution.

The second component is:

$$\mathbb{E}[\hat{V}^\pi_G] = \sum_{k=1}^{\infty} \mathbb{E}\left[\gamma^{\tau(k+1)+\upsilon(k)} (F^\pi + \tilde{F}^\pi)^{\tau(k+1)-1} \cdot \sum_{i=0}^{\infty} (1-\varepsilon) \varepsilon^i \gamma^i (G + \tilde{G})^i (R^\pi_G + \tilde{R}^\pi_G) \right]$$

Note that the noise components $\tilde{G}$, $\tilde{F}^\pi$, $\tilde{R}^\pi_G$ depend on the number of transitions observed in the environment. If we observe N transitions, then the expected number of transitions observed in the normal state set is $(1-\varepsilon)N$ and the expected number of transitions observed in the rare event state set is εN. Hence, we assume that the noise component $\tilde{F}^\pi$ is negligible compared to $\tilde{G}$, and $\tilde{R}^\pi_G$. Hence, to establish bias-variance estimates for $\hat{V}^\pi_G$, we need to look at $\mathbb{E}\left[(G+\tilde{G})(R^\pi_G + \tilde{R}^\pi_G)\right]$. Similarly to (Mannor et al., 2007), we assume that $\mathbb{E}[\tilde{G}] = 0$ and $\mathbb{E}[\tilde{R}^\pi_G] = 0$. Hence, the remaining term which will determine the bias and variance is $\mathbb{E}[\tilde{G}\tilde{R}^\pi_G]$, which captures the correlations between the transition and model estimates, due to the fact that they are estimated from the same samples. This expectation can be derived directly from the formulas in (Mannor et al., 2007).

We would like to point out that we could also have applied the analysis of (Mannor et al., 2007) directly to P^π. However, this would lead to very loose bounds, because their results depend on the inverse of the minimum number of samples obtained for any transition, and we expect that there will be very few transitions into the rare event set. In our analysis, only the second term depends on numbers of transitions into the rare events states, so we can focus our analysis on the effect of the rare events on the bias and variance in our estimates.

Also, note that the purpose of the algorithm is to sample rare events proportionately to their contribution to the value function for all states. Hence, intuitively, it will reduce bias and variance in the second component by oversampling the rare events, and thus decreasing the noise components $\tilde{G}$ and $\tilde{R}^{\pi}_{G}$. Given the same amount of data, the errors in $\tilde{F}$ and $\tilde{R}^{\pi}_{F}$, but not by much.

7. Learning with Rare Events and Function Approximation

If the state space is very large or continuous, function approximation must be used to estimate the value function. Here, we are concerned with the case of linear function approximation, in which the value of a state is estimated as:

$$V^{\pi}(s) \approx \theta\phi(s), \tag{7}$$

where θ is a parameter vector that needs to be estimated and $\phi(s)$ is a set of features corresponding to state s. In this case, the eligibility traces are also represented as a vector $\mathbf{e}$ of the same size as θ. We now extend the REASA algorithm to deal with this case. First, note that in this case, we may not be able to have a state-dependent probability of obtaining a rare event state, because specifying this on a state-by-state basis would be too expensive. Hence, we will assume for the moment, without loss of generality, that the true rare event probability ε is constant over the entire state space. We discuss possible extension to this in Section 9. The algorithm will estimate a parameter $\hat{\varepsilon}$ by taking the view that, at a high level, the agent switches between the normal states $S \setminus T$ and the rare-event states T. These are now treated as two states in a high-level MDP, and $\hat{\varepsilon}$ is estimated like in REASA, on this 2-state system.

Algorithm 2 presents the approach, which adapts the algorithm of Precup et al. (2001). Unlike in the tabular case, here importance sampling corrections have to be made to account for the difference in the distribution of observed features, as well as for the difference in the TD target. As explained in Precup et al. (2001), these corrections, which are collected in the trajectory weight c, can result in high variance. However, since we assume that the sets of normal and rare event states are disjoint, we can assume, without loss of generality, that they are represented by disjoint features as well. In this case, step 7i of Algorithm 2 can be eliminated, and variance will be greatly improved.

Proposition 2. *Under standard stochastic approximation conditions, Algorithm 2 converges in the limit, with probability 1, to the same estimates as the on-policy TD-learning algorithm.*

Algorithm 2 Rare-event Adaptive Importance Sampling with Function Approximation

Input: Rare event set $T \subset S$, true rare-event probability ε, and parameter $\delta > 0$, used to keep the sampling distribution non-zero everywhere.

1. Initialize parameter vector θ arbitrarily.
2. Initialize rare-event sampling parameter: $\hat{\varepsilon} \leftarrow 1/2$.
3. Initialize $\hat{T} \leftarrow 0$, $\hat{U} \leftarrow 0$.
4. Initialize eligibility vector: $\mathbf{e} \leftarrow 0$.
5. Initialize the total importance sampling trajectory weight: $c \leftarrow 1$.
6. Select the initial state s_0.
7. Repeat for $t = 0, 1, \ldots$:
   (a) Update the eligibility trace of the current state
   $$\mathbf{e} = \mathbf{e} + c\phi(s_t).$$
   (b) Select an action $a_t \sim \pi(s_t, \cdot)$.
   (c) Select whether a rare event happens, according to $\hat{\varepsilon}$, and sample s_{t+1} from f or g accordingly. Observe the reward r_{t+1}.
   (d) Compute the importance sampling weight w_t according to (5).
   (e) Compute the importance-sampling TD-error:
   $$\Delta_t = w_t(r_{t+1} + \gamma\hat{V}^{\pi}(s_{t+1})) - \hat{V}^{\pi}(s_t),$$
   where $\hat{V}^{\pi}$ is computed according to (7).
   (f) If $s_{t+1} \in T$, then:
   $$\hat{T} \leftarrow ((1-\alpha_T)\hat{T} + \alpha_T\varepsilon(r_{t+1} + \gamma\hat{V}^{\pi}(s_{t+1})),$$
   else
   $$\hat{U} \leftarrow (1-\alpha_U)\hat{U} + \alpha_U(1-\varepsilon)(r_{t+1} + \gamma\hat{V}^{\pi}(s_{t+1})).$$
   (g) Update the parameter vector: $\theta \leftarrow \theta + \alpha\mathbf{e}\Delta_t$, where $\alpha \in [0,1]$ is a learning rate.
   (h) Update the rare event probabilities:
   $$\hat{\varepsilon} \leftarrow \min\left(\max\left(\delta, \frac{|\hat{T}|}{|\hat{T}| + |\hat{U}|}\right), 1-\delta\right).$$
   (i) Update the trajectory weight: $c \leftarrow cw_t$.
   (j) Update eligibility traces:
   $$\mathbf{e} \leftarrow \gamma\lambda w_t \mathbf{e}.$$

8. Experimental Results

8.1. Random MDPs

We first compare the performance of REASA to on-line TD(λ) and to ASA on a testbed of randomly generated

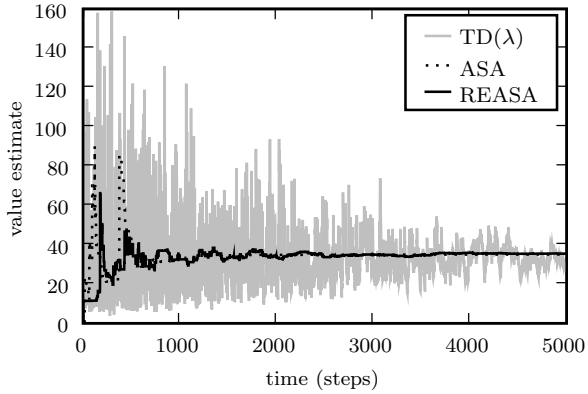

Figure 1. Value function estimate for state 0.

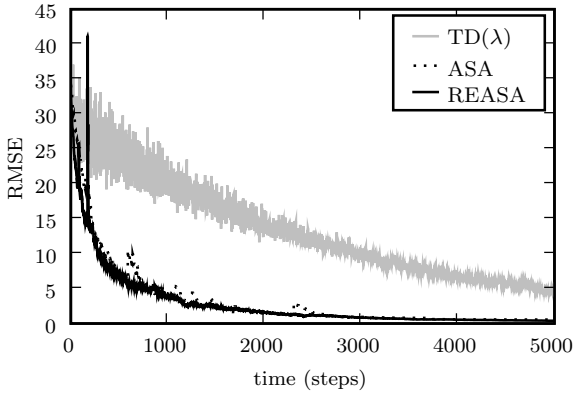

Figure 2. Root MSE for value function estimate for state 0.

Markov chains. Each environment contains 10 regular states and one rare event state. Each regular state can transition to seven other regular states (chosen randomly) with probabilities drawn from a uniform distribution, and to the rare event state with probability $\varepsilon = 0.001$. The rewards for transitioning between the regular states and from the rare event state to the regular states are drawn from a normal distribution with mean 1.0 and standard deviation 0.5, with negative values being discarded (so that we can run ASA). The rewards for transitioning to the rare event state are drawn from a normal distribution with mean $10/\varepsilon$ and standard deviation $1/\varepsilon$. The initial state is state 0, and the discount factor is $\gamma = 0.7$.

In the following results, a step is considered to be one transition for both ASA and REASA, but for TD(λ), a "step" actually consists of 2300 real time steps. We chose this number of steps so that the probability of observing at least one rare event transition in each episode is approximately 0.9. Therefore, we put TD(λ) at a significant advantage in terms of the number of samples that it is provided. In Figure 1 we plot the estimate for the value function at the initial state over time, averaged across 70 independent runs. We use a value of $\lambda = 0.7$ and the learning rates are on decreasing schedules that have been tuned separately for each of the algorithms. Figure 2 shows the root mean squared error for the value function estimate at the initial state, again averaged across 70 independent runs.

The learning and error curves for REASA and ASA are nearly indistinguishable, and both outperform TD(λ). We note that in the case of ASA, the original transition probability distribution is needed, and the algorithm has full control over the transition probabilities that are used in the simulation (an unlikely case in many practical applications). We observe that despite the fact that REASA can only know and control the rare event probability, it performs nearly as well as ASA.

8.2. Policy Evaluation for Network Planning

In order to demonstrate REASA in a practical setting with a large state space, we use a network planning task in which a reinforcement learning agent has to build and maintain a telecommunications network linking ten North American cities. Each pair of cities has a certain traffic demand, ranging from 3GBs[2] to 60GBs initially, and this demand grows stochastically at a rate of approximately 3% per year. The goal is to place links between the cities in order to deliver this data. Links consist of bundles of fiber optic cables, and each fiber can carry a specific unit of bandwidth. Building links between the cities incurs a large one-time cost of \$500k/mile. Once a link has been built, the capacity of the link can be increased by activating fibers, in units of 25GBs; this incurs a cost of \$30k/mile. The revenue from traffic is generated daily: traffic delivered generates a reward of \$1k/GBs/mile, and undelivered traffic is penalized at a rate of \$200k/GBs/mile every hour.

Link failures occur with a small probability, completely severing a link for a short period of time. Without considering link failures, a minimum spanning tree (MST) could be built, with enough activated fibers to carry the traffic. However, in such a network, any link failure would disconnect the network, which would lead to undelivered traffic and a high penalty. Hence, link failures in a network that lacks robustness are rare events according to our definition. On each day, each link goes down with probability $1/1460$, or approximately once every four years. When a link fails, it remains down for a random amount of time that is normally distributed with a mean of 12 hours and standard deviation of 2 hours. In a tree network with 9 links, this is equivalent to seeing at least one link fail with probability of approximately 0.00896 each day during the 10 year simulation period; this is our rare event probability.

[2]We use GBs to represent an average sustained traffic rate of 1 gigabyte per second; because the time interval under consideration is always roughly the same, we also use it as a unit of traffic, with an abuse of notation.

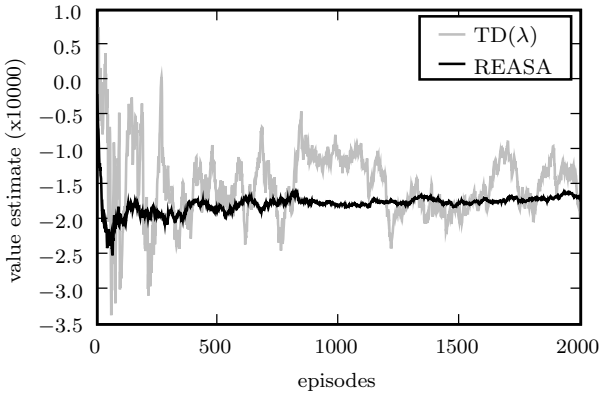

Figure 3. Value estimate for tree network.

We implemented a network planning agent with a simple heuristic policy, which first builds a tree network and then monitors the links, adding capacity when the utilization of a link reaches 90%. We use REASA and TD(λ) to estimate the value of this policy. We represent the network state as a vector of binary features, and use linear function approximation to represent the value function. In order to cope with the high dimensionality, we use a fairly coarse state representation, consisting of: indicator variables regarding whether each of the possible links have been built; indicator variables for each link, which are true if the link is currently failing; and the percentage utilization of each link, partitioned into 4 bins: $[0]$, $(0, 0.6]$, $(0.6, 0.9]$, and $(0.9, 1.0]$. For our 10 node network, this corresponds to 270 binary features plus an additional bias feature.

We use a discount factor of 0.95 and we set $\lambda = 1.0$. We use a decaying schedule for the learning rate parameter α, starting with a value of $\alpha_0 = 2^{-15}$ for $T = 100$ episodes, then using $\alpha_0/2$ for $2T$ episodes, $\alpha_0/4$ for $4T$ episodes, etc. We note that α_0 is extremely small due to the fact that the rewards often have large magnitude and can vary between -10^7 and 10^5. In the following results, an episode consists of a simulated 10-year time span.

In Figure 3, we show the value estimate for the initial tree network state. We see that REASA converges quickly, while the TD(λ) estimates have high variance and converge quite slowly. On longer runs, the TD(λ) estimates do converge to the same value as REASA. REASA estimates the optimal failure probability to be 0.155, which in a tree network with 9 links corresponds to each link going down approximately every 54 days; this is quite far from the original failure probability of once every 1460 days.

The rate of convergence is crucial for applications such as the network task. Here, each episode corresponds to a simulated 10 year period, and these simulations are computationally expensive to run, because on each day, a routing algorithm has to be run to determine the reward. Hence, the gains obtained by REASA are significant.

9. Conclusions and Future Work

We presented an approach for reinforcement learning in environments with rare events, aimed at reducing the variance of RL algorithms. Our algorithm modifies the sampling probability of the rare events, and makes minimal assumptions on the simulator available to the agent. The empirical results demonstrate the viability of our approach for solving large-scale problems. Future work will include measuring empirically the bias and variance of the algorithm. We would also like to lift the assumption that the rare event probability is constant for the function approximation case. Note that Algorithm 2 can be easily adapted to compute $\hat{T}$ and $\hat{U}$ as a function of the features available. Hence, if a representation of $\varepsilon(s)$ as a function of the available features ϕ is given, we could estimate $\hat{\varepsilon}$ as a function of features as well. It is possible also to learn the true rare event probabilities ε from data, but we anticipate that in practice this may be difficult.

Abstract

What type of algorithms and statistical techniques support learning from very large datasets over long stretches of time? We address this question through a memory bounded version of a variational EM algorithm that approximates inference in a topic model. The algorithm alternates two phases: "model building" and "model compression" in order to always satisfy a given memory constraint. The model building phase expands its internal representation (the number of topics) as more data arrives through Bayesian model selection. Compression is achieved by merging data-items in clumps and only caching their sufficient statistics. Empirically, the resulting algorithm is able to handle datasets that are orders of magnitude larger than the standard batch version.

1. Introduction

Consider a collection of surveillance cameras monitoring at an airport. The cameras learn a model of their environment without supervision. Moreover, they learn for many years without significant interruption. Gradually, as more data is captured, the cameras build a joint model of visual object categories.

This problem is akin to the way children learn to understand the world through the *continuous* process of mostly unsupervised learning. As children grow up they build an increasingly sophisticated internal representation of object categories that continuously restructures itself.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

In this paper we ask ourselves: What statistical techniques are suitable for this "*lifelong learning task*"? First, we need a class of models that can naturally expand as more data arrives, i.e. it's capacity should not be bounded a priori. Second, these models should allow efficient learning algorithms, both in terms of time and space. For instance, we should not have to store every single piece of information that has been captured. Our technique must produce a sequence of model estimates that reflect new information as it arrives, and the time required to produce each model update must scale modestly as more data is acquired. Finally, we require that the sequence of learned models are sufficiently similar to those that would be produced by a batch algorithm with access to the entire history of data observed at the time of each model update.

Nonparametric Bayesian techniques such as the Dirichlet Process (DP) (Ferguson, 1973) and the Hierarchical Dirichlet Process (HDP) (Teh et al., 2006) satisfy our first desideratum, in that they naturally increase their model complexity with the available data. However, most existing Nonparametric Bayesian approaches are batch algorithms: they require every single data-point to be stored and revisited during learning. A batch algorithm could be naively applied to the continuous learning scenario, but all data would need to be cached and a new batch learning process would be run on the entire dataset to produce each model update. This would violate our second criterion in that the time and space requirements would increase unacceptably as the system ages.

Here we propose a more flexible setup, where we impose a bound on the available memory but still allow the model order to increase with more data. We *compress* the data and the internal representation of the model without losing much in terms of model accuracy. The effect is that time and space requirements scale much more gradually over the lifetime of the system. The memory bound does impose a limit on the total capacity of the model, but this trade-off

is flexible and can be adjusted online, i.e. as the model is learned. Experiments with a memory bounded variational approximation to HDP show that this technique can handle datasets many times larger than the standard implementations and results in substantially shorter run-times.

2. A Memory Bounded Variational Topic Model

At a high level the idea is to use a variational approximation related to LDA (Blei et al., 2003) and HDP (Teh et al., 2006). Memory savings are achieved by "clumping" together data-cases. That is, we constrain groups of datapoints to have equal topic assignment variational distributions: $q(z_{ij}) = q(z_{i'j'}) = q(z_c)$ when points x_{ij} and $x_{i'j'}$ are members of the clump c. This allows us to achieve memory savings, because variational optimization performed under this constraint requires only the sufficient statistics of the data-cases in a clump, and the system can forget the exact identities of the summarized data points. Similarly, we will also clump entire documents (or images) by tying their variational distributions over topics: $q(\boldsymbol{\pi}_j) = q(\boldsymbol{\pi}_{j'}) = q(\boldsymbol{\pi}_s)$ if document j and j' belong to the same document group s. This tying of variational distributions guarantees that learning optimizes a lower bound to the exact free energy objective function, where the bound is increasingly loose with more tying. This idea was also leveraged in (Verbeek et al., 2003) and (Kurihara et al., 2006) to accelerate learning of Mixtures of Gaussians and DP Mixtures of Gaussians by using KD-trees.

In the following we will talk about documents, but we note that this refers to other structured objects such as images as well.

2.1. The Variational Topic Model

The following Bayesian topic model is our starting point,

$$p(\mathbf{x}, \mathbf{z}, \boldsymbol{\eta}, \boldsymbol{\pi}, \boldsymbol{\alpha}) = \prod_{ij} p(\mathbf{x}_{ij}|z_{ij}; \boldsymbol{\eta})\, \pi_{j,z_{ij}} \left[\prod_k p(\boldsymbol{\eta}_k|\boldsymbol{\beta})\right] \left[\prod_j \mathcal{D}(\boldsymbol{\pi}_j; \boldsymbol{\alpha})\right] \left[\prod_k p(\alpha_k)\right] \tag{1}$$

where $\mathbf{x}_{ij}$ is word i in document j and z_{ij} denotes the topic that generated $\mathbf{x}_{ij}$. $\boldsymbol{\pi}_j$ denotes the mixture of topics that generated the words in document j, with $\sum_k \pi_{jk} = 1$. $\boldsymbol{\pi}_j$ are distributed according to a Dirichlet distribution with parameter $\boldsymbol{\alpha}$. Boldface symbols denote vector valued quantities. In this expression we will assume that $p(\mathbf{x}|z, \boldsymbol{\eta})$ is in the exponential family[1],

$$p(\mathbf{x}|z = k, \boldsymbol{\eta}) = \exp\left[\sum_l \eta_{kl}\, \phi_l(\mathbf{x}) - A_k(\boldsymbol{\eta}_k)\right] \tag{2}$$

and $p(\boldsymbol{\eta}|\beta)$ is conjugate to $p(\mathbf{x}|z, \boldsymbol{\eta})$,

$$p(\boldsymbol{\eta}_k|\boldsymbol{\beta}) = \exp\left[\sum_l \beta_l \eta_{kl} - \beta_0 A_k(\boldsymbol{\eta}_k) - B(\boldsymbol{\beta})\right] \tag{3}$$

The posterior distributions over $\boldsymbol{\pi}, \boldsymbol{\eta}, \mathbf{z}$ are approximated variationally as

$$q(\boldsymbol{\eta}) = \prod_k q(\boldsymbol{\eta}_k; \boldsymbol{\xi}_k) \tag{4}$$

$$q(\boldsymbol{\pi}) = \prod_j \mathcal{D}(\boldsymbol{\pi}_j; \boldsymbol{\zeta}_j) \tag{5}$$

$$q(\mathbf{z}) = \prod_{ij} q(z_{ij}) \tag{6}$$

where we have introduced variational parameters $\{\boldsymbol{\xi}_{kl}, \zeta_{kj}, q_{ijk}\}$, the latter subject to $\sum_k q_{ijk} = 1$. Furthermore, $\mathcal{D}$ denotes a Dirichlet distribution while $q(\boldsymbol{\eta}_k; \boldsymbol{\xi}_k)$ is also conjugate to $p(\mathbf{x}|z = k, \boldsymbol{\eta})$,

$$q(\boldsymbol{\eta}_k; \boldsymbol{\xi}_k) = \exp\left[\sum_l \xi_{kl}\eta_{kl} - \xi_{k0} A_k(\boldsymbol{\eta}_k) - B_k(\boldsymbol{\xi}_k)\right] \tag{7}$$

By writing down the variational free energy and minimizing it over $\boldsymbol{\xi}, \boldsymbol{\zeta}$ we find the following intuitive updates,

$$\xi_{kl} = F_{kl} + \beta_l; \qquad F_{kl} \triangleq \sum_{ij} q_{ijk}\, \phi_l(\mathbf{x}_{ij}) \tag{8}$$

$$\xi_{k0} = N_k + \beta_0; \qquad N_k \triangleq \sum_{ij} q_{ijk} \tag{9}$$

$$\zeta_{kj} = N_{kj} + \alpha_k; \qquad N_{kj} \triangleq \sum_i q_{ijk} \tag{10}$$

and

$$q_{ijk} \leftarrow \frac{1}{Z_{ij}} \frac{\exp\left[\sum_l \mathbb{E}[\eta_{kl}|\xi_{kl}]\, \phi_{kl}(\mathbf{x}_{ij})\right]}{\exp\left[\mathbb{E}[A_k(\boldsymbol{\eta}_k)|\xi_{k0}]\right]}\, \exp\left[\psi(\zeta_{kj})\right] \tag{11}$$

where Z_{ij} enforces the constraint $\sum_k q_{ijk} = 1$ and the expectations are over $q(\boldsymbol{\eta})$.

To learn the parameters $\{\alpha_k\}$ we first introduce gamma priors,

$$p(\boldsymbol{\alpha}) = \prod_k \mathcal{G}(\alpha_k; a, b) \tag{12}$$

[1] Strictly speaking, the exponential family includes additional multiplicative terms $h(\mathbf{x})$ in the expression for $p(\mathbf{x}|\boldsymbol{\eta})$ and $g(\boldsymbol{\eta})$ in the expression for $p(\boldsymbol{\eta}|\boldsymbol{\beta})$. We have left these terms out to simplify the derivation and because for most well known distributions they are simply 1. However, it is straightforward to include them.

Using the bounds in (Minka, 2000) we can derive the following updates if we first insert the updates for $\boldsymbol{\xi}$ and $\boldsymbol{\zeta}$ into the free energy,

$$\alpha_k \leftarrow \frac{(a-1)+\alpha_k \sum_j \left[\psi(\zeta_{kj})-\psi(\alpha_k)\right]}{b+\sum_j \left[\psi(\zeta_j)-\psi(\alpha)\right]} \tag{13}$$

with $\zeta_j = \sum_k \zeta_{kj}$ and $N_j = \sum_k N_{kj}$.

2.2. Optimizing the Number of Topics K

Our strategy to search for a good value of K is to *truncate* the topic distributions as $q(z_{ij} > K) = 0$ (see also (Teh et al., 2008)). This will have the effect that most terms in the free energy with $k > K$ will cancel, the exception being the prior terms $p(\alpha_k),\ k > K$. For these terms we know that the value for α_k minimizing the free energy is given by the MAP value of the gamma-prior $\alpha_k = \frac{a-1}{b},\ k > K$. Inserting this back into the free energy we accumulate $K_{\max} - K$ terms

$$\Lambda = a\log b - \log\Gamma(a) + (a-1)\log\frac{a-1}{b} - (a-1) \tag{14}$$

where $K_{\max}$ is the maximum number of topics.

It is guaranteed that there exists a solution with lower free energy if we increase K. The reason is that we relax a self-imposed constraint on variational parameters (that $q(z_{ij} > K) = 0$). As K increases the relative improvement in free energy quickly attenuates. The final value for K is obtained by thresholding this relative improvement.

The *nesting* property (models with larger K are better) is the same for variational approximations to the DP in (Kurihara et al., 2006) and HDP (Teh et al., 2008). This raises the question if we can take the infinite limit for our model as well. The problem is that $(K_{\max} - K)\Lambda \rightarrow \infty$ as $K_{\max} \rightarrow \infty$. This can be traced back to the fact that we should have added a proper prior $p(K)$ which would have diminished the contribution at large K. Instead we choose an improper, constant prior to avoid the need to estimate likely values for K a priori. However, it is still possible to work with infinite free energies because we are only interested in the relative *change* in free energy after increasing K, which is a finite quantity.

In our experiments we chose $a = 1$ and $b = 0.5$, so that the MAP prior value of α_k is 0.

2.3. Clumping Data-Items and Documents

We will now tie some of the variational distributions $\{q_{ijk}\}$ across different data-items within and across documents (images) to a "clump distribution" q_{ck}. Similarly, we will tie some document specific distributions over topics $\{q(\boldsymbol{\pi}_j)\}$ into a document group $q(\boldsymbol{\pi}_s)$. Note that since we impose constraints on the variational distributions this has the effect of loosening the variational bound.

Define D_s to be the number of documents in a document group, N_c the number of data-items in a word clump, N_{cs} the number of words in document group s and word clump c and finally $\Phi^c_{kl} \triangleq \sum_{ij\in c} \phi_{kl}(\mathbf{x}_{ij})$. In terms of these we further define,

$$N_{ks} \triangleq \sum_c q_{ck} N_{cs} \tag{15}$$

$$N_k \triangleq \sum_c q_{ck} N_c \tag{16}$$

$$F_{kl} \triangleq \sum_c q_{ck}\ \Phi^c_{kl} \tag{17}$$

With these definitions we derive the following "clumped" update rules for the variational parameters ξ_{kl} and ζ_{ks},

$$\xi_{kl} = F_{kl} + \beta_l \tag{18}$$

$$\xi_{k0} = N_k + \beta_0 \tag{19}$$

$$\zeta_{ks} = \tfrac{N_{ks}}{D_s} + \alpha_k \tag{20}$$

and

$$q_{ck} \leftarrow \frac{1}{Z_c}\frac{\exp\left[\sum_l \mathbb{E}[\eta_{kl}|\xi_{kl}]\ \frac{\Phi^c_{kl}}{N_c}\right]}{\exp\left[\mathbb{E}[A_k(\boldsymbol{\eta}_k)|\xi_{k0}]\right]}\ \exp\left[\sum_s \frac{N_{sc}}{N_c}\psi(\zeta_{ks})\right] \tag{21}$$

The update for $\boldsymbol{\alpha}$ becomes

$$\alpha_k \leftarrow \frac{(a-1)+\alpha_k \sum_s D_s \left[\psi(\zeta_{ks})-\psi(\alpha_k)\right]}{b+\sum_s D_s \left[\psi(\zeta_s)-\psi(\alpha)\right]} \tag{22}$$

An expression for the free energy, after inserting expressions 18, 19 and 20, is given by eq. 29 in the appendix.

3. Incremental Learning with a Memory Constraint

Our algorithm processes data in small groups composed of E documents, which we refer to as *epochs*. After the arrival of each epoch the algorithm proceeds in two stages: a model building phase during which a new model estimate is produced, and a compression phase in which decisions are made as to which words and documents to clump. The sufficient statistics of each clump are computed and data summarized by clumps are purged from memory. The assignment distributions $q(z)$ of purged data and topic distributions of merged documents $q(\boldsymbol{\pi})$ are discarded as well. The clump sufficient statistics are retained along with the current model estimate, which serves as a starting point for the next round of learning.

Model Building Phase (Algorithm 3.1)

Input: Previous model $\{\xi_{kl}, \zeta_{ks}, \alpha_k, \Phi^c_{kl}, N_{cs}, D_s\}$, and current epoch of E documents.
Initialize $\zeta_{jk} = \alpha_k$ for $j = |S| + 1, \cdots, |S| + E$
Iterate eqs. 21, 18, 19, 20, and 22 until convergence
repeat
  Rank splits and merges according to criteria in (Ueda et al., 1999)
  for $i = 1$ **to** 10 **do**
    Split i-th ranked candidate topic along principal component
    Restricted iteration of eqs. 21, 18, 19, and 20 until convergence
    Evaluate change in eq. 29 resulting from split
  end for
  for $i = 1$ **to** 10 **do**
    Merge i-th ranked pair of topics
    Evaluate change in eq. 29 resulting from merge
  end for
  Select split or merge that yielded largest change in eq. 29
  Iterate eqs. 21, 18, 19, and 20 until convergence
until Change in eq. 29 is less than threshold

3.1. Model Building Phase

The model building phase optimizes the free energy under the parameter tying constraints induced by the choice of clumps in previous compression phases. We perform a split-merge procedure similar to (Ueda et al., 1999) to determine the number of topics, using the heuristics in that work to rank topic suitability for split or merge. In our experiments we use Gaussian topic distributions, so splits are proposed along the principal component of the topic. The split proposals are refined by restricted variational updates. That is: equations 21, 18, 19, 20, and 22 are iterated but only for data-points whose highest responsibility is to the split topic, and the points may be assigned only to the two descendent topics. Merges are carried out by instantiating a new topic with the data-points with highest responsibility to the merged topics. A total of 10 splits and 10 merges are proposed, and evaluated by the resultant change in free energy (eq. 29). The top ranked change is then used to initialize full variational updates (which involve all data points). The model building phase halts once the change in free energy divided by its previous value is below a threshold, which was chosen to be $1E-5$ in our experiments. The procedure is summarized in algorithm 3.1.

3.2. Compression Phase

The goal of the compression phase is to determine groups of data-points that are to be summarized by clumps, and to identify documents that are to be merged into document groups.

Clumps are identified using a greedy top down splitting procedure. Because datapoints summarized by clumps are ultimately discarded, the compression process is irreversible. Therefore it is of fundamental importance to predict the locations of future data when deciding which points to clump. In order to estimate this, we rank cluster splits according to a modified free energy (eq. 30) in which the data sample size is artificially increased by a factor $\frac{T_{pts}}{\sum_c N_c}$ and the number of documents is scaled by $\frac{T_{docs}}{\sum_s D_s}$, where T_{pts} and T_{docs} are the target number of data-points and documents expected during the lifetime of the system. This is equivalent to using the data empirical distribution as a predictive model of future data. If we determine clumps using the standard free energy, then the algorithm fails to split large groups of points that are likely to split once more data has arrived. Instead, it wastes memory by placing "stray" points in their own clumps.

We initialize the process by hard assigning each clump or data-point to the cluster with highest responsibility during the previous model building phase. We then proceed through each cluster and split it along the principal component, and refine this split by iterating restricted variational updates equations for the points in the cluster. The updates are modified by the data magnification factors:

$$\xi_{kl} = \left(\frac{T_{pts}}{\sum_c N_c}\right) F_{kl} + \beta_l \tag{23}$$

$$\xi_{k0} = \left(\frac{T_{pts}}{\sum_c N_c}\right) N_k + \beta_0 \tag{24}$$

$$\alpha_k \leftarrow \frac{(a-1) + \left(\frac{T_{docs}}{\sum_s D_s}\right) \alpha_k \sum_j \left[\psi(\zeta_{ks}) - \psi(\alpha_k)\right]}{b + \left(\frac{T_{docs}}{\sum_s D_s}\right) \sum_s \left[\psi(\zeta_s) - \psi(\alpha)\right]} \tag{25}$$

Updates for q_{ck} and ζ_{ks} are unchanged. After the clusters are refined, the data-points are then hard assigned to the sub-cluster with greatest responsibility, and the proposed split is ranked according to the resultant change in eq. 30. We then greedily split the cluster with highest rank. The process repeats itself, with new clusters ranked in the same way described above. We cache the results of each split evaluation to avoid redundant computation. After we have reached a given memory bound we extract the partitions resulting from this recursive splitting procedure as our new clumps.

Each clump must store sufficient statistics for full covariance Gaussian components which require $\frac{d^2+3d}{2}$ values, where d is the dimension of the feature space. In addition, $|S|$ (the number of document groups) values must be

Clump Compression (Algorithm 3.2)

Input: Output from model building phase: $\{q_{ck}, \Phi^c_{kl}, N_{cs}, D_s\}$, current epoch of E documents and memory bound M.
Hard partition clumps: $r_c = \arg\max_k q_{ck}$
while $MC < M$ (eq. 26) **do**
  for $i = 1$ **to** K **do**
    Split i-th cluster along principal component
    Iterate data magnified restricted updates until convergence
    Hard partition clumps into child clusters
    Evaluate change in eq. 30 resulting from split
  end for
  Select split that yielded largest change in eq. 30
  $K = K + 1$
end while

stored to represent the counts N_{cs} for each clump. Note that from this perspective, it only makes sense to create clumps within a cluster if it contains more than $\frac{d+3}{2} + \frac{1}{d}$ data-points. If not, then it is more efficient to store the individual data-points and we refer to them as "singlets". The total memory cost of summarizing the data is then

$$MC = \left(\frac{d^2 + 3d}{2}\right)|N_c > 1| + |S||N_c > 1| + d|N_c = 1|, \tag{26}$$

where $|N_c > 1|$ is the number of clumps with more than 1 data-item in them, and $|N_c = 1|$ is the number of singlets. The clump compression procedure is summarized in algorithm 3.2.

Document merging provides another way of controlling the memory cost, by reducing the number of image groups $|S|$. We use the following simple heuristic to rank the suitability of merging document groups s and s':

$$DM_{s,s'} = \frac{\sum_k \mathbb{E}[\pi_{sk}]\mathbb{E}[\pi_{s'k}]}{||\mathbb{E}[\boldsymbol{\pi}_s]||||\mathbb{E}[\boldsymbol{\pi}_{s'}]||} \tag{27}$$

Clumping and document merging enable a number of potential schemes for controlling space and time costs, depending on the application. We note that the time complexity per variational iteration scales as $O(K(|N_c > 1| + |N_c = 1|) + |S|K)$ and the space required to store $q(z_c)$ distributions is $O(K(|N_c > 1| + |N_c = 1|))$.

4. Experiments

We test our approach with two machine vision experiments. The first is an image segmentation task, and the second is an object recognition and retrieval task.

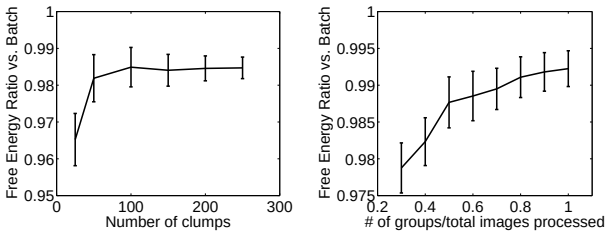

Figure 1. Image Segmentation experiment. Left: Free energy ratio as a function of the number of clumps permitted by the memory bound. Right: Free energy ratio versus the number of image groups relative to the total number of images processed.

4.1. Joint Image Segmentation

Our first experient is a joint image segmentation problem. The dataset is the Faces-Easy category of the Caltech 101 image dataset (Fei-Fei et al., 2004) consisting of 435 images. Each image contains a face centered in the image, but the lighting conditions and background vary. In terms of the vocabulary of the preceding sections, each image is a document and each pixel in the image is a word. Pixels are represented as five dimensional vectors of the following features: X and Y position relative to the center of the image, and three color coordinates in the CIELAB colorspace. The goal of our experiment is to find similar image regions across the multiple images, in an unsupervised way. We emphasize that our main objective is to study the efficiency of our algorithm, not to produce a state of the art image segmentation algorithm.

The images were scaled to be 200 by 160 pixels in size. Thus, the total size of the dataset is 32,000 pixels per image, times 435 images, times 5 features per pixel equals 69,600,000 real numbers. Each pixel requires an assignment distribution. Our baseline implementation (i.e. a batch algorithm that processes all images in memory at once and does not use pixel clumping or image merging) was only able to jointly segment 30 images simultaneously, before running out of memory. The majority of memory is used to store the assignment distributions of pixels, and this is problematic as the number of topics increases during learning, since the space requirements scale as $O(NK)$, where N is the total number of pixels and K is the number of topics.

We first compare the memory bounded approach to the baseline implementation on a joint segmentation task of 30 images in order to judge the impact of the pixel clumping approximation. We vary the upper limit on the number of clumps used to summarize the data during the compression phase, and compare the free energy bounds produced by the memory bounded algorithm to those produced by the baseline implementation. We define the free energy ratio

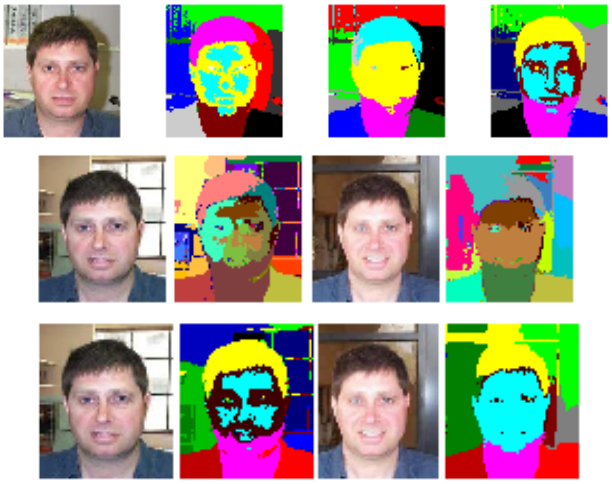

Figure 2. Top row: From left to right: an example segmentation produced by the baseline method, memory bounded algorithm with 30% of total images and 125 clumps, and the memory bounded algorithm with no images merged and 125 clumps. Row 2: Example clump distributions. Pixels of the same color are summarized in a single clump. Row 3: segmentations corresponding to clumps in row 2.

as $1 - \frac{FE_{batch} - FE_{mb}}{|FE_{batch}|}$. This process was repeated for different subsets of 30 images from the dataset. In the memory bounded approach, images were processed in epochs of five images at a time. Figure 1 summarizes the results. We find that performance tends to saturate beyond a certain number of clumps.

We also note a significant run time advantage of the memory bounded algorithm over the batch method. The average run time of the batch method was 3.09 hours versus 0.68 hours for the memory bounded approach.

Next we study the impact of image (document) merges on the relative performance of the memory bounded algorithm versus the baseline batch algorithm, while varying the maximum number of image (document) groups permitted. The results are shown in figure 1.

We find little qualitative difference between segmentations produced by the baseline and memory bounded algorithms. The possible exception is in the case when the memory bounded algorithm is run with a large number of image merges, in which case the algorithm seemed to discover fewer topics than the batch and memory bounded algorithm with only word clumping. Example image segmentations and clump distributions are shown in figure 2.

Finally, we demonstrate the memory bounded algorithm on the full dataset of 435 images, which is more than an order of magnitude larger than can be handled with the baseline algorithm. We process images in *epochs* of 10 images at a time, for a total of 44 learning rounds. The upper limit on the number of clumps was set to 1000, which was likely many more than required since there were only 85 inferred topics. Because the number of documents was relatively small, we chose not to use document merges. The total run time of the algorithm was 15 hours. Figure 3 shows the number of topics as a function of the number of images processed, and the run time required during each image round. The run time is longer during learning rounds in which more new topics are discovered, because more split-merge operations are necessary. The memory required for the memory bounded algorithm was 22 MB to store the current image epoch and clumps, less than 1MB for the current model estimate, and 235 MB for assignment distributions, for a total of 257 MB. In contrast, the baseline batch implementation would have required 531 MB to store all 435 images, 8.8155 GB to store assignment distributions for each pixel assuming 85 topics, and less than 1 MB for the model, for a total of 9.3 GB. (All memory amounts assume double precision floating point.) The memory bounded implementation therefore achieved a memory savings factor of about 38 with very little loss in accuracy.

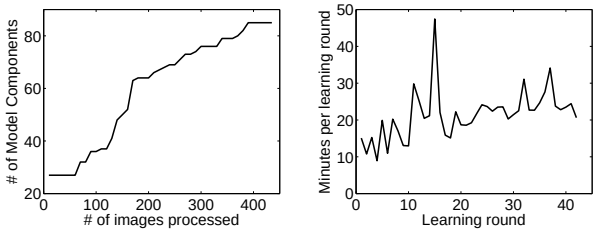

Figure 3. Joint segentation of 435 faces. The left plot shows the number of topics recovered as the system processes images. The right plot shows the run time for each learning round. This fluctuates with the number of new topics discovered during each round and tends to increase gradually with the total number of topics.

Figure 4 shows example joint segmentations produced by the memory bounded algorithm. These images were retrieved by first computing responsibilities for every image in the dataset, with respect to the final model estimate produced by the MB algorithm. Then, the images were sorted according to those that have the most pixels assigned to the largest topic. The largest topic indeed corresponds to a face, and is represented by the olive green segment in the figure. Other topics shared across images include hair and certain backgrounds.

4.2. Object Recognition and Retrieval

Our object recognition and retrieval experiment involves all 101 object categories in the Caltech 101 dataset. We randomly select 3000 training images and 1000 test images. We extract 128-dimensional SIFT (Lowe, 2004) local ap-

Figure 4. Examples of joint segmentation produced after processing all Caltech Face images. Pixels that are the same color have highest responsibility to the same topic. These images were retrieved by sorting images according to those that have the most pixels assigned to the largest topic, which is the olive green colored face segment in each image.

pearance descriptors from 500 randomly chosen locations in each image. The scale of each feature is also chosen randomly. In the language of topic models, each feature descriptor is a word, and the collection of feature descriptors in an image forms a document. This image representation is known as 'bag-of-features', because images are modeled as unordered collections of feature descriptors whose geometric positions are ignored. This dataset proved too large to compare directly to the batch algorithm

We train a single topic model on all training images, using epochs of 60 images at a time. Because hundreds of topics are discovered we use diagonal covariance Gaussians and adjust equation 26 accordingly. Given a test image $\tilde{\mathbf{x}}$, retrieval is performed by ranking each training image's similarity to the test image. To develop the similarity measure we begin with $\log \prod_i p(\tilde{\mathbf{x}}_{ij}|\mathbf{x})$, which is the log-probability that the detections in the test image were generated by training image j given the training set. Then we variationally lower bound this quantity to obtain a test free energy and drop all constant terms not involving the test image and index j. Finally we lower bound this quantity by assuming that detections in the test image are hard assigned to the topic with highest responsibility (this leads to an expression that is much faster to evaluate with neglible impact on retrieval performance.) The retrieval score is:

$$score(j) = \sum_i \max_k \Big\{ \sum_l \mathbb{E}[\eta_{kl}|\xi_{kl}]\ \phi_{kl}(\tilde{\mathbf{x}}_{ij}) - \mathbb{E}[A_k(\boldsymbol{\eta}_k)|\xi_{k0}] + \psi(\zeta_{kj}) - \psi(\sum_k \zeta_{kj}) \Big\} \quad (28)$$

where the expectations are with respect to $q(\boldsymbol{\eta})$ learned during training and ξ_{kl} and ζ_{kj} are from training as well. ζ_{kj}

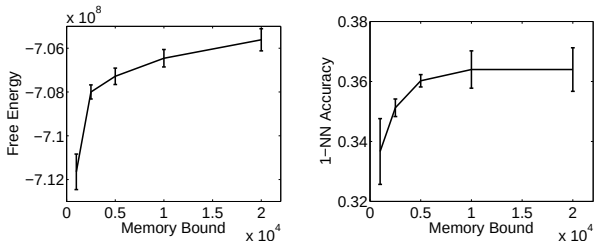

Figure 5. Object Recognition and Retrieval. Left: Training set free energy as a function of the memory bound. Right: 1-NN classification accuracy as a function of memory bound (measured as the equivalent number of data-points that could be stored in the same space).

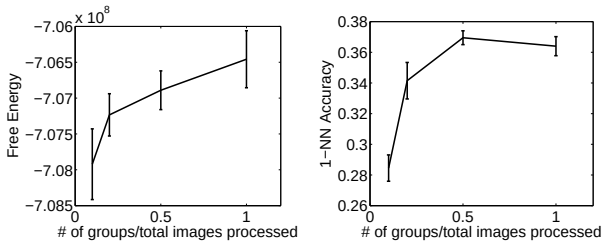

Figure 6. Object Recogniton and Retrieval. Left: Training set free energy versus the ratio of document groups to the total number of images processed. Right: 1-NN classification accuracy versus the ratio of document groups to total number of images processed.

are re-estimated for images that were merged into a document group during training. We compute nearest neighbor (1-NN) classification accuracy by classifying the test image to the class label of the highest scoring image in the training set.

Figure 5 shows the training set free energy and 1-NN classification accuracy as a function of the memory bound M (measured as the equivalent number of data points that could be stored in the same space.) Because we used diagonal covariance matrices, there were enough clumps even at low levels of memory to maintain comparable classification performance. We note that the training free energy increases with memory as expected, and that the 1-NN accuracy tends to saturate as memory increases.

Figure 6 shows the 1-NN accuracy and training free energy when the percentage of document groups relative to the number of total images processed is varied (the memory bound M is held fixed at 10000). We note that the classification performance suffers substantially when only small numbers of document groups are permitted. We use a heuristic for determining documents to merge (eq. 27). It is possible that a well motivated criterion (perhaps derived from the free energy) would give better performance.

5. Conclusion

Machine learning has largely focussed on algorithms that run for a relatively short period of time, fitting models of finite capacity on a data-set of fixed size. We believe that this scenario is unrealistic if we aim at building truly intelligent systems. We have identified nonparametric Bayesian models as promising candidates that expand their model complexity in response to new incoming data. The flip-side is that nonparametric Bayesian algorithms are "example-based" and as such require one to cache and process repeatedly every data-case ever seen. The objectives of infinite, adaptive model capacity on the one hand and efficiency, both in time and space on the other therefore seem to be fundamentally at odds with each other.

In this paper we have made a first step towards resolving this issue by introducing a class of models that can adapt their model complexity adaptively but are able to do so at a fraction of the memory requirements and processing times necessary for their batch counterparts. There is no magic of course: with a fixed memory budget there is a limit to how complex the model can be, but we have shown that one can learn much larger models reliably with much less memory than a naive implementation would allow. Moreover, our learning algorithms allow a flexible tradeoff between memory requirements and model complexity requirements that can be adapted online.

Intuitively, our method may be thought of as a two level clustering process. At the bottom level, data is clustered into clumps in order to limit time and space costs. At the top level, clumps are clustered to form topics in order to ensure good generalization performance.

Potential application areas of the techniques introduced here are manyfold. For instance, we can imagine learning topic models from very large text corpora or the world wide web to understand its structure and facilitate fast searching algorithms. Another exciting direction is to build a taxonomy of visual object categories from a continuous stream of video data captured by surveillance cameras.

Localized Multiple Kernel Learning

Department of Computer Engineering, Boğaziçi University, TR-34342, Bebek, İstanbul, Turkey

Abstract

Recently, instead of selecting a single kernel, multiple kernel learning (MKL) has been proposed which uses a convex combination of kernels, where the weight of each kernel is optimized during training. However, MKL assigns the same weight to a kernel over the whole input space. In this paper, we develop a localized multiple kernel learning (LMKL) algorithm using a gating model for selecting the appropriate kernel function locally. The localizing gating model and the kernel-based classifier are coupled and their optimization is done in a joint manner. Empirical results on ten benchmark and two bioinformatics data sets validate the applicability of our approach. LMKL achieves statistically similar accuracy results compared with MKL by storing fewer support vectors. LMKL can also combine multiple copies of the same kernel function localized in different parts. For example, LMKL with multiple linear kernels gives better accuracy results than using a single linear kernel on bioinformatics data sets.

1. Introduction

Kernel-based methods such as the support vector machine (SVM) gained much popularity due to their success. For classification tasks, the basic idea is to map the training instances from the input space to a feature space (generally a higher dimensional space than the input space) where they are linearly separable. The SVM discriminant function obtained after training is:

$$f(\boldsymbol{x}) = \langle \boldsymbol{w}, \Phi(\boldsymbol{x}) \rangle + b \tag{1}$$

where $\boldsymbol{w}$ is the weight coefficients, b is the threshold, and $\Phi(\boldsymbol{x})$ is the mapping function to the corresponding feature space. We do not need to define the mapping function explicitly and if we plug $\boldsymbol{w}$ vector from dual formulation into (1), we obtain the discriminant:

$$f(\boldsymbol{x}) = \sum_{i=1}^{n} \alpha_i y_i \underbrace{\langle \Phi(\boldsymbol{x}), \Phi(\boldsymbol{x}_i) \rangle}_{K(\boldsymbol{x}, \boldsymbol{x}_i)} + b$$

where n is the number of training instances, $\boldsymbol{x}_i$, and $K(\boldsymbol{x}, \boldsymbol{x}_i) = \langle \Phi(\boldsymbol{x}), \Phi(\boldsymbol{x}_i) \rangle$ is the corresponding kernel.

Each $\Phi(\boldsymbol{x})$ function has its own characteristics and corresponds to a different kernel function and leads to a different discriminant function in the original space. Selecting the kernel function (i.e., selecting the mapping function) is an important step in SVM training and is generally performed using cross-validation.

In recent studies (Lanckriet et al., 2004a; Sonnenburg et al., 2006), it is reported that using multiple different kernels instead of a single kernel improves the classification performance. The simplest way is to use an unweighted sum of kernel functions (Pavlidis et al., 2001; Moguerza et al., 2004). Using an unweighted sum gives equal preference to all kernels and this may not be ideal. A better strategy is to learn a weighted sum (e.g., convex combination); this also allows extracting information from the weights assigned to kernels. Lanckriet et al. (2004b) formulate this as a semidefinite programming problem which allows finding the combination weights and support vector coefficients together. Bach et al. (2004) reformulate the problem and propose an efficient algorithm using sequential minimal optimization (SMO). Their discriminant function can be seen as an unweighted summation of discriminant values (but a weighted summation of kernel functions) in different feature spaces:

$$f(\boldsymbol{x}) = \sum_{m=1}^{p} \langle \boldsymbol{w}_m, \Phi_m(\boldsymbol{x}) \rangle + b \tag{2}$$

where m indexes kernels, $\boldsymbol{w}_m$ is the weight coefficients, $\Phi_m(\boldsymbol{x})$ is the mapping function for feature space m, and p is the number of kernels. By plugging $\boldsymbol{w}_m$ de-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

rived from duality conditions into (2), we obtain:

$$f(\boldsymbol{x}) = \sum_{m=1}^{p} \eta_m \sum_{i=1}^{n} \alpha_i y_i \underbrace{\langle \Phi_m(\boldsymbol{x}), \Phi_m(\boldsymbol{x}_i) \rangle}_{K_m(\boldsymbol{x}, \boldsymbol{x}_i)} + b \quad (3)$$

where the kernel weights satisfy $\eta_m \geq 0$ and $\sum_{m=1}^{p} \eta_m = 1$. The kernels we combine can be the same kernel with different hyperparameters (e.g., degree in polynomial kernel) or different kernels (e.g., linear, polynomial, and Gaussian kernels). We can also combine kernels over different data representations or different feature subsets.

Using a fixed combination rule (unweighted or weighted) assigns the same weight to a kernel over the whole input space. Assigning different weights to a kernel in different regions of the input space may produce a better classifier. If data has underlying localities, we should give higher weights to appropriate kernel functions (i.e., kernels which match the complexity of data distribution) for each local region. Lewis et al. (2006) propose to use a nonstationary combination method derived with a large-margin latent variable generative method. They use a log-ratio of Gaussian mixtures as the classifier. Lee et al. (2007) combine Gaussian kernels with different width parameters to capture the underlying local distributions, by forming a compositional kernel matrix from Gaussian kernels and using it to train a single classifier.

In this paper, we introduce a localized formulation of the multiple kernel learning (MKL) problem. In Section 2, we modify the discriminant function of the MKL framework proposed by Bach et al. (2004) with a localized one and describe how to optimize the parameters with a two-step optimization procedure. Section 3 explains the key properties of the proposed algorithm. We then demonstrate the performance of our localized multiple kernel learning (LMKL) method on toy, benchmark, and bioinformatics data sets in Section 4. We conclude in Section 5.

2. Localized Multiple Kernel Learning

We describe the LMKL framework for binary classification SVM but the derivations in this section can easily be extended to other kernel-based learning algorithms. We propose to rewrite the discriminant function (2) of Bach et al. (2004) as follows, in order to allow local combinations of kernels:

$$f(\boldsymbol{x}) = \sum_{m=1}^{p} \eta_m(\boldsymbol{x}) \langle \boldsymbol{w}_m, \Phi_m(\boldsymbol{x}) \rangle + b \quad (4)$$

where $\eta_m(\boldsymbol{x})$ is the *gating function* which chooses feature space m as a function of input $\boldsymbol{x}$. $\eta_m(\boldsymbol{x})$ is defined up to a set of parameters which are also learned from data, as we will discuss below. By modifying the original SVM formulation with this new discriminant function, we get the following optimization problem:

$$\begin{aligned} &\min \frac{1}{2} \sum_{m=1}^{p} \|\boldsymbol{w}_m\|^2 + C \sum_{i=1}^{n} \xi_i \\ &\text{w.r.t. } \boldsymbol{w}_m, b, \boldsymbol{\xi}, \eta_m(\boldsymbol{x}) \\ &\text{s.t. } y_i \left(\sum_{m=1}^{p} \eta_m(\boldsymbol{x}_i) \langle \boldsymbol{w}_m, \Phi_m(\boldsymbol{x}_i) \rangle + b \right) \geq 1 - \xi_i \quad \forall i \\ &\xi_i \geq 0 \quad \forall i \end{aligned} \quad (5)$$

where C is the regularization parameter and $\boldsymbol{\xi}$ is the slack variables as usual. Note that the optimization problem in (5) is not convex due to the nonlinearity introduced in the separation constraints.

Instead of trying to solve (5) directly, we can use a two-step alternate optimization algorithm inspired from Rakotomamonjy et al. (2007), to find the parameters of $\eta_m(\boldsymbol{x})$ and the discriminant function. The first step is to solve (5) with respect to $\boldsymbol{w}_m$, b, and $\boldsymbol{\xi}$ while fixing $\eta_m(\boldsymbol{x})$ and the second step is to update the parameters of $\eta_m(\boldsymbol{x})$ using a gradient-descent step calculated from the objective function in (5). The objective value obtained for a fixed $\eta_m(\boldsymbol{x})$ is an upper bound for (5) and the parameters of $\eta_m(\boldsymbol{x})$ are updated according to the current solution. The objective value obtained at the next iteration can not be greater than the current one due to the use of gradient-descent procedure and as iterations progress with a proper step size selection procedure (see Section 3.1), the objective value of (5) never increases. Note that this does not guarantee convergence to the global optimum and the initial parameters of $\eta_m(\boldsymbol{x})$ may affect the solution quality.

For a fixed $\eta_m(\boldsymbol{x})$, we obtain the Lagrangian of the primal problem in (5) as follows:

$$\begin{aligned} L_D = &\frac{1}{2} \sum_{m=1}^{p} \|\boldsymbol{w}_m\|^2 + \sum_{i=1}^{n} (C - \alpha_i - \beta_i) \xi_i + \sum_{i=1}^{n} \alpha_i \\ &- \sum_{i=1}^{n} \alpha_i y_i \left(\sum_{m=1}^{p} \eta_m(\boldsymbol{x}_i) \langle \boldsymbol{w}_m, \Phi_m(\boldsymbol{x}_i) \rangle + b \right) \end{aligned}$$

and taking the derivatives of L_D with respect to the primal variables gives:

$$\begin{aligned} &\frac{\partial L_D}{\partial \boldsymbol{w}_m} \Rightarrow \boldsymbol{w}_m = \sum_{i=1}^{n} \alpha_i y_i \eta_m(\boldsymbol{x}_i) \Phi_m(\boldsymbol{x}_i) \quad \forall m \\ &\frac{\partial L_D}{\partial b} \Rightarrow \sum_{i=1}^{n} \alpha_i y_i = 0 \\ &\frac{\partial L_D}{\partial \xi_i} \Rightarrow C = \alpha_i + \beta_i \quad \forall i \,. \end{aligned} \quad (6)$$

From (5) and (6), the dual formulation is obtained as:

$$\begin{aligned}
&\max \sum_{i=1}^{n} \alpha_i - \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} \alpha_i \alpha_j y_i y_j K_\eta(\boldsymbol{x}_i, \boldsymbol{x}_j) \\
&\text{w.r.t. } \boldsymbol{\alpha} \\
&\text{s.t. } \sum_{i=1}^{n} \alpha_i y_i = 0 \\
&\quad C \geq \alpha_i \geq 0 \quad \forall i
\end{aligned} \tag{7}$$

where the *locally combined kernel matrix* is defined as:

$$K_\eta(\boldsymbol{x}_i, \boldsymbol{x}_j) = \sum_{m=1}^{p} \eta_m(\boldsymbol{x}_i) \underbrace{\langle \Phi_m(\boldsymbol{x}_i), \Phi_m(\boldsymbol{x}_j) \rangle}_{K_m(\boldsymbol{x}_i, \boldsymbol{x}_j)} \eta_m(\boldsymbol{x}_j) \; .$$

This formulation corresponds to solving a canonical SVM dual problem with the kernel matrix $K_\eta(\boldsymbol{x}_i, \boldsymbol{x}_j)$, which should be positive semidefinite. We know that multiplying a kernel function with outputs of a nonnegative function for both input instances, known as quasi-conformal transformation, gives a positive semidefinite kernel matrix (Amari & Wu, 1998). So, the locally combined kernel matrix can be viewed as applying a quasi-conformal transformation to each kernel function and summing them to construct a combined kernel matrix. The only restriction is to have nonnegative $\eta_m(\boldsymbol{x})$ to get a positive semidefinite kernel matrix.

Choosing among possible kernels can be considered as a classification problem and we assume that the regions of use of kernels are linearly separable. In this case, the gating model can be expressed as:

$$\eta_m(\boldsymbol{x}) = \frac{\exp(\langle \boldsymbol{v}_m, \boldsymbol{x} \rangle + v_{m0})}{\sum_{k=1}^{p} \exp(\langle \boldsymbol{v}_k, \boldsymbol{x} \rangle + v_{k0})}$$

where $\boldsymbol{v}_m, v_{m0}$ are the parameters of this gating model and the softmax guarantees nonnegativity. One can use more complex gating models for $\eta_m(\boldsymbol{x})$ or equivalently implement the gating not in the original input space but in a space defined by a basis function, which can be one or some combination of the $\Phi_m(\boldsymbol{x})$ in which the SVM works (thereby also allowing the use of nonvectorial data). If we use a gating model which is constant (not a function of $\boldsymbol{x}$), our algorithm finds a fixed combination over the whole input space, similar to the original MKL formulation.

The proposed method differs from taking subsets of the training set and training a classifier in each subset then combining them. For example, Collobert et al. (2001) define such a procedure which learns an independent SVM for each subset and reassigns instances to subsets by training a gating model with a cost function. Our approach is different in that LMKL couples subset selection and combination of local classifiers in a joint optimization problem. LMKL is similar to but also different from the mixture of experts framework (Jacobs et al., 1991) in the sense that the gating model combines kernel-based experts and is learned together with experts; the difference is that in the mixture of experts, experts individually are classifiers whereas in our formulation, there is no discriminant per kernel.

For a given $\eta_m(\boldsymbol{x})$, we can say that the objective value of (7) is equal to the objective value of (5) due to strong duality. We can safely use the objective function of (7) as $J(\eta)$ function to calculate the gradients of the primal objective with respect to the parameters of $\eta_m(\boldsymbol{x})$. To train the gating model, we take derivatives of $J(\eta)$ with respect to $\boldsymbol{v}_m, v_{m0}$ and use gradient-descent:

$$\begin{aligned}
\frac{\partial J(\eta)}{\partial v_{m0}} &= -\frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{p} \alpha_i \alpha_j y_i y_j \eta_k(\boldsymbol{x}_i) K_k(\boldsymbol{x}_i, \boldsymbol{x}_j) \\
&\qquad \eta_k(\boldsymbol{x}_j)\Big(\delta_m^k - \eta_m(\boldsymbol{x}_i) + \delta_m^k - \eta_m(\boldsymbol{x}_j)\Big) \\
\frac{\partial J(\eta)}{\partial \boldsymbol{v}_m} &= -\frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{p} \alpha_i \alpha_j y_i y_j \eta_k(\boldsymbol{x}_i) K_k(\boldsymbol{x}_i, \boldsymbol{x}_j) \\
&\qquad \eta_k(\boldsymbol{x}_j)\Big(\boldsymbol{x}_i\left[\delta_m^k - \eta_m(\boldsymbol{x}_i)\right] + \boldsymbol{x}_j\left[\delta_m^k - \eta_m(\boldsymbol{x}_j)\right]\Big)
\end{aligned}$$

where δ_m^k is 1 if $m = k$ and 0 otherwise. After updating the parameters of $\eta_m(\boldsymbol{x})$, we are required to solve a single kernel SVM with $K_\eta(\boldsymbol{x}_i, \boldsymbol{x}_j)$ at each step.

The complete algorithm of LMKL with the linear gating model is summarized in Algorithm 1. Convergence of the algorithm can be determined by observing the change in $\boldsymbol{\alpha}$ or the parameters of $\eta_m(\boldsymbol{x})$.

Algorithm 1 LMKL with the linear gating model

1: Initialize $\boldsymbol{v}_m$ and v_{m0} to small random numbers for $m = 1, \ldots, p$
2: **repeat**
3: Calculate $K_\eta(\boldsymbol{x}_i, \boldsymbol{x}_j)$ with gating model
4: Solve canonical SVM with $K_\eta(\boldsymbol{x}_i, \boldsymbol{x}_j)$
5: $v_{m0}^{(t+1)} \Leftarrow v_{m0}^{(t)} - \mu^{(t)} \dfrac{\partial J(\eta)}{\partial v_{m0}}$ for $m = 1, \ldots, p$
6: $\boldsymbol{v}_m^{(t+1)} \Leftarrow \boldsymbol{v}_m^{(t)} - \mu^{(t)} \dfrac{\partial J(\eta)}{\partial \boldsymbol{v}_m}$ for $m = 1, \ldots, p$
7: **until** convergence

After determining the final $\eta_m(\boldsymbol{x})$ and SVM solution, the resulting discriminant function is:

$$f(\boldsymbol{x}) = \sum_{i=1}^{n}\sum_{m=1}^{p} \alpha_i y_i \eta_m(\boldsymbol{x}) K_m(\boldsymbol{x}, \boldsymbol{x}_i) \eta_m(\boldsymbol{x}_i) + b \; . \tag{8}$$

3. Discussions

We explain the key properties and possible extensions of the proposed algorithm in this section.

3.1. Computational Complexity

In each iteration, we are required to solve a canonical SVM problem with the combined kernel obtained with the current gating model and to calculate the gradients of $J(\eta)$. The gradient calculation step has ignorable time complexity compared to the SVM solver. The step size of each iteration, $\mu^{(t)}$, should be determined with a line search method which requires additional SVM optimizations for better convergence. The computational complexity of our algorithm mainly depends on the complexity of the canonical SVM solver used in the main loop, which can be reduced by using hot-start (i.e., giving previous $\boldsymbol{\alpha}$ as input). The number of iterations before convergence clearly depends on the training data and the step size selection procedure. The time complexity for testing is also reduced as a result of localizing. $K_m(\boldsymbol{x}, \boldsymbol{x}_i)$ in (8) needs to be evaluated only if both $\eta_m(\boldsymbol{x})$ and $\eta_m(\boldsymbol{x}_i)$ are nonzero.

3.2. Extensions to Other Kernel-Based Algorithms

LMKL can also be applied to kernel-based algorithms other than binary classification SVM, such as regression and one-class SVMs. We need to make two basic changes: (a) optimization problem and (b) gradient calculations from the objective value found. Otherwise, the same algorithm applies.

3.3. Knowledge Extraction

The MKL framework is used to extract knowledge about the relative contributions of kernel functions used in combination. If kernel functions are evaluated over different feature subsets or data representations, the important ones have higher combination weights. With our LMKL framework, we can deduce similar information based on different regions of the input space.

Our proposed method also allows combining multiple copies of the same kernel to obtain localized discriminants, thanks to the nonlinearity introduced by the gating model. For example, we can combine linear kernels with the gating model to obtain nearly piecewise linear boundaries.

4. Experiments

We implement the main body of our algorithm in C++ and solve the optimization problems with MOSEK optimization software (Mosek, 2008). Our experimental methodology is as follows: Given a data set, a random one-third is reserved as the test set and the remaining two-thirds is resampled using 5×2 cross-validation to generate ten training and validation sets, with stratification. The validation sets of all folds are used to optimize C by trying values 0.01, 0.1, 1, 10, and 100. The best configuration (the one that has the highest average accuracy on the validation folds) is used to train the final SVMs on the training folds and their performance is measured over the test set. So, for each data set, we have ten test set results.

We perform simulations with three commonly used kernels: linear kernel (K_L), polynomial kernel (K_P), and Gaussian kernel (K_G):

$$K_L(\boldsymbol{x}_i, \boldsymbol{x}_j) = \langle \boldsymbol{x}_i, \boldsymbol{x}_j \rangle$$
$$K_P(\boldsymbol{x}_i, \boldsymbol{x}_j) = (\langle \boldsymbol{x}_i, \boldsymbol{x}_j \rangle + 1)^q$$
$$K_G(\boldsymbol{x}_i, \boldsymbol{x}_j) = \exp\left(-\left\|\boldsymbol{x}_i - \boldsymbol{x}_j\right\|^2 / s^2\right) .$$

We use the second degree ($q = 2$) polynomial kernel and estimate s in the Gaussian kernel as the average nearest neighbor distance between instances of the training set. All kernel matrices are calculated and normalized to unit trace before training. The step size of each iteration, $\mu^{(t)}$, is fixed as 0.01 without performing line search and a total of 50 iterations are performed.

4.1. Toy Data Set

In order to illustrate our proposed algorithm, we create a toy data set, named GAUSS4, which consists of 1200 data instances generated from four Gaussian components (two for each class) with the following prior probabilities, mean vectors and covariance matrices:

$$p_{11} = 0.25 \quad \mu_{11} = \begin{pmatrix} -3.0 \\ +1.0 \end{pmatrix} \quad \Sigma_{11} = \begin{pmatrix} 0.8 & 0.0 \\ 0.0 & 2.0 \end{pmatrix}$$
$$p_{12} = 0.25 \quad \mu_{12} = \begin{pmatrix} +1.0 \\ +1.0 \end{pmatrix} \quad \Sigma_{12} = \begin{pmatrix} 0.8 & 0.0 \\ 0.0 & 2.0 \end{pmatrix}$$
$$p_{21} = 0.25 \quad \mu_{21} = \begin{pmatrix} -1.0 \\ -2.2 \end{pmatrix} \quad \Sigma_{21} = \begin{pmatrix} 0.8 & 0.0 \\ 0.0 & 4.0 \end{pmatrix}$$
$$p_{22} = 0.25 \quad \mu_{22} = \begin{pmatrix} +3.0 \\ -2.2 \end{pmatrix} \quad \Sigma_{22} = \begin{pmatrix} 0.8 & 0.0 \\ 0.0 & 4.0 \end{pmatrix}$$

where data instances from the first two components are of class 1 (labeled as positive) and others are of class 2 (labeled as negative)[1]. We perform two sets of experiments on GAUSS4 data set: (K_L-K_P) and (K_L-K_L-K_L).

[1]MATLAB implementation of LMKL with an SMO-based canonical SVM solver and GAUSS4 dataset are available at `http://www.cmpe.boun.edu.tr/~gonen/lmkl`.

First, we train both MKL and LMKL for (K_L-K_P) combination. Figure 1(a) shows the classification boundaries calculated and the support vectors stored by MKL which assigns combination weights 0.30 and 0.70 to K_L and K_P, respectively. Using the kernel matrix obtained combining K_L and K_P with these weights, we do not achieve a good approximation to the optimal Bayes' boundary. As we see in Figure 1(b), LMKL divides the input space into two regions and uses the polynomial kernel to separate one component from two others quadratically and the linear kernel for the other component. We see that the locally combined kernel matrix obtained from K_L and K_P with the linear gating model learns a classification boundary very similar to the optimal Bayes' boundary. Note that the softmax function in the gating model achieves a smooth transition between kernels.

The effect of combining multiple copies of the same kernel can be seen in Figure 1(c) which shows the classification and gating model boundaries of LMKL with (K_L-K_L-K_L) combination. Using linear kernels in three different regions enables us to approximate the optimal Bayes' boundary in a piecewise linear manner. Instead of using complex kernels such as the Gaussian kernel, local combination of simple kernels (e.g., linear and polynomial kernels) can produce accurate classifiers and avoid overfitting. For example, the Gaussian kernel achieves 89.67 per cent average testing accuracy by storing all training instances as support vectors. However, LMKL with three linear kernels achieves 92.00 per cent average testing accuracy by storing 23.18 per cent of training instances as support vectors on the average.

Initially, we assign small random numbers to the gating model parameters and this gives nearly equal combination weights for each kernel. This is equivalent to taking an unweighted summation of the original kernel matrices. The gating model starts to give crisp outputs as iterations progress and the locally combined kernel matrix becomes more sparse (see Figure 2). The kernel function values between data instances from different regions become 0 due to the multiplication of the gating model outputs. This localizing characteristics is also effective for the test instances. If the gating model gives crisp outputs for a test instance, the discriminant function in (8) is calculated over only the support vectors having nonzero gating model outputs for the selected kernels. Hence, discriminant function value for a data instance is mainly determined by the neighboring training instances and the active kernel function in its region.

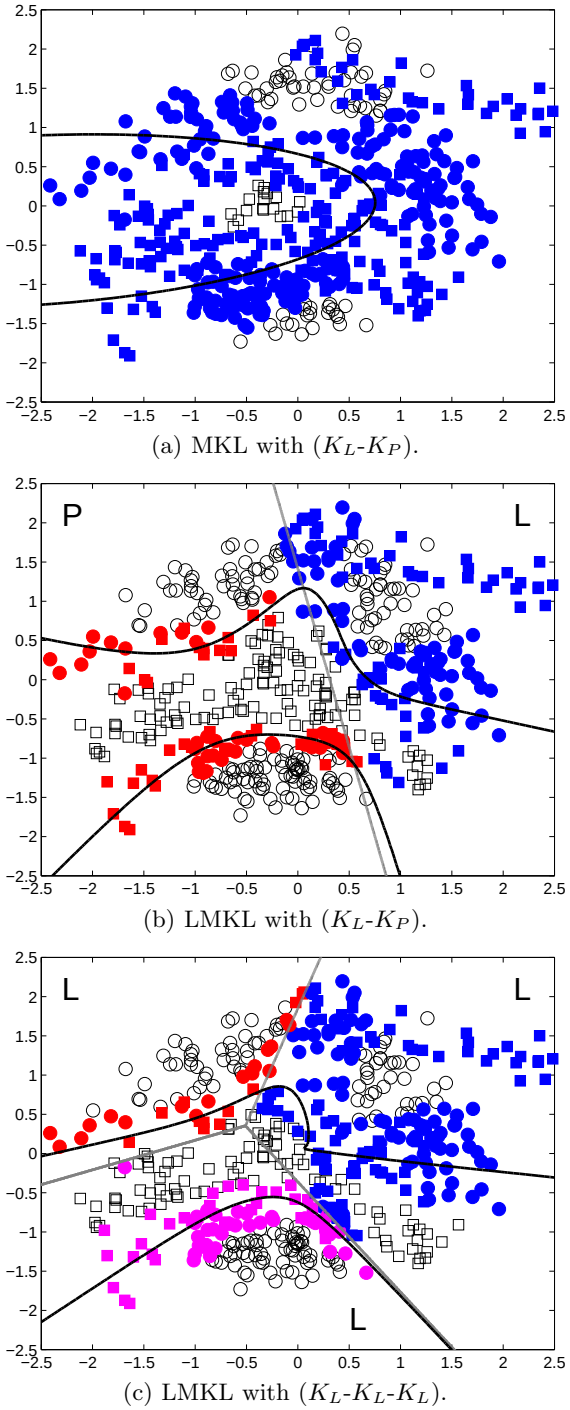
4.2. Benchmark Data Sets

We perform experiments on ten two-class benchmark data sets from the UCI machine learning repository and Statlog collection. In the result tables, we report the average testing accuracies and support vector percentages. The average accuracies and support vector percentages are made bold if the difference between the two compared classifiers is significant using the 5×2 cross-validation paired F test (Alpaydın, 1999).

Figure 3(a)-(b) illustrate the difference between MKL and LMKL on BANANA data set with (K_L-K_P) combination. We can see that MKL can not capture the localities exist in the data by combining linear and polynomial kernels with fixed combination weights (it assigns 1.00 to K_P ignoring the linear kernel). However, LMKL finds a more reasonable decision boundary using much fewer support vectors by dividing the input space into two regions using the linear gating model. The average testing accuracy increases from 70.52 to 84.46 per cent and the support vector count is halved (decreases from 82.36 to 41.28 per cent).

The classification and gating model boundaries found by LMKL with (K_L-K_L-K_L) combination on BANANA data set can be seen in Figure 3(c). The gating model divides the input space into three regions and in each region a local and (nearly) linear decision boundary is induced. Combination of these local boundaries with softmax gating gives us a more complex boundary.

The results by MKL and LMKL for (K_P-K_G) and canonical SVMs with K_L, K_P, K_G are given in Table 1. LMKL achieves statistically similar accuracies compared with MKL on all data sets. LMKL stores significantly fewer support vectors on HEART, PIMA, and WDBC data sets. With direct comparison of average values, the localized variant performs better on seven and eight out of ten data sets in terms of testing accuracy and support vector percentage, respectively. Other kernel combinations behave similarly.



(a) MKL with (K_L-K_P).

(b) LMKL with (K_L-K_P).

(c) LMKL with (K_L-K_L-K_L).

Figure 3. Separating hyperplanes (black solid lines) and support vectors (filled points) on BANANA data set. The gray solid lines shows the boundaries calculated from the gating models by considering them as classifiers which select a kernel function. Both accuracy increases and support vector count decreases.

We also combine $p = 2, \ldots, 5$ linear kernels on benchmark data sets with LMKL. Table 1 (to the right) compares the results of canonical SVM with the linear kernel and LMKL with three linear kernels. LMKL uses statistically fewer support vectors on six out of ten data sets and on three of these (BANANA, PIMA, and SPAMBASE), accuracy is significantly improved. With direct comparison of average values, LMKL performs better than canonical SVM on seven and eight out of ten data sets in terms of accuracy and support vector percentages, respectively. Using localized linear kernels also improves testing time due to evaluating linear kernels over only neighboring support vectors, instead of evaluating it over all support vectors.

Using Wilcoxon's signed rank test on ten data sets (see Table 1), when different kernels are combined, LMKL stores significantly fewer support vectors than MKL; when multiple copies of the same (linear) kernel are combined, LMKL achieves significantly higher accuracy than canonical SVM using a single kernel.

4.3. Bioinformatics Data Sets

We perform experiments on two bioinformatics data sets in order to see the applicability of LMKL to real-life problems. These translation initiation site data sets are constructed by using the same procedure described by Pedersen and Nielsen (1997). Each data instance is represented by a window of 200 nucleotides. Each nucleotide is encoded by five bits and the position of the set bit indicates whether the nucleotide is A, T, G, C, or N (for unknown).

As in benchmark data sets when combining different kernels, LMKL achieves statistically similar accuracy results compared with MKL by storing fewer support vectors for all combinations (see Table 2). For example, using (K_P-K_G), LMKL needs on the average 24.55 and 22.32 per cent fewer support vectors on ARABIDOPSIS and VERTEBRATES data sets, respectively.

We combine $p = 2, \ldots, 5$ linear kernels on bioinformatics data sets using LMKL. Table 2 shows that LMKL with three linear kernels improves the average accuracy statistically significantly. LMKL also uses significantly fewer support vectors (the decrease is almost one-third) on these data sets.

5. Conclusions

This work introduces a localized multiple kernel learning framework for kernel-based algorithms. The proposed algorithm consists of: (a) a gating model which assigns weights to kernels for a data instance, (b) a kernel-based learning algorithm with the locally combined kernel matrix. The training of these two components are coupled and the parameters of both components are optimized together by using a two-step alternate optimization procedure in a joint manner.

For binary classification tasks, the algorithm of the proposed framework with linear gating is derived and tested on ten benchmark and two bioinformatics data sets. LMKL achieves statistically similar accuracy results compared with MKL by storing fewer support vectors. Because kernels are evaluated locally (i.e., zero weighted kernels for a test instance are not calculated), the whole testing process is also much faster. This framework allows using multiple copies of the same kernel in different regions of the input space, obtaining more complex boundaries than what the underlying kernel is capable of. In order to illustrate this advantage, we combine different number of linear kernels on all data sets and learn piecewise linear boundaries. LMKL with three linear kernels gives significantly better accuracy results than canonical SVM with linear kernel on bioinformatics data sets.

Abstract

Quite a bit is known about minimizing different kinds of regret in experts problems, and how these regret types relate to types of equilibria in the multiagent setting of repeated matrix games. Much less is known about the possible kinds of regret in online convex programming problems (OCPs), or about equilibria in the analogous multiagent setting of repeated convex games. This gap is unfortunate, since convex games are much more expressive than matrix games, and since many important machine learning problems can be expressed as OCPs. In this paper, we work to close this gap: we analyze a spectrum of regret types which lie between *external* and *swap* regret, along with their corresponding equilibria, which lie between *coarse correlated* and *correlated* equilibrium. We also analyze algorithms for minimizing these regret types. As examples of our framework, we derive algorithms for learning correlated equilibria in polyhedral convex games and extensive-form correlated equilibria in extensive-form games. The former is exponentially more efficient than previous algorithms, and the latter is the first of its type.

1. Introduction

We wish to build agents that can learn to act effectively in multiagent decision problems. We represent such problems as general-sum games: each agent i is given a feasible region A_i from which to choose an action a_i. The payoff to agent i depends not only on i's choice, but also on the actions $a_{\neg i}$ chosen by other agents. Since we are modeling learning, we assume that each agent knows only its own feasible region and observes only its own payoff structure. So, an agent cannot simply compute an equilibrium of the game and play it (even leaving aside the complexity of such a computation and the problem of coordinating with other agents on an equilibrium). All an agent can do is *learn* a preferred course of action by playing the game repeatedly and observing its own payoffs.

What, then, is an appropriate goal for a learning agent? Unlike zero-sum games, general-sum games do not have a well-defined *value*: even if we had complete knowledge of the game and all players were completely rational, we would not be able to predict how much payoff we should receive. Instead, researchers have defined other goals for learning agents. One popular one is regret minimization. For example, a number of previous algorithms have been designed to minimize *external regret* (defined in Sec. 2) in convex games, including Generalized Gradient Descent (Gordon, 1999b), GIGA (Zinkevich, 2003), Follow the Perturbed Leader (Kalai & Vempala, 2003), Lagrangian Hedging (Gordon, 2006), and algorithms based on Fenchel duality (Shalev-Shwartz & Singer, 2006).

However, no external regret may not be a sufficient goal: a set of agents can all achieve no external regret (which guarantees that the empirical distribution of joint play converges to the set of *coarse correlated equilibria*, defined in Sec. 4) and still have an incentive to change their play. For example, a no-external-regret learner can consistently observe that its average payoff per trial would have been higher if it had chosen action a' every time that it actually played a, and yet never switch to playing action a' in these situations. To avoid such behavior, we seek algorithms that provide guarantees stronger than no external regret. In a seminal paper, Foster and Vohra (1997) present an algorithm that exhibits no *internal regret* (defined in Sec. 2) in matrix games, and further, show that if all players achieve no internal regret, the empirical distribution of joint play converges to the set of *correlated*

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

equilibria (see Sec. 4). This guarantee rules out precisely the anomalous behavior described above.

Stoltz and Lugosi (2007) generalize these results to convex games. Extending the framework of Greenwald and Jafari (2003) for matrix games, they define a continuum of regret measures called Φ-regret, as well as corresponding Φ-equilibria, for convex games. Given a feasible region A, Φ is a collection of *action transformations*; that is, each $\phi \in \Phi$ is a function from A to itself. An agent calculates its Φ-regret by comparing the losses it obtained during its past history of play to the losses it would have obtained had it transformed each action it played according to some $\phi \in \Phi$.

Different choices of Φ lead to different types of regret and corresponding equilibria. In matrix games, the only two regret types known to be of interest are the above-mentioned external and internal regret. No internal regret is equivalent to no *swap* regret, in which Φ is the set of all transformations from A to itself. In convex games, by contrast, there is a much richer variety of regret concepts. We identify and analyze two novel regret types, which we call *extensive-form* and *finite-element* regret. We also analyze *linear* regret. Each of these regret types is distinct from the others and from external and swap regret. In fact, they form a progression: no swap regret (the strongest property) implies no finite element regret, which implies no linear regret, which implies no extensive-form regret, which implies no external regret (the weakest property).

Different regret types require different regret-minimization algorithms. For convex games, until recently, most algorithms minimized only external regret. More recently, Stoltz and Lugosi (2007) proved the existence of a no-swap-regret algorithm, and Hazan and Kale (2007) derived an algorithm that exhibits no Φ-regret for any set Φ which is the convex hull of a finite set of transformations. Simultaneously and independently, we developed an algorithm similar to Hazan and Kale's: our algorithm handled more-general representations of transformation sets, but required exact fixed-point calculations (Gordon et al., 2007).

Unfortunately, constructing an algorithm according to Stoltz and Lugosi's proof would be prohibitively expensive: both the time and space requirements would grow exponentially with the number of rounds. And, Hazan and Kale's algorithm, which runs in time polynomial in the number of corners of Φ, can also be prohibitively expensive: for example, if A is the unit cube in $\mathbb{R}^d$ and Φ is the set of linear transformations that map A to itself, then Φ, which is the Cartesian product of d copies of the unit L_1 ball, has $(2d)^d$ corners.

In this work, we extend our earlier algorithms and proofs, unifying them with Hazan and Kale's. The result is an algorithm which accommodates more-efficient representations of Φ. In the example above, the natural representation of Φ is as a set of $d \times d$ matrices satisfying certain linear constraints. Using this representation, our algorithm runs in time polynomial in d—an exponential speedup. In general, we can efficiently achieve no linear regret so long as we can efficiently optimize over the set of linear mappings from A to itself.

We also instantiate our algorithm for extensive-form and finite-element regret. These regret types are important in practice: extensive-form regret corresponds to extensive-form correlated equilibrium (Forges & von Stengel, 2002), arguably the most natural notion of equilibrium in extensive-form games. And, our no-finite-element-regret algorithm, with a simple modification described below, guarantees that the empirical distribution of joint play converges to a correlated equilibrium.

For extensive-form regret, our algorithm is polynomial in the dimension of the action set A; we are not aware of any prior no-extensive-form-regret algorithms. For finite-element regret, our algorithm is polynomial in the dimension of the action set and in the size of a finite-element mesh that covers Φ. Although the necessary mesh for some choices of Φ is quite large, our algorithm is still by far the most efficient known that guarantees convergence to correlated equilibrium.

2. The General Algorithm

When playing a repeated convex game, a single agent's learning problem is called an **online convex program** (OCP): in each round t, the agent chooses an action $a_t \in A$. At the same time, forces external to the agent choose a convex loss function $l_t \in L$. (A loss is just a negative payoff.) The agent observes l_t and pays $l_t(a_t)$. The action space A is assumed to be a convex and compact subset of $\mathbb{R}^d$. The set L includes convex loss functions with bounded subgradients. The commonly studied **experts problem** is a special case of an OCP in which the feasible region is the probability simplex in $\mathbb{R}^d$.

A **learning algorithm** takes as input a sequence of loss functions l_t and produces as output a sequence of actions a_t. Action a_t may depend on $l_1 \dots l_{t-1}$, but not on l_t or later loss functions. The learner's objective is to minimize its cumulative loss, $L_t = \sum_{t=1}^{T} l_t(a_t)$.

The minimum achievable loss depends on the specific sequence l_t. To measure how well a learning algorithm

performs against a given sequence, we calculate its **regret**. The simplest type of regret is called **external** regret, and is defined as follows:

$$\rho_t^{\text{EXT}} = \sup_{a \in A} \sum_{t=1}^{T} (l_t(a_t) - l_t(a))$$

That is, the external regret is the difference between the actual loss achieved and the smallest possible loss that could have been achieved on the sequence l_t by playing a fixed $a \in A$.

We say that an algorithm $\mathcal{A}$ exhibits **no external regret** for feasible region A and set L if we can guarantee that its average external regret per trial eventually falls below any $\epsilon > 0$, regardless of the particular sequence l_t. In other words, $\mathcal{A}$ exhibits no external regret if there is a function $f(T, A, L)$ which is $o(T)$ for any fixed A and L, such that for all $a \in A$, $t \geq 1$

$$\sum_{t=1}^{T} l_t(a_t) \leq \sum_{t=1}^{T} l_t(a) + f(T, A, L) \tag{1}$$

The function f can depend on A and L in complicated ways, but usually depends on properties like the diameter of A under some norm, or the length of $\partial l(a)$ under some norm for $a \in A$ and $l \in L$.

More generally, an agent can consider replacing its sequence $a_1 \dots a_t$ with $\phi(a_1) \dots \phi(a_t)$, where ϕ is some **action transformation**, that is, a measurable function that maps A into itself. If Φ is a set of such action transformations, we define an algorithm's **Φ-regret** as

$$\rho_t^{\Phi} = \sup_{\phi \in \Phi} \sum_{t=1}^{T} (l_t(a_t) - l_t(\phi(a_t)))$$

and we say that it exhibits **no Φ-regret** if it satisfies the following analogue of Eq. 1: for all $\phi \in \Phi$, $t \geq 1$

$$\sum_{t=1}^{T} l_t(a_t) \leq \sum_{t=1}^{T} l_t(\phi(a_t)) + g(T, A, L, \Phi) \tag{2}$$

where $g(T, A, L, \Phi)$ is $o(T)$ for any fixed A, L, and Φ.

Note that external regret is just Φ-regret with Φ equal to the set of constant transformations: i.e., $\Phi_{\text{EXT}} = \{\phi_x \mid x \in A\}$, where $\phi_x(a) = x$. By setting Φ to larger, more flexible transformation sets, we can define stronger varieties of regret. However, before studying any specific regret types in detail, we next discuss how to achieve no Φ-regret for general Φ.

2.1. General Φ

In this section, we develop an algorithm $\mathcal{A}$ that exhibits no Φ-regret for any suitable $\Phi \subset A \mapsto A$. The algorithm itself is fairly simple, and embodies essentially the same idea that was proposed earlier by Gordon et al. (2007) and Hazan and Kale (2007). However, we develop the idea here so that it applies to a more general class of transformation sets Φ than considered previously, and provide a proof that it achieves no Φ-regret under more general conditions. Our extra generality is crucial for developing efficient implementations for important choices of Φ including linear, extensive-form, and finite-element transformations.[1]

Our Φ-regret minimizing algorithm $\mathcal{A}$ is described in Fig. 1. It takes as input a sequence of loss functions $l_t \in L$ and outputs a sequence of actions $a_t \in A$, which, we will show, satisfies Eq. 2.

In designing $\mathcal{A}$, we assume that we have access to subroutines $\mathcal{A}'$ and $\mathcal{A}''$. The subroutine $\mathcal{A}'$ computes approximate fixed points of transformations $\phi \in \Phi$. That is, given any $\phi \in \Phi$ and any $\epsilon > 0$, $\mathcal{A}'$ returns some $a \in A$ such that $\|a - \phi(a)\|_A \leq \epsilon$. Here, $\|\cdot\|_A$ is an arbitrary norm on $\mathbb{R}^d$. The subroutine $\mathcal{A}''$ is an external-regret minimizing algorithm whose feasible region is Φ; we assume that its regret bound is $o(T)$ whenever we can provide a bound (in an appropriate norm) on the subgradients of the loss functions it encounters.

Since algorithm $\mathcal{A}$ accesses the transformation set Φ only through the subroutines $\mathcal{A}'$ and $\mathcal{A}''$, it does not depend on any special properties of Φ beyond the existence of these subroutines. To state our theorem, though, we will embed Φ in a vector space, as follows. Since $A \subset \mathbb{R}^d$, we can write $\phi \in \Phi$ as a d-tuple of "coordinate" functions $(\psi_1, \psi_2, \dots, \psi_d)$, $\psi_i : A \to \mathbb{R}$. For all $\phi \in \Phi$ and $i = 1 \dots d$, we assume ψ_i is a member of some reproducing-kernel Hilbert space (RKHS) $\mathcal{H} \subset A \mapsto \mathbb{R}$.[2] Finally, we assume that Φ is a convex and compact subset of $\mathcal{H}^d$.

To make these assumptions concrete, suppose for example that Φ is the convex hull of a finite set of transformations $\{\phi^1, \dots, \phi^p\}$: i.e.,

$$\Phi = \left\{ \textstyle\sum_{j=1}^{p} \alpha_j \phi^j \mid \alpha_j \geq 0, \sum_{j=1}^{p} \alpha_j = 1 \right\}$$

(This is the case treated by Hazan and Kale.) If we take $\mathcal{H}$ to be the span of all of the coordinate functions ψ_i^j, then Φ is a simplex in $\mathcal{H}^d$ with corners ϕ^j, for $j = 1 \dots p$. (In general, Φ's shape may be much more

[1] Hazan and Kale's algorithm is efficient in the special case of external transformations. Indeed, this section's algorithm specializes to their algorithm in this case.

[2] A Hilbert space is a (possibly infinite-dimensional) vector space that has an inner product. A reproducing-kernel Hilbert space is a Hilbert space of real- or complex-valued functions in which evaluation at the point a is a continuous linear functional for any a.

Given feasible region A, transformation set Φ, initial transformation $\phi_1 \in \Phi$, and subroutines $\mathcal{A}'$ and $\mathcal{A}''$.

For $t = 1, \ldots, T$:

1. Send transformation ϕ_t to the fixed-point algorithm $\mathcal{A}'$, along with accuracy parameter $\epsilon_t = 1/\sqrt{t}$. Receive action a_t satisfying $\|\phi_t(a_t) - a_t\|_A \leq \epsilon_t$.
2. Play a_t; observe loss function l_t and incur loss $l_t(a_t)$.
3. Define $m_t : \Phi \mapsto \mathbb{R}$ by $m_t(\phi) = l_t(\phi(a_t))$.
4. Send m_t to the no-external-regret algorithm $\mathcal{A}''$. Receive transformation $\phi_{t+1} \in \Phi$.

Figure 1. Algorithm $\mathcal{A}$.

complicated than a simplex, as we will see for example in the definition of Φ_{FE} below.)

To bound the Φ-regret of algorithm $\mathcal{A}$, we will need bounds on the actions a and the loss-function subgradients $\partial l(a)$, for all $l \in L$ and $a \in A$. In particular, we will suppose that $\|a\|_A \leq C_1$ and $\|\partial l(a)\|_{A^*} \leq C_2$, for any $a \in A$, any $l \in L$, and some constants $C_1, C_2 > 0$. Here $\|\cdot\|_{A^*}$ is the norm that is dual to $\|\cdot\|_A$.

Theorem 1 *Fix a convex and compact feasible region A and a set of loss functions L satisfying the above norm bounds, as well as a set of transformations $\Phi \subset \mathcal{H}^d$, where $\mathcal{H} \subset A \mapsto \mathbb{R}$ is a RKHS. Assume we are given an algorithm $\mathcal{A}''$ which, for any set of possible loss functions M with bounded subgradients, achieves no external regret on Φ. Also assume we are given an algorithm $\mathcal{A}'$ which can compute an approximate fixed point of any $\phi \in \Phi$. Then algorithm $\mathcal{A}$, using subroutines $\mathcal{A}'$ and $\mathcal{A}''$, achieves no Φ-regret.*

PROOF: Define the set of functions $M \subset \Phi \mapsto \mathbb{R}$ as $M = \{l(\phi(a)) \mid l \in L, a \in A\}$. Note that each $m \in M$ is convex because each $l \in L$ is convex and $\phi(a)$ is linear in ϕ. Moreover, the norm of the subgradient of any $m \in M$ at any point $\phi \in \Phi$ is bounded by $C_1 C_2$. (A proof of this fact, as well as a definition of the appropriate norm, is given by Gordon et al. (2008).)

Because $\mathcal{A}''$ exhibits no external regret on Φ with the bounded-subgradient set of potential loss functions M,

$$\sum_{t=1}^{T} m_t(\phi_t) \leq \sum_{t=1}^{T} m_t(\phi) + f(T, \Phi, M) \quad \forall \phi \in \Phi$$

where f is sublinear in T. So, by the definition of m_t,

$$\sum_{t=1}^{T} l_t(\phi_t(a_t)) \leq \sum_{t=1}^{T} l_t(\phi(a_t)) + f(T, \Phi, M) \quad \forall \phi \in \Phi$$

But, since $\|\phi_t(a_t) - a_t\|_A \leq \epsilon_t$ and $\|\partial l_t(a_t)\|_{A^*} \leq C_2$, we have by Hölder's inequality that $l_t(a_t) \leq l_t(\phi_t(a_t)) + \epsilon_t C_2$. So,

$$\sum_{t=1}^{T} l_t(a_t) \leq \sum_{t=1}^{T} (l_t(\phi(a_t)) + \epsilon_t C_2) + f(T, \Phi, M) \quad \forall \phi \in \Phi$$

Since $C_2 \sum_{t=1}^{T} \epsilon_t = O(\sqrt{T})$, this is exactly the desired no-Φ-regret guarantee. □

Clearly, the run-time of $\mathcal{A}$ depends on the run-times of its subroutines. In particular, since $\mathcal{A}$ requires that $\mathcal{A}'$'s accuracy parameter ϵ approach 0 as T increases, it is important that $\mathcal{A}'$ run efficiently even for small ϵ. We will discuss run-times in more detail in the context of specific examples below. For now, we note the following trivial generalization of a result due to Hazan and Kale: if the fixed-point algorithm $\mathcal{A}'$ is a FPTAS, and if the no-external-regret algorithm $\mathcal{A}''$ runs in polynomial time, then $\mathcal{A}$ can process T actions and loss functions in time polynomial in T. Hazan and Kale allow run-times to be polynomial in the number of corners of Φ (among other parameters); this renders their efficiency guarantees meaningless when Φ has many corners. With our more-efficient representations of Φ, we can replace the dependence on the number of corners with parameters like the dimension of Φ and the norm bounds for $a \in A$ and ∂l for $l \in L$; since these latter parameters can be much smaller, the result will be a much faster run-time.

As described so far, the algorithm $\mathcal{A}$ is deterministic if its subroutines $\mathcal{A}'$ and $\mathcal{A}''$ are. Below, we will also define a randomized variant of $\mathcal{A}$, to strengthen the connection to game-theoretic equilibria.

2.2. Finite-dimensional Φ

We defined algorithm $\mathcal{A}$ in terms of a generic set of transformations $\Phi \subset \mathcal{H}^d$, where $\mathcal{H}$ is a RKHS, and each element of $\mathcal{H}$ is a real-valued function on A. (So, each $\phi \in \Phi$ is a d-tuple of real-valued functions on A, which we interpret as a function from A to $\mathbb{R}^d$.)

Because of the reproducing-kernel property, computing component $\psi_i(a)$ of some $\phi \in \mathcal{H}^d$ for $a \in A$ is the same as computing the inner product $\langle \psi_i, K(a) \rangle$. In other words, each ψ_i is the composition of a fixed, possibly-nonlinear function $K(\cdot)$ with a linear mapping $\langle \psi_i, \cdot \rangle$. This is the so-called "kernel trick" (Cortes & Vapnik, 1995): first, K computes a vector of features of the action a. The inner product with ψ_i then combines all of these features to produce the final output $\psi_i(a)$. To evaluate $\phi(a)$ in its entirety, we can compute $K(a)$ once, and then evaluate the d inner products $\langle \psi_1, K(a) \rangle, \ldots, \langle \psi_d, K(a) \rangle$.

In this paper, we are chiefly interested in cases where the dimension of $\mathcal{H}$ is manageable, so that we can di-

rectly write down and work with the transformations $\phi \in \mathcal{H}^d$. So, for the remainder of the paper, we will assume that $\mathcal{H}$ is isomorphic to $\mathbb{R}^p$ for some finite p. We will also restrict our interest to linear loss functions $l_t(a) = a \cdot \partial l_t$. This is without loss of generality, since we can achieve no regret for a sequence of convex loss functions l_t by working with appropriately-chosen linear lower bounds on each l_t (Gordon, 1999a).

With these additional assumptions, the steps of $\mathcal{A}$ can be simplified: each derived loss function m_t is linear, and can be described by its subgradient as follows:

$$\partial m_t(\phi) = \partial(l_t(\phi(a_t))) = \partial(\phi(a_t) \cdot \partial l_t) = \partial l_t K(a_t)^{\mathrm{T}}$$

The subgradient ∂m_t is a $d \times p$ matrix, since ∂l_t is a d-vector and $K(a_t)$ is a p-vector. Each transformation ϕ also corresponds to a $d \times p$ matrix (a d-tuple of p-vectors). To evaluate the loss function m_t on a transformation ϕ, we take the dot product $\partial m_t \cdot \phi$, which is defined to be $\mathrm{tr}(\partial {m_t}^{\mathrm{T}} \phi) = \mathrm{tr}(K(a_t) \partial {l_t}^{\mathrm{T}} \phi) = \mathrm{tr}(\partial {l_t}^{\mathrm{T}} \phi K(a_t)) = \partial {l_t}^{\mathrm{T}} \phi K(a_t)$.

As we will see in the next section, a number of interesting transformation sets can be represented as $d \times p$ matrices. Representing transformations and subgradients in this way means we can manipulate them efficiently, and, in turn, design efficient no-regret algorithms.

3. Specific Algorithms

We now instantiate our algorithm with various transformation sets Φ. We define each Φ as a set of $d \times p$ matrices ϕ, together with a kernel function $K : A \mapsto \mathbb{R}^p$, with the guarantee that $\phi K(a) \in A$ for all $a \in A$ and $\phi \in \Phi$. To minimize each ensuing regret type, we go on to identify efficient subroutines $\mathcal{A}'$ and $\mathcal{A}''$ for finding fixed points and achieving no external regret. (All other calculations in our algorithm are $O(pd)$, so these subroutines will usually be what limits our efficiency.)

For completeness, we also mention Φ_{EXT}, the set of constant transformations on A, and Φ_{SWAP}, the set of all measurable transformations on A. Φ_{EXT} is the weakest form of regret of interest here, and Φ_{SWAP} the strongest. These are the only two regret types known to be of interest in matrix games (no swap regret and no internal regret are equivalent in this setting).

In convex games, however, there is a much richer variety of interesting regret concepts. Below, we analyze linear, finite-element, and extensive-form regret, corresponding to transformation sets Φ_{LIN}, Φ_{FE}, and Φ_{EF}. As we will see, in general, $\Phi_{\mathrm{EXT}} \subset \Phi_{\mathrm{EF}} \subset \Phi_{\mathrm{LIN}} \subset \Phi_{\mathrm{FE}} \subset \Phi_{\mathrm{SWAP}}$. So, no swap regret implies no finite-element regret, which implies no linear regret, which implies no extensive-form regret, which implies no external regret. We show in the long version of this paper (Gordon et al., 2008) that these five regret varieties are in fact distinct: it is possible to have, e.g., no Φ_{LIN}-regret while still having positive Φ_{FE}-regret.

Linear Regret The set Φ_{LIN} includes all linear transformations that map A into itself. To achieve no linear regret, we can take K to be the identity. Φ will then be a set of square $d \times d$ matrices. To find a fixed point of $\phi \in \Phi$, we choose an appropriate element of the null space of $\phi - I$, which takes time polynomial in d. The more expensive task is to achieve no external regret on Φ: depending on the form of A, Φ may or may not lend itself to a description in terms of a small number of simple constraints.

If A is a probability simplex, then Φ is the set of stochastic matrices, which can be expressed with $O(d^2)$ linear constraints on the entries of ϕ (this setting yields an algorithm very similar to that of Blum and Mansour (2005)). If A is a unit Euclidean ball, then Φ consists of those matrices whose largest singular value is ≤ 1; this set can be represented using a single semidefinite constraint. For general (convex compact) A, the best choice may be to use either GIGA or lazy projection (Zinkevich, 2003): the difficult step in these algorithms is a Euclidean projection onto Φ, which can be achieved via the ellipsoid algorithm.

Finite-Element Regret The finite-element transformations only apply to polyhedral feasible regions A. For finite-element regret, we will define K as a mapping from a polyhedral feasible set A to a high-dimensional space $K(A)$ called the **barycentric coordinate space**. To construct $K(a)$, we first associate each of the p corners of A with one dimension of $\mathbb{R}^p$. We then triangulate A by dividing it into mutually exclusive and exhaustive d-simplices, so that each corner of A is a corner of one or more simplices.

Now, to calculate $K(a)$, we first determine the simplex in which a lies (or choose one arbitrarily if it is on a boundary) and calculate the weights of a with respect to the $d + 1$ corners of that simplex. That is, if $j(1) \ldots j(d+1)$ are the indices of the corners of the simplex containing a, and if $c_{j(1)} \cdots c_{j(d+1)}$ are their coordinates, we find the weights $b_1 \ldots b_{d+1}$ by solving $a = \sum_i b_i c_{j(i)}$, $\sum_i b_i = 1$. We then set entry $[K(a)]_{j(i)} = b_i$ for each corner $j(i)$, and set all other entries of $K(a)$ to 0.

For example, if $A = [0,1]^2$, we can divide A into two triangles, one with corners $(0,0)$, $(0,1)$, and $(1,1)$, and the other with corners $(0,0)$, $(1,0)$, and $(1,1)$. To calculate $K(\frac{1}{3}, \frac{2}{3})$, note that $(\frac{1}{3}, \frac{2}{3})$ is in the first

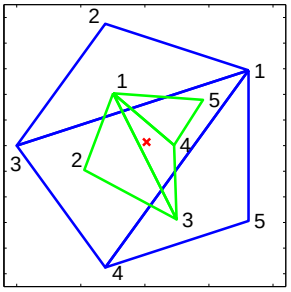

Figure 2. Illustration of barycentric coordinates and Φ_{FE}. A is the outer pentagon, triangulated into three simplices. $K(A)$ is a subset of the simplex in $\mathbb{R}^5$ (not shown). $\phi(A)$ is the distorted pentagon. The $\times$ marks a fixed point of ϕ.

triangle. If we associate corners of A with dimensions of $K(A)$ in the order $(0,0)$, $(0,1)$, $(1,0)$, $(1,1)$, then $K(\frac{1}{3},\frac{2}{3}) = (\frac{1}{3},\frac{1}{3},0,\frac{1}{3})$, since these weights express $(\frac{1}{3},\frac{2}{3})$ as a convex combination of corners 1, 2, and 4.

Given this definition of K, Φ_{FE} is the set of matrices ϕ that map $K(A)$ into A. If A is a simplex, then K will be a linear mapping and $\Phi_{\text{FE}} = \Phi_{\text{LIN}}$. (In general, $\Phi_{\text{FE}} \supset \Phi_{\text{LIN}}$.) For another example, see Fig. 2.

We note that Φ_{FE} can be factored: it is the Cartesian product of p copies of A, since it just needs to map each corner of A to a point inside A. So, to achieve no external regret in Φ, we can separately run p copies of any no-external-regret algorithm for A. A typical cost for doing so might be $O(pd^3)$.[3] To find a fixed point of ϕ, we just need to check each of its linear pieces separately. Each individual check costs $O(d^3)$, and there is one for each simplex in our mesh.

Extensive-Form Regret Let T be a player's **sequence tree**, describing all possible sequences of choices and observations in an extensive-form game (e.g., Fig. 3 (left)). Suppose that each element of the feasible region A is a **sequence weight vector** on T (Forges & von Stengel, 2002), specifying a behavior strategy for the game. Define an **extensive form** transformation as follows: fix a set D of choice nodes in T, along with pure-strategy sequence weight vectors w_b for each $b \in D$. If the original strategy is ever about to play $b \in D$, the transformed strategy deviates, and instead follows w_b. We assume that there are no $b, b' \in D$ with b' an ancestor of b (so that all $b \in D$ are reachable), and that each $b \in D$ has a sibling a with $w_b(a) = 1$. Extensive-form transformations are interesting since they correspond to the incentive constraints in extensive-form correlated equilibrium (Forges & von Stengel, 2002).

We show (Gordon et al., 2008) that each extensive form transformation can be represented by a matrix ϕ, whose rows and columns are indexed by choices, so that any action $w \in A$ is transformed into another action $\phi w \in A$. The entries of ϕ are as follows:

$$\phi_{ab} = \begin{cases} w_b(a) & \text{if } b \preceq a \text{ and } b \in D \\ 1 & \text{if } b = a \text{ and } \forall b' \in D,\ b \notin T_{b'} \\ 0 & \text{otherwise} \end{cases}$$

($T_{b'}$ is the subtree of T rooted at b', so that $b \notin T_{b'}$ means b is not a descendent of b'; $b \preceq a$ means b is an ancestor or a sibling of an ancestor of a in T.) This equation says that column b of ϕ is either: a copy of w_b with entries $w_b(a)$ replaced by 0s for $b \not\preceq a$ (if $b \in D$, cases 1, 3); a single 1 on the diagonal (if neither b nor any of its ancestors is in D, cases 2, 3); or all 0s (if $b \notin D$, but one of b's (strict) ancestors is in D, case 3).

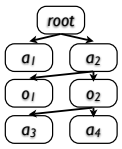
Now, if we take Φ_{EF} to be the convex hull of all such ϕs, then $\Phi_{\text{EF}} \subset \Phi_{\text{LIN}}$, and no Φ_{EF}-regret immediately implies no regret vs. any extensive form transformation. (So, no Φ_{EF}-regret is related to extensive-form correlated equilibrium; see Sec. 4).

For example, if T is as shown in Fig. 3 (left), elements of A are vectors of 4 sequence weights, one each for $a_1 \ldots a_4$. The weight for, e.g., a_3 is $P(a_2 \mid \text{root})P(a_3 \mid o_2)$, the product of the conditional probabilities of all choice nodes along the path from the root to a_3. So, strategy a_1, a_3 yields weights $w = (1,0,0,0)^{\text{T}}$, while a_2, a_3 yields $w' = (0,1,1,0)^{\text{T}}$.

The set Φ_{EF} for this game is shown in Fig. 3 (right). The parameters a, d, e, and f determine the probability that each choice node is included in D: $a \geq 0$ is $P(a_1 \in D)$, $d \geq 0$ is $P(a_2 \in D)$, $e \geq 0$ is $P(a_3 \in D)$, and $f \geq 0$ is $P(a_4 \in D)$. If $a_1 \in D$, parameters b and c specify a strategy for the subtree rooted at a_2. (If $a_1 \notin D$, the game ends right after we reach D, and so we need not specify further choices.) The inequalities listed in Fig. 3 are consistency constraints: e.g., the events $a_2 \in D$ and $a_3 \in D$ are mutually exclusive, so we must have $d + e \leq 1$.

To represent the transformation "play a_2, a_3 instead of a_1," we construct a matrix ϕ by setting $a, b = 1$ and $c, d, e, f = 0$. It is easy to verify that $\phi w = w'$ as expected. On the other hand, the transformation "play a_1 instead of a_2" corresponds to ψ with $d = 1$ and $a, b, c, e, f = 0$; again, it is easy to check $\psi w' = w$.

[3] The precise cost will depend heavily on the shape of A. For general A, most no-external-regret algorithms have a step like solving an LP with feasible region A or projecting onto A by minimum Euclidean distance. These computations cost $O(d^3)$ if we assume that an appropriate measure of the complexity of A is held constant.



$$\begin{bmatrix} 1-a & d & 0 & 0 \\ a & 1-d & 0 & 0 \\ b & 0 & 1-d-e & f \\ c & 0 & e & 1-d-f \end{bmatrix}$$

Figure 3. Φ_{EF} example. $b + c = a$, $d + e \leq 1$, $d + f \leq 1$, and $0 \leq a, b, c, d, e, f \leq 1$.

4. Regret and Equilibria

Algorithm $\mathcal{A}$ achieves no Φ-regret in an online convex program, for any suitable Φ. In this section, we relate this guarantee back to equilibria in convex games.

A game consists of a set of players N, a set of actions A_i for each player $i \in N$, and a payoff function $r_i : \otimes_i A_i \to \mathbb{R}$ for each player $i \in N$. A **matrix** game is one in which each action set is finite. A variant on a matrix game is an **experts** game in which each action set is a probability simplex. Generalizing experts games, a **convex** game is one in which each action set is a convex and compact subset of Euclidean space and each payoff function is multi-linear. In experts games and convex games, players can play interior points; but, assuming polyhedral action sets (PAS), we can generate a corresponding **corner game** by restricting each player's actions to the corners of its action sets.

Following Stoltz and Lugosi (2007), who generalize the definition for matrix games given in Greenwald and Jafari (2003), we define equilibria in convex games in terms of transformation sets.

Definition 2 *Given a game and a collection of transformation sets, $\langle \Phi_i \rangle_{i \in N}$, with each $\Phi_i \subseteq \Phi_{SWAP}$, a probability distribution q over $\otimes_i A_i$ is a $\langle \Phi_i \rangle_{i \in N}$-*equilibrium *iff the expectation over $a \sim q$ satisfies*

$$\mathbb{E}\left[r_i(\phi(a_i), a_{\neg i}) - r_i(a)\right] \leq 0 \quad \forall i \in N,\ \phi \in \Phi_i \qquad (3)$$

Intuitively, an equilibrium is a distribution from which no player prefers to deviate using any transformation in its set. Taking each Φ_i to be the set of swap transformations defines **correlated equilibria**; taking each Φ_i to be the set of external (i.e., constant) transformations defines **coarse correlated equilibria**. These definitions lead to the following propositions, proved by Marks (2008) and Gordon et al. (2007).

Proposition 3 *A correlated equilibrium of the corner game generated from a PAS convex game is also a correlated equilibrium of the convex game itself.*

Proposition 4 *For every correlated equlibrium in a PAS convex game, the corresponding corner game has a payoff-equivalent correlated equilibrium.*

4.1. Repeated Games

As described above, we assume the agents play some game repeatedly and learn by observing the relationship between their actions and their payoffs. In repeated matrix games, Greenwald and Jafari (2003) have shown that if each agent plays according to a no Φ_i-regret algorithm, then the empirical distribution of joint play converges to the set of $\langle \Phi_i \rangle_{i \in N}$-equilibria with probability 1. The **empirical distribution of joint play** at step t is the following distribution over the joint action set, where $a^t \in \otimes_i A_i$ is the joint action played at time step t: $z^t(\alpha) = \left|\{\tau \mid a^\tau = \alpha\}\right|/t$. The analogous result holds for $\langle \Phi_i \rangle_{i \in N}$-equilibrium in repeated convex games (e.g., Stoltz and Lugosi (2007)).

Because extensive-form games are one class of convex games (Forges & von Stengel, 2002), this result implies that, if the agents all play extensive-form regret-minimization algorithms, their play will converge to the set of extensive-form correlated equilibria. (Marks (2008) also provides algorithms with this property, using the less-efficient normal-form representation of extensive-form games.)

We can also say something about convergence to full-fledged correlated equilibria in repeated convex games: define a **randomized** variant of $\mathcal{A}$ as follows. On a trial where the deterministic algorithm would have played $\bar{a}_t$, the randomized algorithm samples its play a_t from any distribution D such that

$$E_D(a_t) = \bar{a}_t \qquad E_D(K(a_t)) = K(\bar{a}_t) \qquad (4)$$

(We still use $\bar{a}_t$, rather than a_t, in constructing m_t.) With such a D, if loss functions are linear, our Φ-regret on A and external regret on Φ differ by a zero-mean random variable; so, we can use standard stochastic convergence results to prove:

Corollary 5 *Under the conditions of Thm. 1, the additional assumption (4), and restricting L to include only linear loss functions, the randomized variant of $\mathcal{A}$ achieves no Φ-regret with probability 1.*

For Φ_{FE}-regret, we can always find a D that satisfies Equation (4); so (Gordon et al., 2007):

Corollary 6 *If, in a repeated PAS convex game, each agent plays only corner points and uses an algorithm that achieves no internal regret for the corner game (such as the randomized version of $\mathcal{A}$ with $\Phi = \Phi_{\text{FE}}$), then the empirical distribution of joint play converges to the set of correlated equilibria of the convex game with probability 1.*

To our knowledge, ours is the most efficient algorithm which can make this claim, by a factor which is exponential in the dimension d.

5. Discussion

We have presented several new forms of regret for online convex programs, analyzed their relationships to one another and to known regret types, and given the first efficient algorithms that directly minimize some of these forms of regret. These algorithms are by far the most efficient known for several purposes, including guaranteeing convergence to a correlated equilibrium in a repeated convex game, and to an extensive-form correlated equilibrium in an extensive-form game. By contrast, most previous OCP algorithms only guarantee convergence to coarse correlated equilibrium, an outcome which may yield much lower payoffs and may leave incentives for rational agents to deviate.

In the process of designing our algorithms, we derived efficient representations of the transformation sets for each of our regret types except Φ_{SWAP}: we wrote each as a nonlinear kernel mapping followed by a linear transformation chosen from an appropriate set of matrices. These representations may be of separate interest for designing future algorithms. In this paper, we were chiefly interested in cases where the dimension of the kernel mapping was manageable, so that we could directly work with the transformation matrices. However, it would be very interesting to try to design "kernelized" no-Φ-regret algorithms. In such algorithms we would never explicitly write down a transformation ϕ, but instead represent it in terms of observed actions and loss functions, thereby making it feasible to use very high-dimensional sets of transformations.

Important application areas for OCPs and convex games include multi-agent planning (in which the feasible region for each player is a set of plans, and interactions include contending for resources) and learning in extensive-form games such as poker. We are particularly interested in extensive-form games; this application requires further developments such as learning efficiently from bandit feedback and abstracting large games into smaller representations which we can work with in real time.

Acknowledgments

The authors would like to thank Martin Zinkevich for very helpful discussions during an early phase of this work. This work was supported in part by a grant from DARPA's Computer Science Study Panel program and in part by a grant from the Sloan Foundation.

Abstract

In real-world machine learning problems, it is very common that part of the input feature vector is incomplete: either not available, missing, or corrupted. In this paper, we present a boosting approach that integrates features with incomplete information and those with complete information to form a strong classifier. By introducing hidden variables to model missing information, we form loss functions that combine fully labeled data with partially labeled data to effectively learn normalized and unnormalized models. The primal problems of the proposed optimization problems with these loss functions are provided to show their close relationship and the motivations behind them. We use auxiliary functions to bound the change of the loss functions and derive explicit parameter update rules for the learning algorithms. We demonstrate encouraging results on two real-world problems — visual object recognition in computer vision and named entity recognition in natural language processing — to show the effectiveness of the proposed boosting approach.

1. Introduction

Boosting is a general supervised learning technique for incrementally building linear combinations of "weak" models to generate a "strong" predicative model. It is one of the most successful and practical methods in machine learning. Over the last decade, it has attracted much attention in the machine learning community and related areas such as statistics. It has been widely applied in many real-world problems such as text filtering and routing, ranking, learning in natural language processing, image retrieval, medical diagnosis, and customer monitoring and segmentation (Schapire, 2004).

It is very common in real-world machine learning problems that part of the input feature vector is incomplete: either not available, missing, or corrupted. In a web-page ranking problem, for example, using click-though data as part of the features, we find that a small number of valid pages have click features and most do not. In the case of object recognition in computer vision, many approaches assume a part-based model. However, certain parts of the object are hard to detect reliably due to small support in the image, occlusion or clutter, which also lead to missing information. Handling these kinds of classification problems containing incomplete information is a very important and realistic task. Excluding popular EM algorithms for generative models, some methods have been recently proposed for discriminative models (Chechik et al., 2007; Koo & Collins, 2005; Quattoni et al., 2005; Shivaswamy et al., 2006; Bi & Zhang, 2004).

In this paper, we show how to handle incomplete data under the boosting approach. We first describe the precise problem we are trying to solve, then we formulate optimization problems where the loss functions consist of two parts, one using partially labeled data and the other using fully labeled data. The primal problems of the proposed optimization problems with these loss functions are provided to show their close relationship and shed light on the rationale behind them. We derive explicit parameter update rules of the learning algorithms by introducing auxiliary functions to bound the change of loss functions. Finally, we demonstrate encouraging results on two real-world problems to show the effectiveness of the proposed boosting approach: visual object recognition in computer vision and named entity recognition in natural language processing.

2. Preliminaries

Let $X \in \mathcal{X}$ be a random variable over data instances to be labeled, and Y be a random variable over corresponding labels ranging over a finite label alphabet $\mathcal{Y}$. The classification task is to learn a mapping from data instances $\mathcal{X}$ to labels $\mathcal{Y}$. Assume we have a set of feature functions $\mathcal{F}_1 := \{f_k(x,y)\}$ where each feature maps $\mathcal{X} \times \mathcal{Y}$ to $\mathbb{R}$. Same as in (Collins et al., 2002; Lebanon & Lafferty, 2002) and without loss of generality, we assume that the range of all feature functions in this paper is $[0,1]$. These feature functions correspond to weak learners in boosting and sufficient statistics in an exponential family model.

Suppose the target predictor can be derived from a scoring function written as a linear combination of feature functions $t(x,y) = \sum_{f_k \in \mathcal{F}_1} \lambda_k f_k(x,y)$. Given a training dataset $\{(x_i, y_i)\}$, it has been shown (Lebanon & Lafferty, 2002) that Adaboost (Freund & Schapire, 1997) combines features to minimize the following exponential loss

$$\sum_{x_i} \sum_{y} q_\lambda(y|x_i) \tag{1}$$

where $q_\lambda(y|x) := \exp \sum_{f_k \in \mathcal{F}_1} \lambda_k \big[f_k(x,y) - f_k(x,\tilde{y}_x)\big]$ is called the unnormalized model, and $\tilde{y}_x$ denotes the label of instance x over the empirical data. Equivalently, it has been shown (Lebanon & Lafferty, 2002) that Logitboost (Friedman et al., 2000) minimizes the following log loss

$$-\sum_{x_i} \log p_\lambda(\tilde{y}_{x_i}|x_i) \tag{2}$$

where $p_\lambda(y|x) := q_\lambda(y|x)/Z_\lambda(x)$ is called the normalized model. Optimizing the two objective functions above can be done by either parallel or sequential updates (Collins et al., 2002; Lebanon & Lafferty, 2002).

Now assume that there is a random variable $h \in \mathcal{H}$ which is *hidden* in some part of the training data $\mathcal{D}_1 := \{(x_i, y_i)\}$ but has been observed in the rest of the training data $\mathcal{D}_2 := \{(x_j, h_j, y_j)\}$. Consider a second set of feature functions $\mathcal{F}_2 := \{f_k(x,h,y)\}$ where each feature maps $\mathcal{X} \times \mathcal{H} \times \mathcal{Y}$ to $\mathbb{R}$. In many real-world applications, the number of fully observed instances is much smaller than that of partially observed instances, that is, $|\mathcal{D}_2| \ll |\mathcal{D}_1|$, since obtaining fully observed instances is either expensive or time-consuming. To take full advantage of all available training data, we need to develop new methods, because the information cannot be fully exploited by the original boosting algorithm.

Hereafter we use subscripts i and j to range over training data in $\mathcal{D}_1$ and $\mathcal{D}_2$ respectively. For a datum (x,h,y), we denote all of its $\mathcal{F}_1$ features by the vector $\mathbf{f}_1(x,y)$ and all of its $\mathcal{F}_2$ features by the vector $\mathbf{f}_2(x,h,y)$.

3. Boosting with Hidden Variables

The challenge in this paper is, besides using the feature set $\mathcal{F}_1$ and training set $\mathcal{D}_1$, how to use the additional feature set $\mathcal{F}_2$ and training set $\mathcal{D}_2$ to obtain a better approximation for the mapping from instances to labels.

To this end, the main object of focus is a mapping from $\mathcal{X} \times \mathcal{H}$ to $\mathcal{Y}$, which is modeled by a conditional probability distribution $p_\lambda(y|x,h)$. This distribution is called the normalized model and is defined parametrically as

$$p_\lambda(y|x,h) \propto e^{\boldsymbol{\lambda}_1^T \cdot [\mathbf{f}_1(x,y) - \mathbf{f}_1(x,\tilde{y}_x)] + \boldsymbol{\lambda}_2^T \cdot [\mathbf{f}_2(x,h,y) - \mathbf{f}_2(x,h,\tilde{y}_x)]}$$

where $\boldsymbol{\lambda}_1$ and $\boldsymbol{\lambda}_2$ are the model's parameter vectors corresponding to features in $\mathcal{F}_1$ and $\mathcal{F}_2$, respectively[1]. To estimate the parameters of the distribution, we can maximize the conditional likelihood of the training data:

$$\mathcal{L}(\lambda) := \sum_i \log p_\lambda(y_i|x_i) + \gamma \sum_j \log p_\lambda(y_j|x_j,h_j)$$

where γ is used to balance the influence of the two data sources on the objective function. Let $q_0(h|x)$ be a fixed distribution representing the prior belief in values of the hidden variable given an instance x, then $p_\lambda(y,h|x) = q_0(h|x)p_\lambda(y|x,h)$ and the first term in $\mathcal{L}(\lambda)$ can be computed based on $p_\lambda(y|x) = \sum_h p_\lambda(y,h|x)$.

We now turn our attention to model the mapping from $\mathcal{X} \times \mathcal{H}$ to $\mathcal{Y}$ by a linear scoring function that is the basis of our Adaboost type algorithms. When h is observed, the mapping is defined based on

$$t_\lambda(x,h,y) := \boldsymbol{\lambda}_1^T \cdot \boldsymbol{f}_1(x,y) + \boldsymbol{\lambda}_2^T \cdot \boldsymbol{f}_2(x,h,y)$$

and when h is hidden, it is defined as $t_\lambda(x,y) := \sum_h q_0(h|x) t_\lambda(x,h,y)$. As before, $q_0(h|x)$ is used to inject prior domain knowledge. To learn the parameters, we pose the minimization of the loss function $\mathcal{E}(\lambda)$ defined as

$$\mathcal{E}(\lambda) := \sum_i \sum_h q_0(h|x) \sum_y q_\lambda(y|x_i,h) + \gamma \sum_j \sum_y q_\lambda(y|x_j,h_j)$$

where $q_\lambda(y|x_i,h)$ is called the unnormalized model

$$q_\lambda(y|x,h) := e^{\boldsymbol{\lambda}_1^T \cdot [\mathbf{f}_1(x,y) - \mathbf{f}_1(x,\tilde{y}_x)] + \boldsymbol{\lambda}_2^T \cdot [\mathbf{f}_2(x,h,y) - \mathbf{f}_2(x,h,\tilde{y}_x)]}$$

The second term in $\mathcal{E}(\lambda)$ can be thought of as the loss incurred for the jth instance over all possible labels, and the first term as the *expected* loss for the ith instance. Note that if $q_0(h|x_j)$ puts a point mass γ on the observed h_j for instances in $\mathcal{D}_2$, then $\mathcal{E}(\lambda)$ can be rewritten compactly as

$$\mathcal{E}(\lambda) = \sum_{x \in \mathcal{D}_1 \cup \mathcal{D}_2} \sum_{h,y} q_0(h|x) q_\lambda(y|x,h)$$

[1] It is equivalent to the more familiar form $p_\lambda(x,h,y) \propto e^{\boldsymbol{\lambda}_1^T \cdot \mathbf{f}_1(x,y) + \boldsymbol{\lambda}_2^T \cdot \mathbf{f}_2(x,h,y)}$ by simply removing the constants $e^{\boldsymbol{\lambda}_1^T \cdot \mathbf{f}_1(x,\tilde{y}_x) + \boldsymbol{\lambda}_2^T \cdot \mathbf{f}_2(x,h,\tilde{y}_x)}$ from the numerator and denominator.

In the next section, we will show that there is a close relationship between minimizing $\mathcal{E}(\lambda)$ and maximizing the lowerbound $\ell(\lambda)$ on $\mathcal{L}(\lambda)$, which is derived based on Jensen's inequality and defined as

$$\ell(\lambda) := \sum_{i,h} q_0(h|x_i) \log p_\lambda(y_i|x_i, h) + \gamma \sum_j \log p_\lambda(y_j|x_j, h_j)$$

By extending q_0 to instances in $\mathcal{D}_2$ as before, we can write

$$\ell(\lambda) = \sum_{x \in \mathcal{D}_1 \cup \mathcal{D}_2} \sum_h q_0(h|x) \log p_\lambda(\tilde{y}_x|x, h)$$

Furthermore, we will show a close relationship between maximizing $\mathcal{L}(\lambda)$ and minimizing the following lowerbound on $\mathcal{E}(\lambda)$ derived by Jensen's inequality

$$\varepsilon(\lambda) := \sum_i \sum_y e^{t_\lambda(x_i,y) - t_\lambda(x_i,y_i)} + \gamma \sum_j \sum_y e^{t_\lambda(x_j,h_j,y) - t_\lambda(x_j,h_j,y_j)}$$

In the test time, depending on whether h is hidden or not, either $p_\lambda(y|x)$ or $p_\lambda(y|x, h)$ can be used to determine the class label of a given instance if we use the probabilistic model. Accordingly, for the linear map, either $t_\lambda(x, y)$ or $t_\lambda(x, h, y)$ can be used.

Our definitions of both normalized and unnormalized models are similar to those in (Lebanon & Lafferty, 2002). If we ignore fully labeled data in $\mathcal{L}(\lambda)$, we get the hidden conditional random field proposed in (Koo & Collins, 2005; Quattoni et al., 2005) by assuming $q_0(h|x)$ to be constant; however, the second term in $\mathcal{L}(\lambda)$ should exist to take advantage of $\mathcal{D}_2$. If we ignore the first term in $\mathcal{E}(\lambda)$, we get the standard boosting algorithm's loss function; however, the first term is needed to take advantage of the partially observed data $\mathcal{D}_1$. In the next section, we will provide the primal problems for the proposed loss functions to motivate the rationale of optimizing them and show their relationships. We then give sequential and parallel algorithms to optimize $\mathcal{E}(\lambda)$ and $\mathcal{L}(\lambda)$ in section 5.

4. Primal and Dual Programs

It is well known (Lebanon & Lafferty, 2002) that for standard boosting with no hidden information, the primal optimization problems for Adaboost and Logitboost are the same except for the additional constraints for the latter to ensure a probabilistic model. For our boosting with incomplete information, this relationship does not exist for the original optimization problems themselves, but rather between $\mathcal{E}(\lambda)$ and $\ell(\lambda)$ which is the lowerbound on $\mathcal{L}(\lambda)$.

Let the set of non-negative measures $\mathcal{M} := \{m : \mathcal{X} \times \mathcal{H} \times \mathcal{Y} \to \mathbb{R}_+\}$, and $\mathcal{F} := \mathcal{F}_1 \cup \mathcal{F}_2$. Let $\mathbf{r}$ be the reference measure $\mathbf{1}$; however, it can be any arbitrary measure that generalizes the objective functions introduced in the previous section.

Theorem 1. *The following optimization program:*

$$\max_\lambda \sum_{x \in D_1 \cup D_2} \sum_{h,y} q_0(h|x) q_\lambda(\tilde{y}_x|x, h) \tag{3}$$

is the dual of $\min_{\mathbf{p} \in \mathcal{S}(\tilde{\mathbf{p}}, \mathbf{q}_0, \mathcal{F})} KL(\mathbf{p}||\mathbf{r})$ *where the extended* $KL(\mathbf{p}||\mathbf{r})$ *is defined as*

$$\sum_{x,h} \tilde{p}(x) q_0(h|x) \sum_y p(y|h, x) \Big[\log \frac{p(y|x, h)}{r(x, h, y)} - 1 \Big] + r(x, h, y)$$

and the set $\mathcal{S}(\tilde{\mathbf{p}}, \mathbf{q}_0, \mathcal{F})$ *is defined as*

$$\Big\{ \mathbf{p} \in \mathcal{M} \Big| \sum_x \tilde{p}(x) \mathbb{E}_{q_0(h|x) p(y|x,h)} \Big[f - \mathbb{E}_{\tilde{p}(y|x)}[f] \Big] = 0, \forall f \in \mathcal{F} \Big\}$$

Proof sketch. The key idea in this theorem is the definition of the extended KL divergence and $\mathcal{S}(\tilde{\mathbf{p}}, \mathbf{q}_0, \mathcal{F})$. Construct the Lagrangian of the dual, which is a constrained optimization problem, take its derivative, and set it to zero. It will give the form of the optimal solution; plug this form back into the Lagrangian, and make the data consistency assumption ($\tilde{\mathbf{p}}$ is the *empirical* probability distribution) $\sum_y \tilde{p}(y|x) f(x, y) = f(x, y_x)$ for $f \in \mathcal{F}_1$ and $\sum_y \tilde{p}(y|x) f(x, h, y) = f(x, h, y_x)$ for $f \in \mathcal{F}_2$, we will obtain the optimization problem in (3) . □

Theorem 2. *The following optimization program:*

$$\max_\lambda \sum_{x \in D_1 \cup D_2} \sum_h q_0(h|x) \log p_\lambda(\tilde{y}_x|x, h) \tag{4}$$

is the dual of $\min_{\mathbf{p} \in \mathcal{S}_\triangle(\tilde{\mathbf{p}}, \mathbf{q}_0, \mathcal{F})} KL(\mathbf{p}||\mathbf{r})$ *where the extended* $KL(\mathbf{p}||\mathbf{r})$ *is defined as in Theorem 1, and*

$$\mathcal{S}_\triangle(\tilde{\mathbf{p}}, \mathbf{q}_0, \mathcal{F}) := \Big\{ \mathbf{p} \in \mathcal{S}(\tilde{\mathbf{p}}, \mathbf{q}_0, \mathcal{F}) \Big| \forall x, h : \sum_y p(y|x, h) = 1 \Big\}$$

The proof of this theorem is similar to that of Theorem 1 and is omitted because of space constraints. As can be seen from the theorems above, the primal optimization problems corresponding to the objective functions $\mathcal{E}(\lambda)$ and $\ell(\lambda)$ are the same except for the additional constraints for the later one to ensure $\sum_y p(y|x, h) = 1$. The extended KL divergence gives the expected discrepancy between $p(y|x, h)$ and the reference measure $r(x, h, y)$ where the expectation is taken with respect to the distribution $\tilde{p}(x) q_0(h|x)$. Hence minimizing the extended KL subject to the constraints forces $p(y|x, h)$ to become similar to $\mathbf{r}$, or in particular when the reference measure is $\mathbf{1}$ or constant, to have more entropy.

5. Learning Algorithms

Convergence of boosting algorithms has been studied in various ways. Much work has been done to prove the convergence in terms of an optimization method, which can be categorized into two approaches: greedy function optimization and greedy feature induction.

In the first approach, the boosting algorithm is viewed as a sequential gradient descent algorithm (Breiman, 1999;

Friedman et al., 2000; Mason et al., 2000) in function space, inspired by numerical optimization and statistical estimation. It is a forward stage-wise additive modeling that approximates the solution by sequentially adding new basis functions without adjusting the parameters and coefficients of those that have already been added. At each iteration, one solves for the optimal basis function and corresponding coefficients to add to the current expansion. This produces new expansion, and the process is repeated.

In the second approach (Collins et al., 2002; Lebanon & Lafferty, 2002), the boosting algorithm is described as a greedy feature induction algorithm to incrementally build random fields. The greediness of the algorithm arises in steps that select the most informative feature. In these steps each feature in a pool of candidate features is evaluated by estimating the reduction in the Kullback-Lieber divergence that would result from adding the feature to the field. This reduction is approximated as a function of a single parameter and is equal to the exponential loss reduction or log loss increment. This approximation is one of the key elements that make it practical to evaluate a large number of candidate features at each stage of the induction algorithm. Various parameter update rules can be derived By using an auxiliary function to bound the change of loss function from above, and thus convergence to the global optimal solution is proved.

In this paper we take the second approach to learn the discriminative model. We construct an auxiliary function to bound the change of exponential loss, $\mathcal{E}(\lambda+\Delta\lambda)-\mathcal{E}(\lambda)$ or log-loss $\mathcal{L}(\lambda)-\mathcal{L}(\lambda+\Delta\lambda)$. Similar to (Collins et al., 2002; Lebanon & Lafferty, 2002), either parallel or sequential updates can be used. By the same argument as in (Collins et al., 2002; Lebanon & Lafferty, 2002), we can show the convergence of these updates to a *local minimum* of the loss function. For simplicity in presenting the results, we introduce some notation for $\tilde{x} \in \mathcal{D}_1 \cup \mathcal{D}_2$:

$$\forall f_k \in \mathcal{F}_1, g_k(\tilde{x}, y) = f_k(\tilde{x}, y) - f_k(\tilde{x}, \tilde{y}_{\tilde{x}}) \quad (5)$$

$$\forall f_k \in \mathcal{F}_2, g_k(\tilde{x}, h, y) = f_k(\tilde{x}, h, y) - f_k(\tilde{x}, h, \tilde{y}_{\tilde{x}}) \quad (6)$$

$$C := \max_{\tilde{x},y,h} \Big(\sum_{f_k \in \mathcal{F}_1} |g_k(\tilde{x}, y)| + \sum_{f_k \in \mathcal{F}_2} |g_k(\tilde{x}, h, y)| \Big) \quad (7)$$

$$\mathbb{E}^+_{p(t)}[\psi(t)] := \sum_{t:\psi(t)>0} p(t)\psi(t) \quad (8)$$

For the normalized model, the learning algorithm with parallel updates is summarized in Algorithm 1 and with the sequential updates in Algorithm 2. For the unnormalized model, the update rules (parallel or sequential) are exactly the same; the only difference is that we will use $q_\lambda(y|x, h)$ rather than $p_\lambda(y|x, h)$ in all the algorithms' equations. For details of the derivation of updating rules in the learning algorithms, see Appendix A.

For ease of presentation, we have assumed that the potentially missing attributes are always the same. This is an interesting and nontrivial situation that occurs in many real-world applications, where the missing attribute h is the information that requires expensive human labeling (see the experiments for example applications). However, our approach can be easily extended to the cases where the data could have different missing attributes. In this more general setting, the i-th training datum has the form (x_i, y_i) with missing information $h_i \in \mathcal{H}_i$, where $\mathcal{H}_i$ can vary for different i's depending on which information is missing. The contribution of this datum to the log loss in the normalized model is simply $-\log p_\lambda(y_i|x_i)$. All the arguments in this paper will go through with some minor changes.

6. Experiments

We evaluate our approach in two real-world problems: visual object recognition in computer vision and named entity recognition in natural language processing. In both cases, we use simple and independent features, so when we calculate the values of A_j^+ and A_j^-, feature expectations can be done efficiently. For simplicity, we set γ to be 1. In practice, this parameter can be set by cross-validation. We set our prior belief in values of the hidden variable given an

until convergence

instance, $q_0(h|x)$ to be constant. In all the experiments, we use parallel updates. We have tried sequential updates and find that they are much slower. Although they can achieve higher likelihood on the training data, the results on the test data remain the same.

We compare our proposed boosting approach with three different baseline algorithms, in both normalized and unnormalized cases. The first baseline algorithm (BL1) uses both sets of features $\mathcal{F}_1$ and $\mathcal{F}_2$, but is trained only on the fully observed training data $\mathcal{D}_2$. The second baseline algorithm (BL2) is trained on all the training data $\mathcal{D}_1 \cup \mathcal{D}_2$ but uses only features $\mathcal{F}_1$, that is, it ignores features $\mathcal{F}_2$ that involve the hidden information h. Notice that the second baseline algorithm is identical to the algorithm in (Lebanon & Lafferty, 2002). The third baseline algorithm (BL3) uses all the training data $\mathcal{D}_1 \cup \mathcal{D}_2$ and both types of features $\mathcal{F}_1 \cup \mathcal{F}_2$ but ignores observed h on fully observed data; that is, it assumes all the data are in the form of $\{(x_i, y_i)\}$. Notice that the third baseline algorithm is similar to the hidden conditional random field (Quattoni et al., 2005).

6.1. Visual Object Recognition

We first consider a visual object recognition task where some of the data have missing features. In this task, we attempt to classify an image based on the existence of an object of interest in the image. We test our approach on the Caltech 4 dataset: airplanes, cars, faces, and motorbikes.

Common approaches to object recognition involve some form of supervision, which may range from manually segmenting the objects (Winn & Shotton, 2006), to specifying a bounding box of the objects (Viola & Jones, 2001), to only indicating the existence of the objects (Fergus et al., 2003). Naturally, there is a trade-off among different levels of supervisions. Manually segmenting the object of interest in an image obviously provides very accurate information for any learning algorithm, but it is very expensive and time-consuming to annotate a large number of images. On the other hand, it is relatively easy to label an image based only on the existence of an object. In our experiment, we assume we have two sets of training images. The first set of images has only class labels associated with them; we represent them as (x, y), where x refers to the image and y refers to its class label. The second set of images has both class label and the contour of the object being manually labeled; we represent them as (x, h, y), where h is the information about the contour of the object. Our learning problem is then in precisely the scenario in which our proposed method is expected to be effective.

We first run an interest-point detector (Kadir & Brady, 2001) to identity regions of interest on each image. Each interest point is represented by a SIFT descriptor (Lowe, 2004) as a 128-dimensional vector. The SIFT descriptors from all the training images are then vector quantized into K visual words (we choose $K = 200$ in our experiment) by k-means clustering. All the images are then represented by a bag-of-words representation by counting the occurrence of each visual word in an image. We denote an image as $x = (x_1, x_2, ..., x_t)$, where t is the number of interest points in x, and each x_i is an entry to a visual word. The information h about the object contour is represented as $h = (h_1, h_2, ..., h_t)$, where h_i is a binary value indicating whether x_i is on the object or not. Since we assume the "bag-of-words" model, the summation over h required for calculating A_j^+ and A_j^- can be solved efficiently by factoring out the contribution of each interest point. Although bag-of-words representation ignores a lot of positional information between features, previous work (Sivic et al., 2005; Fergus et al., 2005) has demonstrated that it to be quite effective in object recognition tasks.

We define the following three sets of features for our boosting algorithm, based on the bag-of-words representation of images. (1) feature $f_{jy'}(x, y)$ is calculated as the count of visual words j in an image x if $y = y'$, and zero otherwise; (2) feature $o_{jy'}(x, h, y)$ is the count of visual words j on the foreground of image x if $y = y'$, and zero otherwise; (3) feature $b_{jy'}(x, h, y)$ is the count of visual words j on the background of image x if $y = y'$, and zero otherwise. Notice that features $f_{jy'}$ are always observed for a training image. Features $o_{jy'}$ and $b_{jy'}$ are observed only when a training image does not have missing information (i.e., the manually labeled object contour). We normalize all the features by the total number of interest points in an image

	accuracy	log-likelihood
Our method	97.22%	-0.0916

BL2	89.86%	-0.7977
BL3	87.64%	-0.8068

unnormalized model

Table 1. Results of our approach on visual object recognition, compared with three baseline algorithms

to make sure their values are between 0 and 1. During testing, we observed the image x, and we try to infer its label y based on the learned model. Although we can also infer y assuming both x and h are observed during testing, it is actually an unrealistic setting in our application. It requires a perfect figure/ground segmentation of the image x. However, since figure/ground segmentation is itself a very challenging problem in computer vision, it is not reasonable to assume we could have this information during the testing. So we do not investigate this case.

Our dataset contains more than 2000 images. We randomly split them equally into training and testing sets. We choose 30% of the training images to be fully observed and the rest to be partially observed. We compare both normalized and unnormalized models with the three baseline algorithms defined above, in terms of classification accuracy and the log-likelihood of the test data. The results are shown in Table 1. We also visualize the most discriminative patches in some sample images in Figure 1. We find that our approach is significantly superior to the three baseline algorithms, in term of both accuracy and log-likelihood on the test images.

6.2. Named Entity Recognition

Named entity extraction (NEE) is a subtask of information extraction in which we try to identify names of persons, locations, and organizations in a given set of documents. One approach to this problem is to do first named entity recognition (NER) and then named entity classification (NEC). In this section we apply our method to the NER problem and demonstrate its effectiveness compared to the baseline systems.

We consider NER as a sequence labeling problem, that is, specifying a sequence of zero and one for a sentence to classify a word as part of a named entity or not. For each word w, its surrounding words in a window of length 5, its part-of-speech tag (when available), and previous predictions represent its local context, which then used by the classifier. The part-of-speech tag is a valuable source of information and is not available in some annotations of the data sets for this task, so we treat it as the hidden variable that is not observed for some portion of the training data. We could use the *sequence* of POS tags of the words in the current window as the hidden variable. In that case, we may use a finite state automata to characterize the eligible sequence of POS tags when we want to sum over their values to speed up the training algorithms. The features that we used are summarized in Table 6.2; they are described in more details in (Carreras et al., 2003).

Feature	Explanation
Lexical	word forms and their positions in the window
Syntactic	part-of-speech tags (when available)
Orthographic	capitalized, include digits, ...
Affixes	the suffixes and prefixes (up to four characters)
Left predict	predicted labels for the two previous words

Table 2. Details of the features used for the NER task. Syntactic features belong to $\mathcal{F}_2$ and the rest of features belong to $\mathcal{F}_1$.

We use the data set of the CONLL 2003 shared task. To reduce the training time, we collapse the original 45 different POS tags into five tags as done in (McCallum et al., 2003). After training the model, we do the classification for each individual position by normalizing the prediction score of the model using the class mass normalization (CMN) procedure as introduced in (Zhu et al., 2003).

We compare our approach to the three baseline systems defined before. There are 5K sentences in $\mathcal{D}_1$, 6K sentences in D_2, and 1K sentences in the test set. The first set of experiments show the performance of our model compared to the baselines when, at the test time, only x is available (see Table 3). In the second set of experiments, (x, h) is given at the test time (see Table 4); for this setting, BL2 and BL3 cannot be used. Our method outperforms baseline systems in both sets of experiments in terms of f-measure and log-likelihood or loss function.

7. Comparison to the Related Work

Originally boosting is considered as a way to boost weak learners to strong learners by: learning weak hypotheses to classify hard examples in each round, and finally combining these weak hypotheses. Another view to boosting is through the statistical perspective which interprets it as: optimizing some objective function via parallel or sequential updates to determine the weights of all possible weak hypotheses (aka features). There is a debate between the statistic and algorithmic perspective; see (Mease & Wyner, 2008) for more information. Our work takes the statistical perspective and do not engage in that debate.

A related algorithm that takes the first perspective to boosting is AdaBoost with confidence-rated predictions in which a weak learner outputs a real value representing the confidence level (Schapire & Singer, 1999). When provided with incomplete input, the weak learner's contribution is its uncertainty about its vote, which is represented by the produced real number. The details of the connection between our approach and confidence-rated AdaBoost will be an interesting topic to explore for future research.

8. Conclusions and Further Work

In this work we have presented a novel boosting approach that extends the traditional boosting framework by incorporating hidden variables such that fully labeled data can be integrated with partially labeled data to form a powerful strong classifier. Thus, compared with both the original boosting algorithms and hidden CRF, our model performs better in two real-world problems by fully exploiting relevant complete information of data resources.

We consider only simple independent features in our model. In fact, the hidden variables may have complex dependencies that respect certain cyclic graph structure; then it may be necessary to use variational methods, such as loopy belief propagation, to compute feature expectation for the values of A^+ and A^-. As future work, we would like to incorporate more complex dependent features in these two applications.

Appendix A. Deriving Learning Algorithms

Exponential loss

We derive parallel updates for exponential loss. Let $\lambda+\Delta\lambda$ be the new parameters value. We find an upper-bound to the change of objective function $\mathcal{E}(\lambda+\Delta\lambda)-\mathcal{E}(\lambda)$ by an *auxiliary function*, and then minimize the bound.

$$\begin{aligned}
&\mathcal{E}(\lambda+\Delta\lambda)-\mathcal{E}(\lambda)= \\
&\sum_{i,h,y} q_0(h|x_i)e^{\lambda.G(x_i,h,y)}\Big(e^{\Delta\lambda.G(x_i,h,y)}-1\Big)+ \\
&\gamma\sum_{j,y} e^{\lambda.G(x_j,h_j,y)}\Big(e^{\Delta\lambda.G(x_j,h_j,y)}-1\Big)\leq \\
&\sum_{i,h,y} q_\lambda(h,y|x_i)\Big(\frac{\sum_k g_k e^{\Delta\lambda s_k(x_i,h,y)C}}{C}+w_{x_i,h,y}-1\Big)+ \\
&\gamma\sum_{j,y} q_\lambda(y|x_j,h_j)\Big(\frac{\sum_k g_k e^{\Delta\lambda s_k(x_j,h_j,y)C}}{C}+w_{x_j,h_j,y}-1\Big) \\
&:=\mathcal{A}(\lambda,\Delta\lambda)
\end{aligned}$$

where $w_{x,y,h}=1-\sum_k\frac{|g_k(x,h,y)|}{C}$, $G(x,h,y)$ is a vector built from $g_k(x,h,y)$, and $s_k(x,h,y)$ is the sign of $g_k(x,h,y)$. We find the stationary point of the auxiliary function $\mathcal{A}(\lambda,\Delta\lambda)$ with respect to $\Delta\lambda_k$ by taking the derivative and setting it to zero, which gives us the updating rules. The sequential updates can also be derived similarly.

Log loss

The objective is to minimize the objective function $-\mathcal{L}(\lambda+\Delta\lambda)+\mathcal{L}(\lambda)$. First we find an upper-bound on the objective function:

$$\begin{aligned}
&\mathcal{L}(\lambda)-\mathcal{L}(\lambda+\Delta\lambda)= \\
&\sum_i\log\sum_{y,h}e^{\lambda+\Delta\lambda\cdot G(x_i,h,y)}-\log\sum_{y,h}e^{\lambda\cdot G(x_i,h,y)}- \\
&\gamma\sum_j\log\sum_y e^{\lambda+\Delta\lambda\cdot G(x_j,h_j,y)}-\log\sum_y e^{\lambda\cdot G(x_j,h_j,y)}= \\
&\sum_i\log\sum_{y,h}p_\lambda(h,y|x)e^{\Delta\lambda\cdot G(x_i,h,y)}+ \\
&\gamma\sum_j\log\sum_y p_\lambda(y|x_j,h_j)e^{\Delta\lambda\cdot G(x_j,h_j,y)}\leq \\
&\sum_i\sum_{y,h}p_\lambda(h,y|x)e^{\Delta\lambda\cdot G(x_i,h,y)} \\
&+\gamma\sum_j\sum_y p_\lambda(y|x_j,h_j)e^{\Delta\lambda\cdot G(x_j,h_j,y)}
\end{aligned}$$

The inequality holds because $\log x\leq x$. The last expression can be upper-bounded again (using a similar technique used for exponential loss), and the resultant upper-bound will be the auxiliary function. It can be shown that the update rules are the same to unnormalized model, but the difference is to use $p_\lambda(\cdot)$ rather than $q_\lambda(\cdot)$. The update rules for sequential updates can be derived similarly.

Grassmann Discriminant Analysis: a Unifying View on Subspace-Based Learning

Jihun Hamm JHHAM@SEAS.UPENN.EDU
Daniel D. Lee DDLEE@SEAS.UPENN.EDU
GRASP Laboratory, University of Pennsylvania, Philadelphia, PA 19104 USA

Abstract

In this paper we propose a discriminant learning framework for problems in which data consist of linear subspaces instead of vectors. By treating subspaces as basic elements, we can make learning algorithms adapt naturally to the problems with linear invariant structures. We propose a unifying view on the subspace-based learning method by formulating the problems on the Grassmann manifold, which is the set of fixed-dimensional linear subspaces of a Euclidean space. Previous methods on the problem typically adopt an inconsistent strategy: feature extraction is performed in the *Euclidean* space while *non-Euclidean* distances are used. In our approach, we treat each subspace as a point in the Grassmann space, and perform feature extraction and classification in the same space. We show feasibility of the approach by using the Grassmann kernel functions such as the Projection kernel and the Binet-Cauchy kernel. Experiments with real image databases show that the proposed method performs well compared with state-of-the-art algorithms.

1. Introduction

We often encounter learning problems in which the basic elements of the data are *sets of vectors* instead of vectors. Suppose we want to recognize a person from multiple pictures of the individual, taken from different angles, under different illumination or at different places. When comparing such sets of image vectors, we are free to define the similarity between sets based on the similarity between image vectors (Shakhnarovich et al., 2002; Kondor & Jebara, 2003; Zhou & Chellappa, 2006).

In this paper, we specifically focus on those data that can be modeled as a collection of linear subspaces. In the example above, let's assume that the set of images of a single person is well approximated by a low dimensional subspace (Turk & Pentland, 1991), and the whole data is the collection of such subspaces. The benefits of using subspaces are two-fold: 1) comparing two subspaces is cheaper than comparing two sets directly when those sets are very large, and 2) it is more robust to missing data since the subspace can 'fill-in' the missing pictures. However the advantages come with the challenge of representing and handling the subspaces appropriately.

We approach the subspace-based learning problems by formulating the problems on the Grassmann manifold, the set of fixed-dimensional linear subspaces of a Euclidean space. With this unifying framework we can make analytic comparisons of the various distances of subspaces. In particular, we single out those distances that are induced from the *Grassmann kernels*, which are positive definite kernel functions on the Grassmann space. The Grassmann kernels allow us to use the usual kernel-based algorithms on this unconventional space and to avoid ad hoc approaches to the problem.

We demonstrate the proposed framework by using the Projection metric and the Binet-Cauchy metric and by applying kernel Linear Discriminant Analysis to classification problems with real image databases.

1.1. Contributions of the Paper

Although the Projection metric and the Binet-Cauchy metric were previously used (Chang et al., 2006; Wolf & Shashua, 2003), their potential for subspace-based learning has not been fully explored. In this work, we provide an analytic exposition of the two metrics as examples of the Grassmann kernels, and contrast the

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

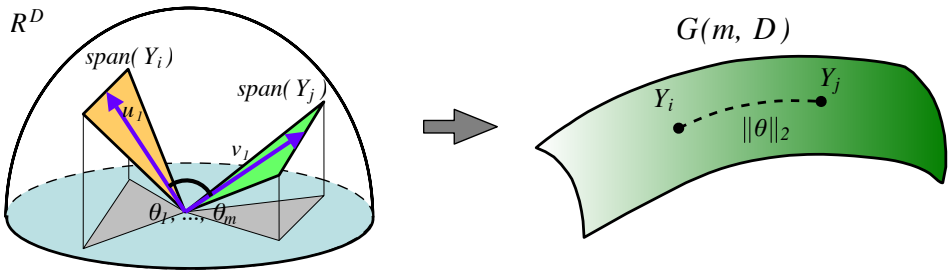

Figure 1. Principal angles and Grassmann distances. Let span(Y_i) and span(Y_j) be two subspaces in the Euclidean space $\mathbb{R}^D$ on the left. The distance between two subspaces span(Y_i) and span(Y_j) can be measured by the principal angles $\boldsymbol{\theta} = [\theta_1, \dots, \theta_m]'$ using the usual innerproduct of vectors. In the Grassmann manifold viewpoint, the subspaces span(Y_i) and span(Y_j) are considered as two points on the manifold $\mathcal{G}(m, D)$, whose Riemannian distance is related to the principal angles by $d(Y_i, Y_j) = \|\boldsymbol{\theta}\|_2$. Various distances can be defined based on the principal angles.

two metrics with other metrics used in the literature.

Several subspace-based classification methods have been previously proposed (Yamaguchi et al., 1998; Sakano, 2000; Fukui & Yamaguchi, 2003; Kim et al., 2007). However, these methods adopt an inconsistent strategy: feature extraction is performed in the *Euclidean* space when *non-Euclidean* distances are used. This inconsistency can result in complications and weak guarantees. In our approach, the feature extraction and the distance measurement are integrated around the Grassmann kernel, resulting in a simpler and better-understood formulation.

The rest of the paper is organized as follows. In Sec. 2 and 3 we introduce the Grassmann manifolds and derive various distances on the space. In Sec. 4 we present a kernel view of the problem and emphasize the advantages of using positive definite metrics. In Sec. 5 we propose the Grassmann Discriminant Analysis and compare it with other subspace-based discrimination methods. In Sec. 6 we test the proposed algorithm for face recognition and object categorization tasks. We conclude in Sec. 7 with a discussion.

2. Grassmann Manifold and Principal Angles

In this section we briefly review the Grassmann manifold and the principal angles.

Definition 1 *The Grassmann manifold $\mathcal{G}(m, D)$ is the set of m-dimensional linear subspaces of the $\mathbb{R}^D$.*

The $\mathcal{G}(m, D)$ is a $m(D-m)$-dimensional compact Riemannian manifold.[1] An element of $\mathcal{G}(m, D)$ can be represented by an orthonormal matrix Y of size D by m such that $Y'Y = I_m$, where I_m is the m by m identity matrix. For example, Y can be the m basis vectors of a set of pictures in $\mathbb{R}^D$. However, the matrix representation of a point in $\mathcal{G}(m, D)$ is not unique: two matrices Y_1 and Y_2 are considered the same if and only if span(Y_1) = span(Y_2), where span(Y) denotes the subspace spanned by the column vectors of Y. Equivalently, span(Y_1) = span(Y_2) if and only if $Y_1 R_1 = Y_2 R_2$ for some $R_1, R_2 \in \mathcal{O}(m)$. With this understanding, we will often use the notation Y when we actually mean its equivalence class span(Y), and use $Y_1 = Y_2$ when we mean span(Y_1) = span(Y_2), for simplicity.

Formally, the Riemannian distance between two subspaces is the length of the shortest geodesic connecting the two points on the Grassmann manifold. However, there is a more intuitive and computationally efficient way of defining the distances using the *principal angles* (Golub & Loan, 1996).

Definition 2 *Let Y_1 and Y_2 be two orthonormal matrices of size D by m. The principal angles $0 \le \theta_1 \le \cdots \le \theta_m \le \pi/2$ between two subspaces* span(Y_1) *and* span(Y_2)*, are defined recursively by*

$$\cos\theta_k = \max_{\boldsymbol{u_k} \in \text{span}(Y_1)} \max_{\boldsymbol{v_k} \in \text{span}(Y_2)} \boldsymbol{u_k}'\boldsymbol{v_k}, \quad \textit{subject to}$$

$$\boldsymbol{u_k}'\boldsymbol{u_k} = 1,\ \boldsymbol{v_k}'\boldsymbol{v_k} = 1,$$

$$\boldsymbol{u_k}'\boldsymbol{u_i} = 0,\ \boldsymbol{v_k}'\boldsymbol{v_i} = 0,\ (i = 1, \dots, k-1).$$

In other words, the first principal angle θ_1 is the smallest angle between all pairs of unit vectors in the first and the second subspaces. The rest of the principal

[1] $\mathcal{G}(m, D)$ can be derived as a quotient space of orthogonal groups $\mathcal{G}(m, D) = \mathcal{O}(D)/\mathcal{O}(m) \times \mathcal{O}(D-m)$, where $\mathcal{O}(m)$ is the group of m by m orthonormal matrices. We refer the readers to (Wong, 1967; Absil et al., 2004) for details on the Riemannian geometry of the space.

angles are similarly defined. It is known (Wong, 1967; Edelman et al., 1999) that the principal angles are related to the geodesic distance by $d_G^2(Y_1, Y_2) = \sum_i \theta_i^2$ (refer to Fig. 1.)

The principal angles can be computed from the Singular Value Decomposition (SVD) of $Y_1'Y_2$,

$$Y_1'Y_2 = U(\cos\Theta)V', \tag{1}$$

where $U = [\boldsymbol{u_1}\ ...\ \boldsymbol{u_m}]$, $V = [\boldsymbol{v_1}\ ...\ \boldsymbol{v_m}]$, and $\cos\Theta$ is the diagonal matrix $\cos\Theta = \mathrm{diag}(\cos\theta_1\ ...\ \cos\theta_m)$. The cosines of the principal angles $\cos\theta_1,\ ...\ , \cos\theta_m$ are also known as *canonical correlations*.

Although the definition can be extended to the cases where Y_1 and Y_2 have different number of columns, we will assume Y_1 and Y_2 have the same size D by m throughout this paper. Also, we will occasionally use $\mathcal{G}$ instead of $\mathcal{G}(m, D)$ for simplicity.

3. Distances for Subspaces

In this paper we use the term *distance* as any assignment of nonnegative values for each pair of points in a space $\mathcal{X}$. A valid *metric* is, however, a distance that satisfies the additional axioms:

Definition 3 *A real-valued function $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is called a metric if*

1. $d(x_1, x_2) \geq 0$,
2. $d(x_1, x_2) = 0$ *if and only if* $x_1 = x_2$,
3. $d(x_1, x_2) = d(x_2, x_1)$,
4. $d(x_1, x_2) + d(x_2, x_3) \leq d(x_1, x_3)$,

for all $x_1, x_2, x_3 \in \mathcal{X}$.

A distance (or a metric) between subspaces $d(Y_1, Y_2)$ has to be invariant under different representations $d(Y_1, Y_2) = d(Y_1R_1, Y_2R_2),\ \ \forall R_1, R_2 \in \mathcal{O}(m)$.

In this section we introduce various distances for subspaces derivable from the principal angles.

3.1. Projection Metric and Binet-Cauchy Metric

We first underline two main distances of this paper.

1. *Projection metric*

$$d_P(Y_1, Y_2) = \left(\sum_{i=1}^{m} \sin^2\theta_i\right)^{1/2} = \left(m - \sum_{i=1}^{m} \cos^2\theta_i\right)^{1/2}. \tag{2}$$

The Projection metric is the 2-norm of the sine of principal angles (Edelman et al., 1999; Wang et al., 2006).

2. *Binet-Cauchy metric*

$$d_{BC}(Y_1, Y_2) = \left(1 - \prod_i \cos^2\theta_i\right)^{1/2}. \tag{3}$$

The Binet-Cauchy metric is defined with the product of canonical correlations (Wolf & Shashua, 2003; Vishwanathan & Smola, 2004).

As the names hint, these two distances are in fact valid metrics satisfying Def. 3. The proofs are deferred until Sec. 4.

3.2. Other Distances in the Literature

We describe a few other distances used in the literature. The principal angles are the keys that relate these distances.

1. *Max Correlation*

$$d_{\mathrm{Max}}(Y_1, Y_2) = \left(1 - \cos^2\theta_1\right)^{1/2} = \sin\theta_1. \tag{4}$$

The max correlation is a distance based on only the largest canonical correlation $\cos\theta_1$ (or the smallest principal angle θ_1). This max correlation was used in previous works (Yamaguchi et al., 1998; Sakano, 2000; Fukui & Yamaguchi, 2003).

2. *Min Correlation*

$$d_{\mathrm{Min}}(Y_1, Y_2) = \left(1 - \cos^2\theta_m\right)^{1/2} = \sin\theta_m. \tag{5}$$

The min correlation is defined similarly to the max correlation. However, the min correlation is more closely related to the Projection metric: we can rewrite the Projection metric as $d_P = 2^{-1/2}\ \|Y_1Y_1' - Y_2Y_2'\|_F$ and the min correlation as $d_{\mathrm{Min}} = \|Y_1Y_1' - Y_2Y_2'\|_2$.

3. *Procrustes metric*

$$d_{CF}(Y_1, Y_2) = 2\left(\sum_{i=1}^{m} \sin^2(\theta_i/2)\right)^{1/2}. \tag{6}$$

The Procrustes metric is the minimum distance between different representations of two subspaces $\mathrm{span}(Y_1)$ and $\mathrm{span}(Y_2)$: (Chikuse, 2003)

$$d_{CF} = \min_{R_1, R_2 \in \mathcal{O}(m)} \|Y_1R_1 - Y_2R_2\|_F = \|Y_1U - Y_2V\|_F,$$

where U and V are from (1). By definition, the distance is invariant of the choice of the

bases of $\text{span}(Y_1)$ and $\text{span}(Y_2)$. The Procrustes metric is also called chordal distance (Edelman et al., 1999). We can similarly define the minimum distance using other matrix norms such as $d_{C2}(Y_1, Y_2) = \|Y_1U - Y_2V\|_2 = 2\sin(\theta_m/2)$.

3.3. Which Distance to Use?

The choice of the best distance for a classification task depends on a few factors. The first factor is the distribution of data. Since the distances are defined with particular combinations of the principal angles, the best distance depends highly on the probability distribution of the principal angles of the given data. For example, d_{Max} uses the smallest principal angle θ_1 only, and may be robust when the data are noisy. On the other hand, when all subspaces are sharply concentrated on one point, d_{Max} will be close to zero for most of the data. In this case, d_{Min} may be more discriminative. The Projection metric d_P, which uses all the principal angles, will show intermediate characteristics between the two distances. Similar arguments can be made for the Procrustes metrics d_{CF} and d_{C2}, which use all angles and the largest angle only, respectively.

The second criterion for choosing the distance, is the degree of structure in the distance. Without any structure a distance can be used only with a simple K-Nearest Neighbor (K-NN) algorithm for classification. When a distance have an extra structure such as triangle inequality, for example, we can speed up the nearest neighbor searches by estimating lower and upper limits of unknown distances (Faragó et al., 1993). From this point of view, the max correlation is not a metric and may not be used with more sophisticated algorithms. On the other hand, the Min Correlation and the Procrustes metrics are valid metrics[2].

The most structured metrics are those which are induced from a positive definite kernel. Among the metrics mentioned so far, only the Projection metric and the Binet-Cauchy metric belong to this class. The proof and the consequences of positive definiteness are the main topics of the next section.

4. Kernel Functions for Subspaces

We have defined a valid metric on Grassmann manifolds. The next question is whether we can define a kernel function compatible with the metric. For this purpose let's recall a few definitions. Let $\mathcal{X}$ be any set, and $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a symmetric real-valued function $k(x_i, x_j) = k(x_j, x_i)$ for all $x_i, x_j \in \mathcal{X}$.

Definition 4 *A real symmetric function is a (resp. conditionally) positive definite kernel function, if* $\sum_{i,j} c_i c_j k(x_i, x_j) \geq 0$, *for all* $x_1, ..., x_n (x_i \in \mathcal{X})$ *and* $c_1, ..., c_n (c_i \in \mathbb{R})$ *for any* $n \in \mathbb{N}$. *(resp. for all* $c_1, ..., c_n (c_i \in \mathbb{R})$ *such that* $\sum_{i=1}^n c_i = 0$.*)*

In this paper we are interested in the kernel functions on the Grassmann space.

Definition 5 *A Grassmann kernel function is a positive definite kernel function on* $\mathcal{G}$.

In the following we show that the Projection metric and the Binet-Cauchy are induced from the Grassmann kernels.

4.1. Projection Metric

The Projection metric can be understood by associating a point $\text{span}(Y) \in \mathcal{G}$ with its projection matrix YY' by an embedding:

$$\Psi_P : \mathcal{G}(m, D) \to \mathbb{R}^{D \times D}, \quad \text{span}(Y) \mapsto YY'. \tag{7}$$

The image $\Psi_P(\mathcal{G}(m, D))$ is the set of rank-m orthogonal projection matrices. This map is in fact an isometric embedding (Chikuse, 2003) and the projection metric is simply a Euclidean distance in $\mathbb{R}^{D \times D}$. The corresponding innerproduct of the space is $\text{tr}\left[(Y_1Y_1')(Y_2Y_2')\right] = \|Y_1'Y_2\|_F^2$, and therefore

Proposition 1 *The Projection kernel*

$$k_P(Y_1, Y_2) = \|Y_1'Y_2\|_F^2 \tag{8}$$

is a Grassmann kernel.

Proof The kernel is well-defined because $k_P(Y_1, Y_2) = k_P(Y_1R_1, Y_2R_2)$ for any $R_1, R_2 \in \mathcal{O}(m)$. The positive definiteness follows from the properties of the Frobenius norm. For all $Y_1, ..., Y_n (Y_i \in \mathcal{G})$ and $c_1, ..., c_n (c_i \in \mathbb{R})$ for any $n \in \mathbb{N}$, we have

$$\begin{aligned} \sum_{ij} c_i c_j \|Y_i'Y_j\|_F^2 &= \sum_{ij} c_i c_j \text{tr}(Y_iY_i'Y_jY_j') \\ = \text{tr}(\sum_i c_i Y_iY_i')^2 &= \|\sum_i c_i Y_iY_i'\|_F^2 \geq 0. \quad \blacksquare \end{aligned}$$

We can generate a family of kernels from the Projection kernel. For example, the square-root $\|Y_i'Y_j\|_F$ is also a positive definite kernel.

[2]The metric properties follow from the properties of matrix 2-norm and F-norm. To check the conditions in Def. 3 for Procrustes we use the equality $\min_{R_1,R_2} \|Y_1R_1 - Y_2R_2\|_{2,F} = \min_{R_3} \|Y_1 - Y_2R_3\|_{2,F}$ for $R_1, R_2, R_3 \in \mathcal{O}(m)$.

4.2. Binet-Cauchy Metric

The Binet-Cauchy metric can also be understood from an embedding. Let s be a subset of $\{1, ..., D\}$ with m elements $s = \{r_1, ..., r_m\}$, and $Y^{(s)}$ be the $m \times m$ matrix whose rows are the $r_1, \ ... \ , r_m$-th rows of Y. If $s_1, s_2, ..., s_n$ are all such choices of the subset s ordered lexicographically, then the Binet-Cauchy embedding is defined as

$$\Psi_{BC} : \mathcal{G}(m, D) \to \mathbb{R}^n, \quad Y \mapsto \left(\det Y^{(s_1)}, ..., \det Y^{(s_n)} \right), \tag{9}$$

where $n = {}_D C_m$ is the number of choosing m rows out of D rows. The natural innerproduct in this case is $\sum_{r=1}^{n} \det Y_1^{(s_i)} \det Y_2^{(s_i)}$.

Proposition 2 *The Binet-Cauchy kernel*

$$k_{BC}(Y_1, Y_2) = (\det Y_1' Y_2)^2 = \det Y_1' Y_2 Y_2' Y_1 \tag{10}$$

is a Grassmann kernel.

Proof First, the kernel is well-defined because $k_{BC}(Y_1, Y_2) = k_{BC}(Y_1 R_1, Y_2 R_2)$ for any $R_1, R_2 \in \mathcal{O}(m)$. To show that k_{BC} is positive definite it suffices to show that $k(Y_1, Y_2) = \det Y_1' Y_2$ is positive definite. From the Binet-Cauchy identity, we have

$$\det Y_1' Y_2 = \sum_s \det Y_1^{(s)} \det Y_2^{(s)}.$$

Therefore, for all $Y_1, ..., Y_n (Y_i \in \mathcal{G})$ and $c_1, ..., c_n (c_i \in \mathbb{R})$ for any $n \in \mathbb{N}$, we have

$$\begin{aligned} \sum_{ij} c_i c_j \det Y_i' Y_j &= \sum_{ij} c_i c_j \sum_s \det Y_i^{(s)} \det Y_j^{(s)} \\ &= \sum_s \left(\sum_i c_i \det Y_i^{(s)} \right)^2 \geq 0. \end{aligned}$$ ∎

We can also generate another family of kernels from the Binet-Cauchy kernel. Note that although $\det Y_1' Y_2$ is a Grassmann kernel we prefer using $k_{BC}(Y_1, Y_2) = \det(Y_1' Y_2)^2$, since it is directly related to principal angles $\det(Y_1' Y_2)^2 = \prod \cos^2 \theta_i$, whereas $\det Y_1' Y_2 \neq \prod \cos \theta_i$ in general.[3] Another variant $\arcsin k_{BC}(Y_1, Y_2)$ is also a positive definite kernel[4] and its induced metric $d = (\arccos(\det Y_1' Y_2))^{1/2}$ is a conditionally positive definite metric.

4.3. Indefinite Kernels from Other Metrics

Since the Projection metric and the Binet-Cauchy metric are derived from positive definite kernels, all the kernel-based algorithms for Hilbert spaces are at our disposal. In contrast, other metrics in the previous sections are not associated with any Grassmann kernel. To show this we can use the following result (Schoenberg, 1938; Hein et al., 2005):

Proposition 3 *A metric d is induced from a positive definite kernel if and only if*

$$\hat{k}(x_1, x_2) = -d^2(x_1, x_2)/2, \quad x_1, x_2 \in \mathcal{X} \tag{11}$$

is conditionally positive definite.

The proposition allows us to show a metric's non-positive definiteness by constructing an indefinite kernel matrix from (11) as a counterexample.

There have been efforts to use indefinite kernels for learning (Ong et al., 2004; Haasdonk, 2005), and several heuristics have been proposed to make an indefinite kernel matrix to a positive definite matrix (Pekalska et al., 2002). However, we do not advocate the use of the heuristics since they change the geometry of the original data.

5. Grassmann Discriminant Analysis

In this section we give an example of the Discriminant Analysis on Grassmann space by using kernel LDA with the Grassmann kernels.

5.1. Linear Discriminant Analysis

The Linear Discriminant Analysis (LDA) (Fukunaga, 1990), followed by a K-NN classifier, has been successfully used for classification.

Let $\{\boldsymbol{x_1}, ..., \boldsymbol{x_N}\}$ be the data vectors and $\{y_1, ..., y_N\}$ be the class labels $y_i \in \{1, ..., C\}$. Without loss of generality we assume the data are ordered according to the class labels: $1 = y_1 \leq y_2 \leq ... \leq y_N = C$. Each class c has N_c number of samples.

Let $\boldsymbol{\mu_c} = 1/N_c \sum_{\{i|y_i=c\}} \boldsymbol{x_i}$ be the mean of class c, and $\boldsymbol{\mu} = 1/N \sum_i \boldsymbol{x_i}$ be the overall mean. LDA searches for the discriminant direction $\boldsymbol{w}$ which maximizes the Rayleigh quotient $L(\boldsymbol{w}) = \boldsymbol{w}' S_b \boldsymbol{w} / \boldsymbol{w}' S_w \boldsymbol{w}$ where S_b and S_w are the between-class and within-class covariance matrices respectively:

$$\begin{aligned} S_b &= \frac{1}{N} \sum_{c=1}^{C} N_c (\boldsymbol{\mu_c} - \boldsymbol{\mu})(\boldsymbol{\mu_c} - \boldsymbol{\mu})' \\ S_w &= \frac{1}{N} \sum_{c=1}^{C} \sum_{\{i|y_i=c\}} (\boldsymbol{x_i} - \boldsymbol{\mu_c})(\boldsymbol{x_i} - \boldsymbol{\mu_c})' \end{aligned}$$

The optimal $\boldsymbol{w}$ is obtained from the largest eigenvector of $S_w^{-1} S_b$. Since $S_w^{-1} S_b$ has rank $C - 1$, there are

[3] $\det Y_1' Y_2$ can be negative whereas $\prod \cos \theta_i$, the product of singular values, is nonnegative by definition.

[4] Theorem 4.18 and 4.19 (Schölkopf & Smola, 2001).

$C-1$-number of local optima $W = \{\boldsymbol{w_1}, ..., \boldsymbol{w_{C-1}}\}$. By projecting data onto the space spanned by W, we achieve dimensionality reduction and feature extraction of data onto the most discriminant subspace.

5.2. Kernel LDA with Grassmann Kernels

Kernel LDA can be formulated by using the kernel trick as follows. Let $\boldsymbol{\phi} : \mathcal{G} \to \mathcal{H}$ be the feature map, and $\Phi = [\boldsymbol{\phi_1}...\boldsymbol{\phi_N}]$ be the feature matrix of the training points. Assuming w is a linear combination of the those feature vectors, $\boldsymbol{w} = \Phi\boldsymbol{\alpha}$, we can rewrite the Rayleigh quotient in terms of $\boldsymbol{\alpha}$ as

$$L(\boldsymbol{\alpha}) = \frac{\boldsymbol{\alpha}'\Phi' S_B \Phi\boldsymbol{\alpha}}{\boldsymbol{\alpha}'\Phi' S_W \Phi\boldsymbol{\alpha}} = \frac{\boldsymbol{\alpha}' K(V - \mathbf{1}_N\mathbf{1}_N'/N)K\boldsymbol{\alpha}}{\boldsymbol{\alpha}'(K(I_N - V)K + \sigma^2 I_N)\boldsymbol{\alpha}}, \tag{12}$$

where K is the kernel matrix, $\mathbf{1}_N$ is a uniform vector $[1\ ...\ 1]'$ of length N, V is a block-diagonal matrix whose c-th block is the uniform matrix $\mathbf{1}_{N_c}\mathbf{1}_{N_c}'/N_c$, and $\sigma^2 I_N$ is a regularizer for making the computation stable. Similarly to LDA, the set of optimal $\boldsymbol{\alpha}$'s are computed from the eigenvectors.

The procedures for using kernel LDA with the Grassmann kernels are summarized below:

Assume the D by m orthonormal bases $\{Y_i\}$ are already computed from the SVD of sets in the data.

Training:

1. *Compute the matrix $[K_{\text{train}}]_{ij} = k_P(Y_i, Y_j)$ or $k_{BC}(Y_i, Y_j)$ for all Y_i, Y_j in the training set.*
2. *Solve $\max_{\boldsymbol{\alpha}} L(\boldsymbol{\alpha})$ by eigen-decomposition.*
3. *Compute the $(C-1)$-dimensional coefficients $F_{\text{train}} = \boldsymbol{\alpha}' K_{\text{train}}$.*

Testing:

1. *Compute the matrix $[K_{\text{test}}]_{ij} = k_P(Y_i, Y_j)$ or $k_{BC}(Y_i, Y_j)$ for all Y_i in training set and Y_j in the test set.*
2. *Compute the $(C-1)$-dim coefficients $F_{\text{test}} = \boldsymbol{\alpha}' K_{\text{test}}$.*
3. *Perform 1-NN classification from the Euclidean distance between F_{train} and F_{test}.*

Another way of applying LDA to subspaces is to use the Projection embedding Ψ_P (7) or the Binet-Cauchy embedding Ψ_{BC} (9) directly. A subspace is represented by a D by D matrix in the former, or by a vector of length $n = {}_D C_m$ in the latter. However, using these embeddings to compute S_b or S_w is a waste of computation and storage resources when D is large.

5.3. Other Subspace-Based Algorithms

5.3.1. Mutual Subspace Method (MSM)

The original MSM (Yamaguchi et al., 1998) performs simple 1-NN classification with d_{Max} with no feature extraction. The method can be extended to any distance described in the paper. There are attempts to use kernels for MSM (Sakano, 2000). However, the kernel is used only to represent data in the original space, and the algorithm is still a 1-NN classification.

5.3.2. Constrained MSM

Constrained MSM (Fukui & Yamaguchi, 2003) is a technique that applies dimensionality reduction to bases of the subspaces in the original space. Let $G = \sum_i Y_i Y_i'$ be the sum of the projection matrices and $\{\boldsymbol{v_1}, ..., \boldsymbol{v_D}\}$ be the eigenvectors corresponding to the eigenvalues $\{\lambda_1 \leq ... \leq \lambda_D\}$ of G. The authors claim that the first few eigenvectors $\boldsymbol{v_1}, ..., \boldsymbol{v_d}$ of G are more discriminative than the later eigenvectors, and they suggest projecting the basis vectors of each subspace Y_1 onto the span$(\boldsymbol{v_1}, ..., \boldsymbol{v_l})$, followed by normalization and orthonormalization. However these procedure lack justifications, as well as a clear criterion for choosing the dimension d, on which the result crucially depends from our experience.

5.3.3. Discriminant Analysis of Canonical Correlations (DCC)

DCC (Kim et al., 2007) can be understood as a nonparametric version of linear discrimination analysis using the Procrustes metric (6). The algorithm finds the discriminating direction $\boldsymbol{w}$ which maximize the ratio $L(\boldsymbol{w}) = \boldsymbol{w}' S_B \boldsymbol{w} / \boldsymbol{w}' S_w \boldsymbol{w}$, where S_b and S_w are the nonparametric between-class and within-class 'covariance' matrices:

$$\begin{aligned} S_b &= \sum_i \sum_{j \in B_i} (Y_i U - Y_j V)(Y_i U - Y_j V)' \\ S_w &= \sum_i \sum_{j \in W_i} (Y_i U - Y_j V)(Y_i U - Y_j V)', \end{aligned}$$

where U and V are from (1). Recall that $\text{tr}(Y_i U - Y_j V)(Y_i U - Y_j V)' = \|Y_i U - Y_j V\|_F^2$ is the squared Procrustes metric. However, unlike our method, S_b and S_w do not admit a geometric interpretation as true covariance matrices, and cannot be kernelized either. A main disadvantage of the DCC is that the algorithm iterates the two stages of 1) maximizing the ratio $L(\mathbf{w})$ and of 2) computing S_b and S_w, which results in computational overheads and more parame-

ters to be determined. This reflects the complication of treating the problem in a Euclidean space with a non-Euclidean distance.

6. Experiments

In this section we test the Grassmann Discriminant Analysis for 1) a face recognition task and 2) an object categorization task with real image databases.

6.1. Algorithms

We use the following six methods for feature extraction together with an 1-NN classifier.

1) GDA1 (with Projection kernel), 2) GDA2 (with Binet-Cauchy kernel), 3) Min dist , 4) MSM, 5) cMSM, and 6) DCC.

For GDA1 and GDA2, the optimal values of σ are found by scanning through a range of values. The results do not seem to vary much as long as σ is small enough. The Min dist is a simple pairwise distance which is not subspace-based. If Y_i and Y_j are two sets of basis vectors: $Y_i = \{\boldsymbol{y_{i1}}, ..., \boldsymbol{y_{im_i}}\}$ and $Y_j = \{\boldsymbol{y_{j1}}, ..., \boldsymbol{y_{jm_j}}\}$, then $d_{\mathrm{Mindist}}(Y_i, Y_j) = \min_{k,l} \|\boldsymbol{y_{ik}} - \boldsymbol{y_{jl}}\|_2$. For cMSM and DCC, the optimal dimension l is found by exhaustive searching. For DCC, we have used two nearest-neighbors for B_i and W_i in Sec. 5.3.3. Since the S_w and S_b are likely to be rank deficient, we first reduced the dimension of the data to $N - C$ using PCA as recommended. Each optimization is iterated 5 times.

6.2. Testing Illumination-Invariance with Yale Face Database

The Yale face database and the Extended Yale face database (Georghiades et al., 2001) together consist of pictures of 38 subjects with 9 different poses and 45 different lighting conditions. Face regions were cropped from the original pictures, resized to 24×21 pixels ($D = 504$), and normalized to have the same variance. For each subject and each pose, we model the illumination variations by a subspace of the size $m = 1, ..., 5$, spanned by the 1 to 5 largest eigenvectors from SVD. We evaluate the recognition rate of subjects with nine-fold cross validation, holding out one pose of all subjects from the training set and using it for test.

The recognition rates are shown in Fig. 2. The GDA1 outperforms the other methods consistently. The GDA2 also performs well for small m, but performs worse as m becomes large. The rates of the others also seem to decrease as m increases. An interpretation of the observation is that the first few eigenvectors from the data already have enough information and the smaller eigenvectors are spurious for discriminating the subjects.

6.3. Testing Pose-Invariance with ETH-80 Database

The ETH-80 (Leibe & Schiele, 2003) database consists of pictures of 8 object categories ('apple', 'pear', 'tomato', 'cow', 'dog', 'horse', 'cup', 'car'). Each category has 10 objects that belong to the category, and each object is recorded under 41 different poses. Images were resized to 32×32 pixels ($D = 1024$) and normalized to have the same variance. For each category and each object, we model the pose variations by a subspace of the size $m = 1, ..., 5$, spanned by the 1 to 5 largest eigenvectors from SVD. We evaluate the classification rate of the categories with ten-fold cross validation, holding out one object instance of each category from the training set and using it for test.

The recognition rates are also summarized in Fig. 2. The GDA1 also outperforms the other methods most of the time, but the cMSM performs better than GDA2 as m increases. The rates seem to peak around $m = 4$ and then decrease as m increases. This results is consistent with the observation that the eigenvalues from this database decrease more gradually than the eigenvalues from the Yale face database.

7. Conclusion

In this paper we have proposed a Grassmann framework for problem in which data consist of subspaces. By using the Projection metric and the Binet-Cauchy metric, which are derived from the Grassmann kernels, we were able to apply kernel methods such as kernel LDA to subspace data. In addition to having theoretically sound grounds, the proposed method also outperformed state-of-the-art methods in two experiments with real data. As a future work, we are pursuing a better understanding of probabilistic distributions on the Grassmann manifold.

Abstract

In this paper we show how common speech recognition training criteria such as the Minimum Phone Error criterion or the Maximum Mutual Information criterion can be extended to incorporate a margin term. Different margin-based training algorithms have been proposed to refine existing training algorithms for general machine learning problems. However, for speech recognition, some special problems have to be addressed and all approaches proposed either lack practical applicability or the inclusion of a margin term enforces significant changes to the underlying model, e.g. the optimization algorithm, the loss function, or the parameterization of the model. In our approach, the conventional training criteria are modified to incorporate a margin term. This allows us to do large-margin training in speech recognition using the same efficient algorithms for accumulation and optimization and to use the same software as for conventional discriminative training. We show that the proposed criteria are equivalent to Support Vector Machines with suitable smooth loss functions, approximating the non-smooth hinge loss function or the hard error (e.g. phone error). Experimental results are given for two different tasks: the rather simple digit string recognition task Sietill which severely suffers from overfitting and the large vocabulary European Parliament Plenary Sessions English task which is supposed to be dominated by the risk and the generalization does not seem to be such an issue.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

1. Introduction

A central issue in machine learning is the robust estimation of the model parameters Λ with good generalization ability, based on a finite number of observations. An interesting result from information theory is the PAC bound on the expected risk (Vapnik, 1995). The VC dimension plays an important role in this inequality and is a direct measure for the generalization ability. This bound is general in the sense that it does neither depend on the underlying probability distribution nor on the specific risk function. Furthermore, the bound implies that in general, the consideration of the empirical risk alone is suboptimal (Vapnik, 1995), see Tab. 1. Assuming that the features are in a sphere, the VC dimension of gap-tolerant classifiers is bounded above by an expression which is inversely proportional to the margin, leading to large-margin classifiers (Jebara, 2002).

These theoretical results are the main motivation for Support Vector Machines (SVMs) (Vapnik, 1995), M-SVMs (Weston & Watkins, 1999), or Hidden Markov SVMs (Altun et al., 2003) which have been successfully used for many applications in pattern recognition. The direct application of SVMs in Automatic Speech Recognition (ASR) has not been successful so far. This might be because they are not sufficiently flexible regarding: 1) the choice of the loss function, conventional criteria in ASR are Maximum Mutual Information (MMI), Minimum Classification Error (MCE), or Minimum Phone Error (MPE) which is probably the criterion of choice in ASR; 2) they are unable to cope with the immense amount of data used to train state-of-the-art ASR systems, which are commonly trained on more than 100 hours of speech (>30,000,000 observation vectors). Another problem might be the combinatorial number of classes (number of possible word sequences). Stimulated by the success of SVMs, different margin-based training algorithms have been proposed for ASR, e.g. (Yu et al., 2007; Yin & Jiang, 2007; Sha & Saul, 2007; Li et al., 2007). Although the reported results for these approaches are very promising, the approaches have some shortcomings in particular for large-scale appli-

Table 1. Relative importance of loss and margin terms under different conditions.

Loss	vs.	Margin
infinite data	↔	sparse data
many training errors	↔	few training errors

cations. The approach proposed in (Yu et al., 2007) comes closest to ours but uses MCE on N-best lists without regularization. In most state-of-the-art large-scale ASR systems, however, MPE in combination with strong regularization, i.e., i-smoothing has been established to be the criterion of choice (Povey & Woodland, 2002). In (Yin & Jiang, 2007; Sha & Saul, 2007; Li et al., 2007) not only the margin term is introduced, but the approaches use different optimization algorithms, different loss functions, or different model parameterizations which makes it difficult to evaluate the effect of the margin term in these approaches. Furthermore, none of these papers reports experimental results for competitive large vocabulary systems whose behavior in terms of generalization ability and relative improvements of performance often is different to systems using suboptimal models or for "simple" small vocabulary tasks (e.g. TIDIGITS and TIMIT). A large amount of training data and a relatively large number of training errors are typical of such large vocabulary systems. From this observation, we expect that the margin term has only little impact on the performance of such systems, cf. Tab. 1. In this work, we pursue a similar approach as in (Zhang et al., 2003) where the standard M-SVM with the hinge loss function is approximated by modified logistic regression. To the best of our knowledge, this approach, is computationally unfeasible in ASR because of the pairwise treatment of the correct and all the competing word sequences. To avoid the exponential complexity, our approximations are based on the Hidden Markov SVM proposed in (Altun et al., 2003). Formally similar results can be found in (Jebara, 2002), which are derived from probabilistic reasoning. Using the smoothed segment error of MCE in combination with $N-$best lists and without regularization, the margin-based MCE criterion proposed in (Yu et al., 2007) is recovered as a special instance of our approach.

The remainder of this paper is organized as follows: Sec. 2 reviews SVMs in a notation suitable for our discussion. Approximations to the SVMs with different loss functions, resembling the MMI and MPE criterion are proposed in Sec. 3 and extended to ASR in Sec. 4. Experimental results using these modified criteria are presented for the Sietill and the European Parliament Plenary Sessions (EPPS) English ASR tasks, cf. Sec.6. The results of the latter task give an idea of the importance of the margin in a state-of-the-art large vocabulary system. Finally, Sec. 5 shows that the transducer-based implementation of MMI and MPE differs merely in the choice of the semiring. This section may be skipped at the first reading.

2. Support Vector Machines (SVMs)

According to (Altun et al., 2003), the optimization problem of SVMs for C classes, N observation pairs (x_n, c_n), and feature functions $f_i(x, c)$ can be formulated as follows

$$\hat{\Lambda} = \arg\min_{\Lambda} \left\{ \frac{1}{2}\|\Lambda\|^2 + \frac{J}{N}\sum_{n=1}^{N} l(c_n; d_{n1}, \ldots, d_{nC}) \right\} \quad (1)$$

with $d_{nc} = \sum_i \lambda_i (f_i(x_n, c_n) - f_i(x_n, c))$, or more compactly in vector notation $d_{nc} = \lambda^\top (f(x_n, c_n) - f(x_n, c))$. The empirical constant $J > 0$ is used to balance the margin and the loss terms. The typical loss function of SVMs is the hinge loss function

$$l^{(hinge)}(c_n; d_{n1}, \ldots, d_{nC}) = \max_{c \neq c_n} \{\max\{-d_{nc} + 1, 0\}\}. \quad (2)$$

This effectively reduces the multiclass problem to a two-class problem ("correct" vs. "recognized"). Ideally, the loss function is the margin error

$$l^{(error)}(c_n; d_{n1}, \ldots, d_{nC}) = E[\hat{c}_n | c_n], \quad (3)$$

which in the simplest case counts the errors of the observations, $1 - \delta(\hat{c}_n, c_n)$. For ASR, however, we choose string-based error measures like the phone error. In this loss function, $\hat{c}_n$ is in fact a function of $(c_n; d_{n1}, \ldots, d_{nC})$ and denotes the recognized class (with margin)

$$\hat{c}_n = \begin{cases} \arg\min_{c \neq c_n} \{d_{nc}\} & \text{if } \exists c \neq c_n : d_{nc} < 1 \\ c_n & \text{otherwise.} \end{cases} \quad (4)$$

Due to the definition of the loss function and in contrast to (Altun et al., 2003), this formulation of SVM does not require the introduction of slack variables ξ_n^c subject to $d_{nc} \geq \xi_n^c + 1$ and $\xi_n^c \geq 0$ for all $c \neq c_n$ and n. The resulting optimization problem is non-smooth, but it is only used for theoretical purposes whereas the experiments are carried out with smoothed loss functions as it is common in ASR. In contrast to the multiclass SVM proposed by (Weston & Watkins, 1999), this definition allows for efficient calculation of the sum over the classes in ASR (cf. Sec. 5).

In (Taskar et al., 2003), the size of the margin is set to be proportional to the length of the sequence, e.g. the number of correct symbols. For ASR, due to the additional alignment problem, this is extended such that the margin between two sequences is set to the associated sequence/string accuracy. Note that this extension is reasonable because it guarantees consistency with the above SVM in case of i.i.d. sequences, see Sec. 4 for further details.

Finally, the task of testing consists of finding the class with the highest score

$$\hat{c}(x) = \arg\max_{c} \left\{ \lambda^\top f(x, c) \right\}, \quad (5)$$

which should not be confused with $\hat{c}_n$ in Eq. (4).

3. SVMs with Smooth Loss Functions

This section provides smooth approximations to the SVM in Eq. (1) for different loss functions. More precisely, the loss function is replaced with a smoothed loss function without breaking the large margin nature of the original SVM. These approximations are identical to modified formulations of the well-known training criteria MMI and MPE for Hidden Conditional Random Fields (HCRFs), which are introduced in the next two subsections. Analogously, a similar result can be derived for (lattice-based) MCE. In contrast to (most) other margin-based approaches, these approximations have the advantage that the effect of the margin can be evaluated directly without changing the parameterization of the model, the loss function, or the optimization algorithm.

Keep in mind that the modifications concern only the training, i.e., the calculation of the probabilities in the search remains unchanged:

$$p_\Lambda(c|x) = \frac{\exp(\lambda^\top f(x,c))}{\sum_{c'} \exp(\lambda^\top f(x,c'))}.$$

The resulting decision rule is equivalent to the decision rule in Eq. (5) for SVMs because monotone transformations of the discriminant function do not change the decision rule.

In the next two subsections, we define modified criteria based on the conventional MMI and MPE criteria and show the relationship with SVMs.

3.1. Modified Maximum Mutual Information (MMI)

In ASR, MMI commonly refers to the maximum likelihood (ML) for the class posteriors. We define a modified MMI criterion for log-linear HCRFs [1]

$$\mathcal{F}_\gamma^{(MMI)}(\Lambda) = \frac{1}{2}\|\Lambda\|^2 - \frac{J}{N}\sum_{n=1}^{N}\frac{1}{\gamma}\log\left(\frac{\exp(\gamma\,(\lambda^\top f(x_n,c_n)-1))}{\sum_c \exp(\gamma\,(\lambda^\top f(x_n,c)-\delta(c,c_n)))}\right). \quad (6)$$

See Fig. 1 for a comparison of the hinge loss function, MMI, and modified MMI. The approximation level γ is an additional parameter to control the smoothness of the criterion. The regularization constant is proportional to $\frac{1}{J}$. The major difference to the standard MMI formulation (including L_2-norm regularization) is the additional margin parameter which is non-zero only for the correct class c_n. This margin term can be interpreted as an additional observation dependent prior, weakening the true prior (Jebara, 2002).

It can be shown that the objective function $\mathcal{F}_\gamma^{(MMI)}(\Lambda)$ converges pointwise to the SVM optimization problem using the hinge loss function in Eq. (2) for $\gamma \to \infty$, similar to (Zhang et al., 2003). In other words, $\mathcal{F}_\gamma^{(MMI)}(\Lambda)$ is a smooth approximation to an SVM with hinge loss function, which can be optimized with standard gradient-based optimization techniques. The proof mainly consists of building the limit of the logarithm in Eq. (6):

$$\begin{aligned}
&-\frac{1}{\gamma}\log\left(\frac{\exp(\gamma\,(\lambda^\top f(x_n,c_n)-1))}{\sum_c \exp(\gamma\,(\lambda^\top f(x_n,c)-\delta(c,c_n)))}\right)\\
&=\frac{1}{\gamma}\log\left(1+\sum_{c\neq c_n}\exp(\gamma\,(-d_{nc}+1))\right)\\
&\overset{\gamma\to\infty}{\to}\begin{cases}\max_{c\neq c_n}\{-d_{nc}+1\} & \text{if } \exists c\neq c_n : d_{nc}<1\\ 0 & \text{otherwise.}\end{cases}
\end{aligned}$$

This function can be identified with the hinge loss function in Eq. (2).

We feel that the weak point about the hinge loss in pattern recognition is that it is not the measure used to evaluate the recognition systems eventually. This means that there is some guarantee regarding the generalization for the hinge loss, but *not* the recognition error. Furthermore, it is often unclear how these two quantities are related.

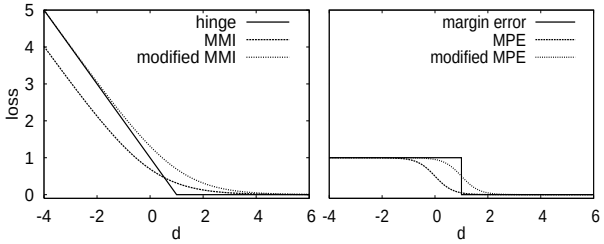

Figure 1. Left: comparison of hinge loss, MMI, and modified MMI, $\gamma = 1$. Right: comparison of margin error loss, MPE, and modified MPE, $\gamma = 3$. In either case $C = 2$, and $d = d_{nc_n}$.

3.2. Modified Minimum Phone Error (MPE)

In contrast to the hinge loss, the recognition error is bounded as illustrated in Fig. 1. Hence, a single observation cannot dominate the objective function. In particular, do not mix up a weighted margin with a weighted error.

We shall show that the modified MPE-like objective function representing a smoothed margin error with L_2-norm regularization,

$$\mathcal{F}_\gamma^{(MPE)}(\Lambda) = \frac{1}{2}\|\Lambda\|^2 + \frac{J}{N}\sum_{n=1}^{N}\sum_c E[c|c_n]\frac{\exp(\gamma\,(\lambda^\top f(x_n,c)-\delta(c,c_n)))}{\sum_{c'}\exp(\gamma\,(\lambda^\top f(x_n,c')-\delta(c',c_n)))}$$

converges to the above SVM optimization problem with a hard and weighted loss function $E[\cdot|\cdot]$ as in Eq. (3), e.g. the phone error. The proof is analogous to the proof for MMI.

[1] The first order features in (Zhang et al., 2003) are a special case of the more general feature functions used here.

The main step is to show that the "posterior probabilities" in $\mathcal{F}_\gamma^{(MPE)}(\Lambda)$ converge to a Kronecker delta such that only a single term contributes to the sum of the empirical risk

$$\begin{aligned}
&\frac{\exp(\gamma\,(\lambda^\top f(x_n, c) - \delta(c, c_n)))}{\sum_{c'} \exp(\gamma\,(\lambda^\top f(x_n, c') - \delta(c', c_n)))} \\
&= \begin{cases} \frac{1}{1+\sum_{c' \neq c_n} \exp(\gamma(-d_{nc'}+1))} & \text{if } c = c_n, \\ \frac{\exp(\gamma(-d_{nc}+1))}{1+\sum_{c' \neq c_n} \exp(\gamma(-d_{nc'}+1))} & \text{otherwise} \end{cases} \\
&\overset{\gamma\to\infty}{\to} \begin{cases} \delta(c, \arg\min_{c \neq c_n} \{d_{nc}\}) & \text{if } \exists c \neq c_n : d_{nc} < 1 \\ \delta(c, c_n) & \text{if } d_{nc_n} > 1 \end{cases} \\
&= \delta(c, \hat{c}_n).
\end{aligned}$$

Note that now we have pointwise convergence almost surely (i.e., everywhere except for points on the decision boundary $d_{nc_n} = 1$ where the loss function is not continuous). As before, $\hat{c}_n$ denotes the recognized class with margin defined in Eq. (4). In summary, we have $\mathcal{F}_\gamma^{(MPE)}(\Lambda) \overset{\gamma\to\infty}{\to} \frac{1}{2}\|\Lambda\|^2 + \frac{J}{N}\sum_{n=1}^N E[\hat{c}_n|c_n]$ which is identical to the SVM optimization problem using the loss function in Eq. (3).

3.3. Optimization

In general, the resulting optimization problems are no longer convex and thus, the optimization might get stuck in local optima. We believe that this problem is inherent in ASR, e.g. due to the time alignment from HMMs. Although it is possible to make the objective function convex by keeping the alignment fixed, the best results on large-scale tasks that are reported in the literature have been obtained by using non-convex objective functions. Finally, the problem of local optima is alleviated by combining the suggested approach with stochastic annealing techniques where the approximation level acts as the temperature.

In fact, the optimization strategy suggested in (Zhang et al., 2003) can be adopted, i.e., find the optimum for a given approximation level and carry out this step iteratively for increasingly finer levels. The optimization can be done with general optimization algorithms, e.g. RProp. The idea of incrementally regulated discriminative margins suggested by (Yu et al., 2007) is along the same lines.

In this work, the approximation level and the margin are chosen beforehand and then kept fixed during the complete optimization. This single step optimization scheme has the advantage that the loss function remains unchanged and that thus, the criterion differs only in the margin term. This approach is reasonable as long as the changes in the initial model are small, e.g. if the discriminative training is initialized with a good ML baseline. This is the typical situation in ASR. Further details and specifics of ASR are discussed in the next section.

4. Automatic Speech Recognition (ASR)

The smooth variants of SVMs introduced in Sec. 3.1 and 3.2 can directly be incorporated into the ASR framework. In this case, the HMM state sequences s_1^T correspond to the classes c. Similar to (Taskar et al., 2003) and (Sha & Saul, 2007), we would like the margin to scale with the length of the speech segments (cf. discussion in Sec. 2). In ASR, a reasonable choice is to set the margin of a sentence to the number of correct phones. More precisely, the simple accuracy $\delta(c, c_n)$ used to represent the margin so far is replaced with the phone accuracy. These approximations directly combine learning theory, HCRFs, and risk-based training of HMMs. Note that Gaussian HMMs (GHMMs) are HCRFs (possibly) with parameter constraints (Heigold et al., 2007).

Typically, MPE is used in combination with the more refined Gaussian regularization centered around Λ_0' (e.g. the maximum likelihood estimate of the generative model), which is comparable with the i-smoothing for GHMMs (Povey & Woodland, 2002). This regularization is combined with the L_2-norm regularization from the SVM

$$J_0^{-1}\|\Lambda\|^2 + J_1^{-1}\|\Lambda - \Lambda_0'\|^2 = J^{-1}\|\Lambda - \Lambda_0\|^2 + \text{const}(\Lambda)$$

with $J^{-1} = J_0^{-1} + J_1^{-1}$ and $\Lambda_0 = \frac{1}{1+\frac{J_1}{J_0}}\Lambda_0'$. Thus, the Gaussian regularization with a properly scaled center Λ_0 (scaling does not change the classification in the maximum approximation) covers the weaker L_2-norm regularization.

Similar to (Heigold et al., 2007), we use n-th order features, e.g. first order features are defined to be $f_{tsd}^{(1st)}(x_1^T, s_1^T) = \delta(s, s_t)x_{td}$. Zeroth and higher order features are defined in a similar fashion. This choice of feature function has the advantage that HCRFs and GHMMs are directly related.

The relationship between SVMs and common training criteria like MMI and MPE allows us to justify some important heuristics typically employed in discriminatively trained ASR systems to achieve good performance: the approximation level γ corresponds to the scaling of the probabilities, i-smoothing is the (refined) regularization term, and the weak unigram language model might be considered an approximation of the margin concept as explained in Sec. 3.1 ("weak prior"). We believe that the frame-based approach proposed to improve the generalization ability is also an attempt to approximate the margin by replacing the context priors (Heigold et al., 2007) by the global relative frequencies.

To apply the existing efficient algorithms, it is important that the margins of the different competing hypotheses can be represented as a weighted transducer sharing the topology with the common lattices, and thus can be integrated into most state-of-the-art systems. This is not always possible in an efficient way for the exact accuracy. Therefore,

approximate accuracies are used. For MPE, an intuitive margin is the approximate phone accuracy (Povey & Woodland, 2002), which is basically the same quantity also used for the loss function[2]. In this case, no additional quantities have to be calculated. The combined acoustic and language model scores are then augmented with these margins by composition. The subsequent steps of the accumulation and estimation remain unchanged. Thus, it is not necessary to modify our transducer-based implementation of the (discriminative) training because the margin can be incorporated by simply configuring an additional composition. The transducer-based implementation also has the advantage that the quantities used for the MMI and MPE accumulation can be represented in terms of *generalized* FB probabilities calculated in *different* semirings. This approach results in the same recursion formulae as used in (Povey & Woodland, 2002), but leads to a unified implementation of the different training criteria. The details on this issue are worked out in the next section.

5. Covariance & Expectation Semiring

In this section, we present an abstraction and generalization of the recursion formulae used for MMI and MPE (Povey & Woodland, 2002). The efficient calculation of the gradient of the objective function is an issue in ASR (and for HCRFs as well) because of the combinatorial number of possible word sequences. The proposed approach unifies these two recursion formulae and extends the speech-specific recursion formula for MPE to HCRFs. As mentioned above, this abstraction is not essential for this work. However, this formalism might be a nice feature of any (probabilistic) transducer library. As an example, it might facilitate the development of more refined training algorithms, e.g. it provides an efficient solution to the unified criterion in (He et al., 2008). The calculation of the gradient under consideration (as probably several other problems in pattern recognition) can be reduced to the calculation of the covariance of two suitably defined random variables, as discussed at the end of this section.

The expectation of the random variable $\mathcal{X}$ w.r.t. the probabilistic transducer $\mathcal{P}$ is defined to be

$$E_{\mathcal{P}}[\mathcal{X}] := \sum_{\pi \in \mathcal{P}} w_{\mathcal{P}}[\pi] w_{\mathcal{X}}[\pi]$$

where $w_{\cdot}[\pi]$ denotes the weight of path π in the respective transducer. The covariance of two (additive) random variables $\mathcal{X}$ and $\mathcal{Y}$ w.r.t. $\mathcal{P}$ is defined to be (with $E_{\mathcal{P}}[\cdot] \equiv E[\cdot]$)

$$\mathrm{Cov}_{\mathcal{P}}(\mathcal{X}, \mathcal{Y}) := \sum_{\pi \in \mathcal{Y}} w_{\mathcal{P}}[\pi] \left(w_{\mathcal{X}}[\pi] - E[\mathcal{X}]\right) \left(w_{\mathcal{Y}}[\pi] - E[\mathcal{Y}]\right).$$

[2] Assume the distance $E[w_1^N, v_1^M]$ between strings w_1^N and v_1^M. Then, the accuracy of string v_1^M given string w_1^N is $A[v_1^M | w_1^N] = N - E[w_1^N, v_1^M]$.

Here, we assume that $\mathcal{P}$, $\mathcal{X}$, and $\mathcal{Y}$ can be represented by acyclic transducers which share the topology, i.e., differ only in the weights. Using these assumptions, we shall show that the covariance can be efficiently calculated by simply exchanging the probability semiring by the expectation semiring in the standard FB algorithm. So, the probability semiring can be used to compute the first order statistics whereas the expectation semiring can be used to compute the second order statistics. It is rather straightforward to define a covariance semiring to calculate third order statistics etc.

We start with introducing the expectation semiring and the abstract definitions which are needed to formulate the propositions.

Expectation semiring. The *expectation semiring* (Eisner, 2001) is a multiplex semiring with weights $(p, v) \in \mathbb{R}^+ \times \mathbb{R}$, and

- $(p_1, v_1) \oplus (p_2, v_2) = (p_1 + p_2, v_1 + v_2)$;
- $(p_1, v_1) \otimes (p_2, v_2) = (p_1 p_2, p_1 v_2 + v_1 p_2)$;
- $\overline{1} = (1, 0)$, $\overline{0} = (0, 0)$.

In addition, the inverse is defined to be $\mathsf{inv}(p, v) = (p^{-1}, -p^{-2}v)$. Observe that the first component corresponds to the probability semiring whereas the second component accounts for the additivity of the random variable. The (partial) path weight of path π is the "product" of the corresponding arc weights $w_{\mathcal{P}}[a]$, $w_{\mathcal{P}}[\pi] = \bigotimes_{a \in \pi} w_{\mathcal{P}}[a]$.

FB potentials. The *forward potential* α_q at the state q of the transducer $\mathcal{P}$ is the sum of the weights of all partial paths π going from the initial state *init* to the state q

$$\alpha_q := \bigoplus_{\pi = (init, q) \in \mathcal{P}} w_{\mathcal{P}}[\pi].$$

These quantities are efficiently calculated by recursion

$$\alpha_{init} = \overline{1} \qquad \alpha_q = \bigoplus_{a = (p, q) \in \mathcal{P}} \alpha_p \otimes w_{\mathcal{P}}[a].$$

The "sum" is over all arcs a of the transducer $\mathcal{P}$ connecting the state p with q. The backward potentials β_q are defined similarly on the transposed $\mathcal{P}$.

Posteriors. The *posterior* transducer $\mathcal{Q}(\mathcal{P})$ associated with the transducer $\mathcal{P}$ has the arc weights

$$w_{\mathcal{Q}(\mathcal{P})}[a] := \left(\bigoplus_{\pi \in \mathcal{P} : a \in \pi} w_{\mathcal{P}}[\pi] \right) \otimes \mathsf{inv}\left(\bigoplus_{\pi \in \mathcal{P}} w_{\mathcal{P}}[\pi] \right).$$

The weight of arc $a = (p, q)$ can be expressed in terms of the above defined forward and backward potentials

$$w_{\mathcal{Q}(\mathcal{P})}[a] = \left(\alpha_p \otimes w_{\mathcal{P}}[a] \otimes \beta_q \right) \otimes \mathsf{inv}(\beta_{init}).$$

Here, we used the fact that β_{init} equals the "normalization constant" in the case of a unique initial state *init*. To make the analogy of the calculation of the expectation and the covariance more clear, we first state the well-known proposition based on the probability semiring.

Proposition 1. *Assume an acyclic transducer $\mathcal{P}$ with probability semiring, and a weighted transducer $\mathcal{X}$ with log semiring. $\mathcal{P}$ and $\mathcal{X}$ share the topology. Then,*

$$E_{\mathcal{P}}[\mathcal{X}] = \sum_{a \in \mathcal{P}} w_{\mathcal{X}}[a] w_{Q(\mathcal{P})}[a].$$

This proposition is then extended to the expectation semiring. Note that for the p-component, we recover the previous proposition.

Proposition 2. *Assume an acyclic transducer $\mathcal{P}$ with probability semiring, and transducers $\mathcal{X}$ and $\mathcal{Y}$ with log semiring. $\mathcal{P}$, $\mathcal{X}$, $\mathcal{Y}$ share the topology. Define the transducer $\mathcal{Z}$ with* expectation semiring *and assign the weights $w_{\mathcal{Z}}[a] = (w_{\mathcal{P}}[a], w_{\mathcal{P}}[a] w_{\mathcal{X}}[a])$ to the arcs. Then,*

$$Cov_{\mathcal{P}}(\mathcal{X}, \mathcal{Y}) = \sum_{a \in \mathcal{Y}} w_{\mathcal{Y}}[a] w_{Q(\mathcal{Z})}[a][v].$$

We conclude this section by showing how the calculation of the gradient of the objective function fits into this framework.

Gradient of objective function. To simplify the discussion, we restrict our consideration to objective functions of the type $\mathcal{F}(\Lambda) = f(E_{\mathcal{P}}[\mathcal{A}])$ rather than using the unified objective function in (He et al., 2008). Here, $\mathcal{P}$ stands for the word lattice with the joint probabilities $p_\Lambda(s_1^T, v_1^M | x_1^T)$ and $\mathcal{A}$ denotes some additive risk (e.g. phone error). In addition, a non-linearity f can be applied to the expectation. Then, building the derivative of this objective function leads to $\nabla \mathcal{F}(\Lambda) = \mathrm{Cov}_{\mathcal{P}}(\mathcal{L}, \nabla \log \mathcal{P})$ with $\mathcal{L} := f'(E_{\mathcal{P}}[\mathcal{A}])\mathcal{A}$. Examples: $\mathcal{A}$ = phone accuracy, $f(x) = x$ (MPE); $\mathcal{A} = \chi_{\mathrm{spk}}$ (characteristic function of spoken sequence, i.e., one for the spoken sequence and zero otherwise), $f(x) = \log x$ (MMI); or $\mathcal{A} = \chi_{\mathrm{spk}}$, $f(x)$ =sigmoid function (MCE).

6. Experimental Results

The presented approaches were evaluated on two different tasks. First, we tested the proposed criterion on the German digit string recognition task Sietill (Heigold et al., 2007), which due to its small size allows for a thorough experimental evaluation. Second, experiments were carried out on the large vocabulary EPPS English task, which represents a realistic ASR task. The baseline MPE result was part of our 2007 TC-STAR evaluation system, which performed best in the restricted and public evaluation conditions for both English and Spanish (Lööf et al., 2007). For completeness, we provide some description of the speech recognition systems. Non-experts, however, can skip these technical parts, keeping in mind that highly competitive systems are used for the discriminative training.

Table 2. Corpus statistics.

Task	Corpus	Data [h]	#run. words [k]	#frames [k]
Sietill	Train	5.5	43	1,980
	Test	5.5	43	1,980
EPPS En	Train	92.0	661	33,120
	Dev06	3.2	27	1,152
	Eval06	3.2	30	1,152
	Eval07	2.9	27	1,044

Our modified MMI criterion is identical with the recently proposed boosted MMI (Povey et al., 2008). These results, however, should be interpreted with some care because in most experiments, the boosting factor is not the only change. Probably, there is a single experiment which is directly comparable with our results on the EPPS task, i.e., which modifies only the boosting factor and which is set upon a state-of-the-art baseline. Very much like our results on the EPPS task, this result supports the hypothesis that the effect of the margin on such systems is marginal.

6.1. Sietill

The recognition system is based on gender-dependent whole-word HMMs. For each gender, 214 distinct states plus one for silence are used. The vocabulary consists of the 11 German digits (including the pronunciation variant 'zwo'). The observation vectors consist of 12 cepstral features without derivatives. The gender-independent Linear Discriminant Analysis (LDA) is applied to 5 consecutive frames and projects the resulting feature vector to 25 dimensions (Heigold et al., 2007). The corpus statistics is summarized in Tab. 2. The ML baseline system uses Gaussian mixtures with globally pooled variances and serves as initialization of the log-linear HMMs. The margin is represented by the approximate word accuracy and has been chosen to be the point where the word error rate (WER) on the training corpus begins to increase rapidly. The final performance turned out to be rather insensitive to the exact value. The optimization was carried out using RProp. Fig. 2 shows the progress of the word error rate (WER) vs. the iteration index on the test corpus. Margin-based MMI was validated on log-linear mixture models of different complexity (16 and 64 densities per HMM state with first order features only) and on a purely log-linear model with second and third order features (instead of using only first order features). The discriminative training was initialized with the respective ML baseline model except for the experiments including third order features. These were initialized with the model from frame-based training (Heigold et al., 2007). The discriminative results were all obtained

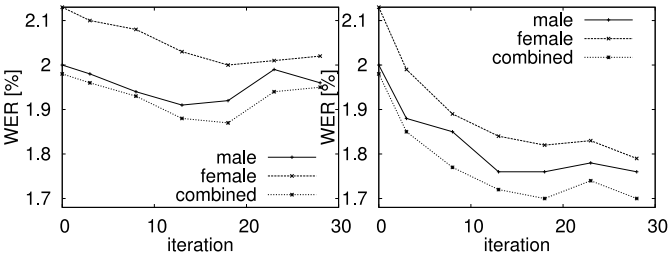

Figure 2. Effect of margin: progress of word error rate (WER) on Sietill test corpus, MMI (left) vs. modified MMI (right) (16 densities/mixture).

Table 3. Word error rates (WER) for Sietill test corpus.

Dns/Mix	Criterion	Margin	WER [%]
16	ML	-	1.98
	MMI	-	1.88
		word	1.72

using a regularization term. Tab. 3 summarizes the results. The results clearly benefit from the additional margin term, both regarding the performance and the robustness. This might be because the training data are separable for the given configurations. For the experiments using second and third order features ('1+f2+3') the training was initialized with the models from frame-based MMI training which benefits from the margin only slightly (cf. Sec. 4).

6.2. EPPS English

This task contains recordings from the European Parliament Plenary Sessions (EPPS). The corpus statistics of the different EPPS corpora can be found in Tab. 2. The acoustic front end comprises MFCC features augmented by a voicing feature. 9 consecutive frames are concatenated and the resulting vector is projected to 45 dimensions by means of LDA. The MFCC features are warped using a fast variant of the Vocal Tract Length Normalization (VTLN). On top of this, Speaker Adaptive Training (SAT) is applied. The triphones are clustered using CART, resulting in 4,501 generalized triphone states. The HMM states are modeled by Gaussian mixtures with globally pooled variances. The ML baseline system is made up of approximately 900,000 densities. For recognition, a lexicon with 50,000 entries in combination with a 4-gram language model was used (Lööf et al., 2007). The development (Dev06) and evaluation (Eval06) data from the evaluation campaign 2006 as described in Tab. 2 were used to tune the different parameters (e.g. language model scale or the number of MPE iterations). The evaluation data from the evaluation campaign 2007 (Eval07) were used only for testing.

Table 4. Word error rates (WER) for EPPS English corpus, MPE with different margins.

LM (train)	Margin	WER [%] Dev06	Eval06	Eval07
1g	-	13.4	10.1	11.5
	word	13.4	10.2	11.3
	phone	13.3	10.2	11.3
2g	-	13.3	10.3	11.6
	word	13.2	10.2	11.3
	phone	13.2	10.2	11.3

Table 5. Word error rates (WER) for EPPS English corpus, interdependence of weak language model and phone margin.

Crit.	Margin	LM (train)	WER [%] Dev06	Eval06	Eval07
ML	-	-	14.4	10.8	12.0
MPE	no	1g	13.4	10.1	11.5
		2g	13.3	10.3	11.6
	yes	1g	13.3	10.2	11.3
		2g	13.2	10.2	11.3

The word-conditioned lattices used in MPE training were generated with the VTLN/voicedness system in combination with a bigram language model. Since the lattices are dominated by silence and noise arcs, the lattices were filtered. The idea behind this filtering is to correct the posteriors for accumulation of discriminative statistics. For the acoustic rescoring during discriminative training, the exact match approach is used, i.e., the word boundary times are kept fixed.

The margins are tuned on a small fraction of the training corpus such that the margin-based approach in combination with a bigram language model and the standard MPE setup with a unigram language model have the same WER. Independent control experiments imply that no further tuning of the margin parameter is required. In the first experiment we have tested the impact of different margins on the performance, more specifically we have tested the approximate word and phone accuracies according to (Povey & Woodland, 2002). Tab. 4 shows that the differences are marginal. For convenience we decided to use the approximate phone accuracy-based margin for the remaining experiments. In Tab. 5 the interdependence of the weak unigram language model and the margin was investigated. There is ongoing work to clarify the interdependence of the language model used for the optimization and the margin. Using the acoustic model from the standard MPE training, the same 4-gram language model and only each tenth segment, the relative improvement of WER is 5.6% on the training data. This probably indicates that the generalization performance on the test data (Eval07) is not optimal with a relative improvement of 4.2% (and does not appear to be an issue on the development data, i.e., Dev06 and Eval06). The experimental results show the expected tendency, see Tab. 1.

7. Conclusions

We proposed modified formulations of MMI and MPE to include a margin term into the discriminative training of models for ASR. Furthermore, we showed that these modified criteria can directly be used in existing state-of-the-art ASR frameworks, since they can be represented as an additional transducer composition. The modified criteria are directly related to SVMs using a suitable loss function, which allows us to justify some important heuristics used in the discriminative training of acoustic models. The experimental results are consistent with our expectations. For the German digit string recognition task Sietill, where overfitting is achieved after a few iterations, the margin is essential for the robust estimation of the model parameters and allows to achieve significant improvements over the ML baseline. In contrast, on the large vocabulary EPPS English task the observed improvements are transferred well to the test data and the effect under consideration is marginal. So far, we have investigated the effect of the margin for the discriminative re-estimation based on generatively estimated and strongly tuned acoustic models. The benefits due to the margin might be better visible, when the discriminative, margin-based training builds on top of a suboptimal ML baseline. However, models building on top of better baseline models might still have a better absolute performance.

Abstract

We present a principled Bayesian framework for modeling *partial memberships* of data points to clusters. Unlike a standard mixture model which assumes that each data point belongs to one and only one mixture component, or cluster, a partial membership model allows data points to have fractional membership in multiple clusters. Algorithms which assign data points partial memberships to clusters can be useful for tasks such as clustering genes based on microarray data (Gasch & Eisen, 2002). Our Bayesian Partial Membership Model (BPM) uses exponential family distributions to model each cluster, and a product of these distibtutions, with weighted parameters, to model each datapoint. Here the weights correspond to the degree to which the datapoint belongs to each cluster. All parameters in the BPM are continuous, so we can use Hybrid Monte Carlo to perform inference and learning. We discuss relationships between the BPM and Latent Dirichlet Allocation, Mixed Membership models, Exponential Family PCA, and fuzzy clustering. Lastly, we show some experimental results and discuss nonparametric extensions to our model.

1. Introduction

The idea of *partial membership* is quite intuitive and practically useful. Consider, for example, an individual with a mixed ethnic background, say, partly Asian and partly European. It seems sensible to represent that individual as partly belonging to two different classes or sets. Such a partial membership representation may be relevant to predicting that individual's phenotype, or their food preferences. We clearly need models that can coherently represent partial membership.

Note that partial membership is conceptually very different from uncertain membership. Being certain that a person is partly Asian and partly European, is very different than being uncertain about a person's ethnic background. More information about the person, such as DNA tests, could resolve uncertainty, but cannot make the person change his ethnic membership.

Partial membership is also the cornerstone of fuzzy set theory. While in traditional set theory, items either belong to a set or they don't, fuzzy set theory equips sets with a membership function $\mu_k(x)$ where $0 \leq \mu_k(x) \leq 1$ denotes the degree to which x partially belongs to set k.

In this paper we describe a fully probabilistic approach to data modelling with partial membership. Our approach makes use of a simple way of representing partial membership using continuous latent variables. We define a model which can cluster data but which fundamentally assumes that data points can have partial membership in the clusters. Each cluster is represented by an exponential family distribution with conjugate priors (reviewed in section 3). Our model can be seen as a continuous latent variable relaxation of clustering with finite mixture models, and reduces to mixture modelling under certain settings of the hyperparameters. Unlike Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and Mixed Membership models (Erosheva et al., 2004), which also capture partial membership in the form of attribute-specific mixtures, our model does not assume a factorization over attributes and provides a general way of combining exponential family distributions with partial membership. The complete specification of our model is provided in section 4. Learning and inference are carried out using Markov chain Monte Carlo (MCMC) methods. We show in particular that because all the parameters in

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

our model are continuous, it is possible to employ a full hybrid Monte Carlo (HMC) algorithm, which uses gradients of the log probability, for inference (section 5).

Our Bayesian Partial Membership (BPM) model bears interesting relationships to several well-known models in machine learning and statistics, including LDA (Blei et al., 2003), mixed membership models (Erosheva et al., 2004), exponential family PCA (Collins et al., 2002), and Discrete Components Analysis (Buntine & Jakulin, 2006). We discuss these relations in section 6, where we also relate our model to fuzzy k-means. In section 7, we present both synthetic and real-world experimental results using image data and voting patterns of US senators. We conclude with future work in section 8.

2. A Partial Membership Model

We can derive our method for modeling partial memberships from a standard finite mixture model. In a finite mixture model the probability of a data point, $\boldsymbol{x}_n$ given Θ, which contains the parameters for each of the K mixture components (clusters) is:

$$p(\boldsymbol{x}_n|\Theta) = \sum_{k=1}^{K} \rho_k p_k(\boldsymbol{x}_n|\boldsymbol{\theta}_k) \tag{1}$$

where p_k is the probability distribution of mixture component k, and ρ_k is the mixing proportion (fraction of data points belonging to) for component k[1].

Equation 1 can be rewritten using indicator variables $\boldsymbol{\pi}_n = [\pi_{n1}\pi_{n2}\ldots\pi_{nK}]$ as follows:

$$p(\boldsymbol{x}_n|\Theta) = \sum_{\boldsymbol{\pi}_n} p(\boldsymbol{\pi}_n) \prod_{k=1}^{K} p_k(\boldsymbol{x}_n|\boldsymbol{\theta}_k)^{\pi_{nk}} \tag{2}$$

where $\pi_{nk} \in \{0,1\}$ and $\sum_k \pi_{nk} = 1$. Here we can notice that if $\pi_{nk} = 1$ this means that data point n belongs to cluster k (also $p(\pi_{nk} = 1) = \rho_k$). Therefore the π_{nk} denote *memberships* of data points to clusters.

In order to obtain a model for *partial memberships* we can relax the constraint $\pi_{nk} \in \{0,1\}$ to now allow π_{nk} to take any continuous value in the range $[0,1]$. However, in order to compute the probability of the data under this continuous relaxation of a finite mixture model, we need to modify equation 2 as follows:

$$p(\boldsymbol{x}_n|\Theta) = \int_{\boldsymbol{\pi}_n} p(\boldsymbol{\pi}_n) \frac{1}{c} \prod_{k=1}^{K} p_k(\boldsymbol{x}_n|\boldsymbol{\theta}_k)^{\pi_{nk}} d\boldsymbol{\pi}_n \tag{3}$$

[1]This notation differs slightly from standard notation for mixture models.

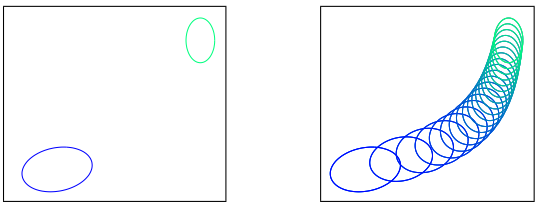

Figure 1. Left: A mixture model with two Gaussian mixture components, or clusters, can generate data from the two distributions shown. Right: Partial membership model with the same two clusters can generate data from all the distributions shown (there are actually infinitely many), which lie between the two original clusters.

The modifications include integrating over all values of $\boldsymbol{\pi}_n$ instead of summing, and since the product over clusters K from equation 2 no longer normalizes we put in a normalizing constant c, which is a function of $\boldsymbol{\pi}_n$ and Θ. Equation 3 now gives us a model for partial membership.

We illustrate the difference between our partial membership model and a standard mixture model in figure 1. Here we can see contours of the Gaussian distributions which can generate data in the mixture model (left) and the partial membership model (right), where both models are using the same two Gaussian clusters. As an example, if one of these clusters represents the ethnicity "White British" and the other cluster represents the ethnicity "Pakistani", then the figure illustrates that the partial membership model will be able to capture someone of mixed ethnicity, whose features may lie in between those of either ethnic group (for example skin color or nose size), better than the mixture model.

3. Conjugate-Exponential Models

In the previous section we derived a partial membership model, given by equation 3. However we have not yet discussed the form of the distribution for each cluster, $p_k(\boldsymbol{x}_n|\boldsymbol{\theta}_k)$, and we will now focus on the case when these distributions are in the exponential family.

An *exponential family distribution* can be written in the form:

$$p_k(\boldsymbol{x}_n|\boldsymbol{\theta}_k) = \exp\{\boldsymbol{s}(\boldsymbol{x}_n)^\top \boldsymbol{\theta}_k + h(\boldsymbol{x}_n) + g(\boldsymbol{\theta}_k)\} \tag{4}$$

where $\boldsymbol{s}(\boldsymbol{x}_n)$ is a vector depending on the data known as the *sufficient statistics*, $\boldsymbol{\theta}_k$ is a vector of *natural parameters*, $h(\boldsymbol{x}_n)$ is a function of the data, and $g(\boldsymbol{\theta}_k)$ is a function of the parameters which ensures that the probability normalizes to one when integrating or summing over $\boldsymbol{x}_n$. We will use the short-hand $\boldsymbol{x}_n \sim \text{Expon}(\boldsymbol{\theta}_k)$ to denote that $\boldsymbol{x}_n$ is drawn from an

exponential family distribution with natural parameters $\boldsymbol{\theta}_k$.

If we plug the exponential family distribution (equation 4) into our partial membership model (equation 3) it follows that:

$$\boldsymbol{x}_n|\boldsymbol{\pi}_n, \Theta \sim \text{Expon}(\sum_k \pi_{nk}\boldsymbol{\theta}_k) \tag{5}$$

where $\boldsymbol{x}_n$ comes from the *same* exponential family distribution as the original clusters p_k, but with *new* natural parameters which are a convex combination of the natural parameters of the original clusters, $\boldsymbol{\theta}_k$, weighted by π_{nk}, the partial membership values for data point $\boldsymbol{x}_n$. Computation of the normalizing constant c is therefore always tractable when p_k is in the exponential family.

A probability distribution $p(\boldsymbol{\theta}_k)$ is said to be *conjugate* to the exponential family distribution $p(\boldsymbol{x}_n|\boldsymbol{\theta}_k)$ if $p(\boldsymbol{\theta}_k|\boldsymbol{x}_n)$ has the same functional form as $p(\boldsymbol{\theta}_k)$. In particular, the conjugate prior to the above exponential family distribution can be written in the form:

$$p(\boldsymbol{\theta}) \propto \exp\{\boldsymbol{\lambda}^\top\boldsymbol{\theta} + \nu g(\boldsymbol{\theta})\} \tag{6}$$

where $\boldsymbol{\lambda}$ and ν are *hyperparameters* of the prior. We will use the short-hand, $\boldsymbol{\theta} \sim \text{Conj}(\boldsymbol{\lambda}, \nu)$. We now have the tools to define our Bayesian partial membership model.

4. Bayesian Partial Membership Models

Consider a model with K clusters, and a data set $\mathcal{D} = \{\boldsymbol{x}_n : n = 1 \dots N\}$. Let $\boldsymbol{\alpha}$ be a K-dimensional vector of positive hyperparameters. We start by drawing mixture weights from a Dirichlet distribution:

$$\boldsymbol{\rho} \sim \text{Dir}(\boldsymbol{\alpha}) \tag{7}$$

Here $\boldsymbol{\rho} \sim \text{Dir}(\boldsymbol{\alpha})$ is shorthand for $p(\boldsymbol{\rho}|\boldsymbol{\alpha}) = c\prod_{k=1}^K \rho_k^{\alpha_k - 1}$ where $c = \Gamma(\sum_k \alpha_k)/\prod_k \Gamma(\alpha_k)$ is a normalization constant which can be expressed in terms of the Gamma function[2]. For each data point, n, we draw a partial membership vector $\boldsymbol{\pi}_n$ which represents how much that data point belongs to each of the K clusters:

$$\boldsymbol{\pi}_n \sim \text{Dir}(a\boldsymbol{\rho}). \tag{8}$$

The parameter a is a positive scaling constant drawn, for example, from an exponential distribution $p(a) = be^{-ba}$, where $b > 0$ is a constant. We assume that each cluster k is characterized by an exponential family distribution with natural parameters $\boldsymbol{\theta}_k$ and that

$$\boldsymbol{\theta}_k \sim \text{Conj}(\boldsymbol{\lambda}, \nu). \tag{9}$$

Given all these latent variables, each data point is drawn from

$$\boldsymbol{x}_n \sim \text{Expon}(\sum_k \pi_{nk}\boldsymbol{\theta}_k) \tag{10}$$

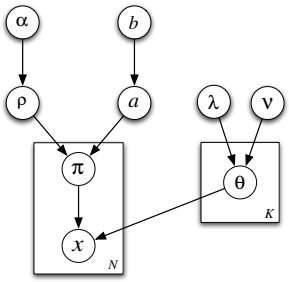

Figure 2. Graphical model for the BPM

In order to get an intuition for what the functions of the parameters we have just defined are, we return to the ethnicity example. Here, each cluster k is an ethnicity (for example, "White British" and "Pakistani") and the parameters $\boldsymbol{\theta}_k$ define a distribution over features for each of the k ethnic groups (for example, how likely it is that someone from that ethnic group likes pizza or marmite or bindi bhaji). The parameter $\boldsymbol{\rho}$ gives the ethnic composition of the population (for example, 75% "White British" and 25% "Pakistani"), while a controls how similar to the population an individual is expected to be (Are 100% of the people themselves 75% "White British" and 25% "Pakistani"? Or are 75% of the people 100% "White British" and the rest are 100% "Pakistani"? Or somewhere in between?). For each person n, $\boldsymbol{\pi}_n$ gives their individual ethnic composition, and finally $\boldsymbol{x}_n$ gives their individual feature values (e.g. how much they like marmite). The graphical model representing this generative process is drawn in Figure 2.

Since the Bayesian Partial Membership Model is a generative model, we tried generating data from it using full-covariance Gaussian clusters. Figure 3 shows the results of generating 3000 data points from our model with $K = 3$ clusters as the value of parameter a changes. We can see that as the value of a increases data points tend to have partial membership in more clusters. In fact we can prove the following lemmas:

Lemma 1 *In the limit that $a \to 0$ the exponential family BPM is a standard mixture model with K components and mixing proportions $\boldsymbol{\rho}$.*

[2]The Gamma function generalizes the factorial to positive reals: $\Gamma(x) = (x-1)\Gamma(x-1)$, $\Gamma(n) = (n-1)!$ for integer n

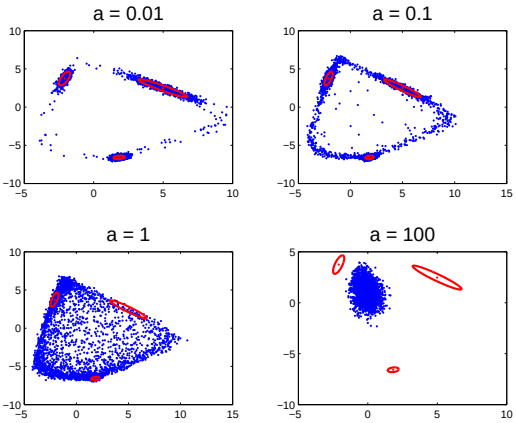

Figure 3. 3000 BPM generated data points with partial assignments to 3 Gaussian clusters shown in red, as parameter a varies.

Lemma 2 *In the limit that $a \to \infty$ the exponential family BPM model has a single component with natural parameters $\sum_k \rho_k \boldsymbol{\theta}_k$.*

Proofs of these lemmas follow simply from taking the limits of equation 8 as a goes to 0 and ∞ respectively.

5. BPM Learning

We can represent the observed data set $\mathcal{D}$ as an $N \times D$ matrix $\mathbf{X}$ with rows corresponding to $\boldsymbol{x}_n$, where D is the number of input features.[3] Let $\boldsymbol{\Theta}$ be a $K \times D$ matrix with rows $\boldsymbol{\theta}_k$ and $\boldsymbol{\Pi}$ be an $N \times K$ matrix with rows $\boldsymbol{\pi}_n$. Learning in the BPM consists of inferring all unknown variables, $\boldsymbol{\Omega} = \{\boldsymbol{\Pi}, \boldsymbol{\Theta}, \boldsymbol{\rho}, a\}$ given $\mathbf{X}$. We treat the top level variables in the graphical model in Figure 2, $\boldsymbol{\Psi} = \{\boldsymbol{\alpha}, \boldsymbol{\lambda}, \nu, b\}$ as fixed hyperparameters, although these could also be learned from data. Our goal is to infer $p(\boldsymbol{\Omega}|\mathbf{X}, \boldsymbol{\Psi})$, for which we decide to employ Markov chain Monte Carlo (MCMC).

Our key observation for MCMC is that even though BPMs contain discrete mixture models as a special case, *all* of the unknown variables $\boldsymbol{\Omega}$ of the BPM are continuous. Moreover, it is possible to take derivatives of the log of the joint probability of all variables with respect to $\boldsymbol{\Omega}$. This makes it possible to do inference using a full Hybrid Monte Carlo (HMC) algorithm on all parameters. Hybrid (or Hamiltonian) Monte Carlo is an MCMC procedure which overcomes the random walk behaviour of more traditional Metropolis or Gibbs sampling algorithms by making use of the derivatives of the log probability (Neal, 1993; MacKay, 2003). In high dimensions, this derivative information can lead to a dramatically faster mixing of the Markov chain, analogous to how optimization using derivatives is often much faster than using greedy random search.

We start by writing the probability of all parameters and variables[4] in our model:

$$p(\mathbf{X}, \boldsymbol{\Omega}|\boldsymbol{\Psi}) = p(\mathbf{X}|\boldsymbol{\Pi}, \boldsymbol{\Theta}) p(\boldsymbol{\Theta}|\boldsymbol{\lambda}, \nu) p(\boldsymbol{\Pi}|a, \boldsymbol{\rho}) p(a|b) p(\boldsymbol{\rho}|\boldsymbol{\alpha}) \tag{11}$$

We assume that the hyperparameter $\nu = 1$, and omit it from our derivation. Since the forms of all distributions on the right side of equation (11) are given in section 4, we can simply plug these in and see that:

$$\begin{aligned}
&\log p(\mathbf{X}, \boldsymbol{\Omega}|\boldsymbol{\Psi}) = \\
&\quad \log\Gamma\left(\textstyle\sum_k \alpha_k\right) - \textstyle\sum_k \log\Gamma(\alpha_k) + \textstyle\sum_k (\alpha_k - 1)\log\rho_k \\
&\quad + \log b - ba + N \log\Gamma\left(\textstyle\sum_k a\rho_k\right) - N \textstyle\sum_k \log\Gamma(a\rho_k) \\
&\quad + \textstyle\sum_n \sum_k (a\rho_k - 1)\log\pi_{nk} + \textstyle\sum_k \left[\boldsymbol{\theta}_k^\top \boldsymbol{\lambda} + \mathrm{g}(\boldsymbol{\theta}_k) + \mathrm{f}(\boldsymbol{\lambda})\right] \\
&\quad + \textstyle\sum_n \left[\left(\sum_k \pi_{nk}\boldsymbol{\theta}_k\right)^\top \boldsymbol{x}_n + \mathrm{h}(\boldsymbol{x}_n) + \mathrm{g}\left(\sum_k \pi_{nk}\boldsymbol{\theta}_k\right)\right]
\end{aligned}$$

The Hybrid Monte Carlo algorithm simulates dynamics of a system with continuous state $\boldsymbol{\Omega}$ on an energy function $\mathcal{E}(\boldsymbol{\Omega}) = -\log p(\mathbf{X}, \boldsymbol{\Omega}|\boldsymbol{\Psi})$. The derivatives of the energy function $\frac{\partial \mathcal{E}(\boldsymbol{\Omega})}{\partial \boldsymbol{\Omega})}$ provide forces on the state variables which encourage the system to find high probability regions, while maintaining detailed balance to ensure that the correct equilibrium distribution over states is achieved (Neal, 1993). Since $\boldsymbol{\Omega}$ has constraints, e.g. $a > 0$ and $\sum_k \rho_k = 1$, we use a tranformation of variables so that the new state variables are unconstrained, and we perform dynamics in this unconstrained space. Specifically, we use $a = e^\eta$, $\rho_k = \frac{e^{r_k}}{\sum_{k'} e^{r_{k'}}}$, and $\pi_{nk} = \frac{e^{p_{nk}}}{\sum_{k'} e^{p_{nk'}}}$. For HMC to be valid in this new space, the chain rule needs to be applied to the derivatives of $\mathcal{E}$, and the prior needs to be transformed through the Jacobian of the change of variables. For example, $p(a)da = p(\eta)d\eta$ implies $p(\eta) = p(a)(da/d\eta) = ap(a)$. We also extended the HMC procedure to handle missing inputs in a principled manner, by analytically integrating them out, as this was required for some of our applications. More details and general pseudocode for HMC can be found in (MacKay, 2003).

6. Related Work

The BPM model has interesting relations to several models that have been proposed in machine learning, statistics and pattern recognition. We describe these relationships here.

[3] We assume that the data is represented in its natural representation for the exponential family likelihood, so that $\boldsymbol{s}(\boldsymbol{x}_n) = \boldsymbol{x}_n$.

[4] A formal distinction between hidden variables, e.g. the $\{\boldsymbol{\pi}_n\}$, and unknown parameters is not necessary as they are both unknowns.

Latent Dirichlet Allocation: Using the notation introduced above, the BPM model and LDA (Blei et al., 2003) both incorporate a K-dimensional Dirichlet distributed $\boldsymbol{\pi}$ variable. In LDA, $\boldsymbol{\pi}_n$ are the mixing proportions of the topic mixture for each document n. Each word in document n can then be seen as having been generated by topic k, with probability π_{nk}, where the word distribution for topic k is given by a multinomial distribution with some parameters, $\boldsymbol{\theta}_k$. The BPM also combines π_{nk} with some exponential family parameters $\boldsymbol{\theta}_k$, but here the way in which they are combined does not result in a mixture model from which another variable (e.g. a word) is assumed to be generated. In contrast, the data points are indexed by n directly, and therefore exist at the document level of LDA. Each data point is assumed to have come from an exponential family distribution parameterized by a weighted sum of natural parameters $\boldsymbol{\theta}$, where the weights are given by π_n for data point n. In LDA, data is organized at two levels (e.g. documents and words). More generally, mixed membership (MM) models (Erosheva et al., 2004), or admixture models, assume that each data attribute (e.g. words) of the data point (e.g. document) is drawn independently from a mixture distribution given the membership vector for the data point, $x_{nd} \sim \sum_k \pi_{nk} P(x|\theta_{kd})$. LDA and mixed membership models do not average natural parameters of exponential family distributions like the BPM. LDA or MM models could not generate the continuous densities in figure 3 from full-covariance Gaussians. The analagous generative process for MM models is given in figure 4. Since data attributes are drawn independently, the original clusters (not explicity shown) are one dimensional and have means at 0, 10 and 20 for both attribute dimensions. We can notice from the plot that this model always generates a mixture of 9 Gaussians, which is a very different behavior than the BPM, and clearly not as suitable for the general modeling of partial memberships. LDA only makes sense when the objects (e.g. documents) being modelled constitute bags of exchangeable sub-objects (e.g. words). Our model makes no such assumption. Moreover, in LDA and MM models there is a discrete latent variable for every sub-object corresponding to which mixture component that sub-object was drawn from. This large number of discrete latent variables makes MCMC sampling in LDA potentially much more expensive than in BPM models.

Exponential Family PCA: Our model bears an interesting relationship to Exponential Family PCA (Collins et al., 2002). EPCA was originally formulated as the solution to an optimization problem based on Bregman divergences, while our model is a fully probabilistic model in which all parameters can be integrated out via MCMC. However, it is possible to think of EPCA as the likelihood function of a probabilistic model, which coupled with a prior on the parameters, would make it possible to do Bayesian inference in EPCA and would render it closer to our model. However, our model was entirely motivated by the idea of partial membership in clusters, which is enforced by forming convex combinations of the natural parameters of exponential family models, while EPCA is based on *linear* combinations of the parameters. Therefore: EPCA does not naturally reduce to clustering, none of the variables can be interpreted as partial memberships, and the coefficients define a plane rather than a convex region in parameter space.

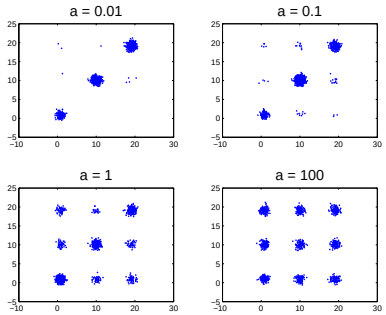

Figure 4. Generative plot for MM model with 3 Gaussian clusters

The recent work of Buntine and Jakulin (Buntine & Jakulin, 2006) focusing on the analysis of discrete data is also closely related to the BPM model. The framework of (Buntine & Jakulin, 2006) section III B expresses a model for discrete data in terms of linear mixtures of dual exponential family parameters where MAP inference is performed. Section V B also provides insights on differences between using dual and natural parameters.

Fuzzy Clustering: The notion that probabilistic models are unable to handle partial membership has been used to argue that probability is a subtheory of or different in character from fuzzy logic (Zadeh, 1965; Kosko, 1992). In this paper we described a probabilistic model for partial membership which may be of use in the many application domains where fuzzy clustering has been used.

Fuzzy K-means clustering (Bezdek, 1981) iteratively minimizes the following objective: $J = \sum_{n=1}^{N}\sum_{k=1}^{K} \pi_{nk}^{\gamma} d^2(\boldsymbol{x}_n, \boldsymbol{c}_k)$, where $\gamma > 1$ is an exponent parameter, π_{nk} represents the degree of membership of

data point n in cluster k ($\sum_k \pi_{nk} = 1$), and $d^2(\boldsymbol{x}_n, \boldsymbol{c}_k)$ is a measure of squared distance between data point $\boldsymbol{x}_n$ and cluster center $\boldsymbol{c}_k$. By varying γ it is possible to attain different amounts of partial membership, where the limiting case $\gamma = 1$ is K-means with no partial membership. Although the π parameters represent partial membership, none of the variables have probabilistic interpretations.

IOMM: Lastly, this work is related to the Infinite Overlapping Mixture Model (IOMM) (Heller & Ghahramani, 2007) in which overlapping clustering is performed, also by taking products of exponential family distributions, much like products of experts (Hinton, 1999). However in the IOMM the memberships of data points to clusters are restricted to be binary, which means that it can not model partial membership.

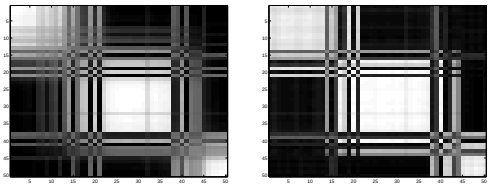
7. Experiments

We generated a synthetic binary data set from the BPM, and used this to test BPM learning. The synthetic data set had 50 data points which each have 32 dimensions and can hold partial memberships in 3 clusters. We ran our Hybrid Monte Carlo sampler for 4000 iterations, burning in the first half. In order to compare our learned partial membership assignments for data points (Π_L) to the true ones (Π_T) for this synthetic data set, we compute ($\hat{U} = \Pi_L \Pi_L^\top$) and ($U^* = \Pi_T \Pi_T^\top$), which basically give the total amount of cluster membership shared between each pair of data points, and is invariant to permutations of cluster labels. Both of these matrices can be seen in figure 5. One can see that the structure of these two matrices is quite similar, and that the BPM is learning the synthetic data reasonably. For a more quantitative measure table 5c gives statistics on the number of pairs of data points whose learned shared membership differs from the true shared membership by more than a given threshold (the range of this statistic is [0,1]).

We also used the BPM to model two "real-world" data sets. The first is senate roll call data from the 107th US congress (2001-2002) (Jakulin, 2004), and the second is a data set of images of sunsets and towers.

The senate roll call data is a matrix of 99 senators (one senator died in 2002 and neither he nor his replacement is included) by 633 votes. It also includes the outcome of each vote, which is treated as an additional data point (like a senator who always voted the actual outcome). The matrix contained binary features for yea and nay votes, and we used the BPM to cluster this data set using $K = 2$ clusters. There are missing values in this dataset but this can easily be dealt with in the HMC log probability calculations by explicitly representing both 0 and 1 binary values and leaving out missing values. The results are given in figure 6. The line in figure 6 represents the amount of membership of each senator in one of the clusters (we used the "Democrat" cluster, where senators on the far left have partial memberships very close to 0, and those on the far right have partial memberships extremely close to 1). Since there are two clusters, and the amount of membership always sums to 1 across clusters, the figure looks the same regardless of whether we are looking at the "Democrat" or "Republican" cluster. We can see that most Republicans and Democrats are tightly clustered at the ends of the line (and have partial memberships very close to 0 and 1), but that there is a fraction of senators (around 20%) which lies somewhere reasonably in between the extreme partial memberships of 0 or 1. Interesting properties of this figure include the location of Senator Jeffords who left the Republican party in 2001 to become an independent who caucused with the Democrats. Also Senator Chafee who is known as a moderate Republican and who often voted with the Democrats (for example, he was the only Republican to vote against authorizing the use of force in Iraq), and Senator Miller a conservative Democrat who supported George Bush over John Kerry in the 2004 US Presidential elections. Lastly, it is interesting to note the location of the Outcome data point, which is very much in the middle. This makes sense since the 107th congress was split 50-50 (with Republican Dick Cheney breaking ties), until Senator Jeffords became an Independent at which point the Democrats had a one seat majority.

We also tried running both fuzzy k-means clustering and Dirichlet Process Mixture models (DPMs) on this data set. While fuzzy k-means found roughly similar rankings of the senators in terms of membership to the "Democrat" cluster, the exact ranking and, in particular, the amount of partial membership ($\pi_{\mathbf{n}}$) each senator had in the cluster was *very* sensitive to the fuzzy exponent parameter, which is typically set by hand. Figure 7a plots the amount of membership for the Outcome data point in black, as well as the most extreme Republican, Senator Ensign, in red, and the most extreme Democrat, Senator Schumer, in blue, as a function of the fuzzy exponent parameter. We can see in this plot that as the assignment of the Outcome data point begins to reach a value even reasonably close to 0.5, the most extreme Republican already has 20% membership in the "Democrat" cluster. This reduction in range does not make sense semantically, and presents a trade-off between finding reasonable values



Statistic	Percent
$\lvert(\hat{U} - U^*)\rvert \leq 0.1$	60.40
$\lvert(\hat{U} - U^*)\rvert \leq 0.2$	84.28
$\lvert(\hat{U} - U^*)\rvert \leq 0.3$	95.48
$\lvert(\hat{U} - U^*)\rvert \leq 0.4$	99.68
$\lvert(\hat{U} - U^*)\rvert \leq 0.5$	100.00

Figure 5. a) left - matrix U^* showing the true shared partial memberships for pairs of data points. b) right - matrix $\hat{U}$ showing the learned shared partial memberships. c) Summary statistics for learned $\hat{U}$. Reports the percentage of pairs in $\hat{U}$ whose difference from U^* in terms of the amount of shared partial memberships is at most the given threshold (0.1 - 0.5).

for π_n in the middle of the range, versus at the extremes. This kind of sensitivity to parameters does not exist in our BPM model, which models both extreme and middle range values well.

We tried using a DPM to model this data set where we ran the DPM for 1000 iterations of Gibbs sampling, sampling both assignments and concentration parameter. The DPM confidently finds 4 clusters: one cluster consists solely of Democrats, one consists solely of Republicans, the third cluster has 9 of the most moderate Democrats and Republicans plus the "vote outcome" variable, and the last cluster has just one member, Hollings (D-SC). Figure 7b is a 100x100 matrix showing the overlap of cluster assignments for pairs of senators, averaged over 500 samples (there are no changes in relative assignments, the DPM is completely confident). The interpretation of the data provided by the DPM is very different from the BPM model's. The DPM does *not* use uncertainty in cluster membership to model Senators with intermediate views. Rather, it creates an entirely new cluster to model these Senators. This makes sense for the data as viewed by the DPM: there is ample data in the roll calls that these Senators are moderate — it is not the case that there is uncertainty about whether they fall in line with hard-core Democrats or Republicans. This highlights the fact that the responsibilities in a mixture model (such as the DPM) cannot and should not be interpreted as partial membership, they are representations of *uncertainty* in full membership. The BPM model, however, explicitly models the partial membership, and can, for example, represent the fact that a Senator might be best characterized as moderate (and quantify how moderate they are). In order to quantify this comparison we calculated the negative log predictive probability (in bits) across senators for the BPM and the DPM (Table 1). We look at a number of different measures: the mean, median, minimum and maximum number of bits required to encode a senator's votes. We also look at the number of bits needed to encode the "Outcome" in particular. On all of these measures

	Mean	Median	Min	Max	"Outcome"
BPM	**187**	**168**	**93**	422	**224**
DPM	196	178	112	**412**	245

Table 1. Comparison between the BPM and a DPM in terms of negative log predictive probability (in bits) across senators.

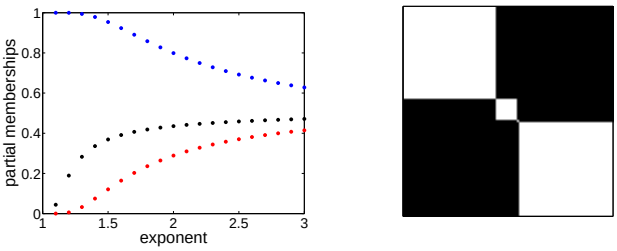


Figure 7. a) left - fuzzy k-means: plot of the partial membership values for the Outcome data point (in black) and the most extreme Republican (in red) and Democrat (in blue) as a function of the fuzzy exponent parameter. b) right - DPMs: an ordered 100x100 matrix showing the fraction of times each pair of senators was assigned to the same cluster, averaged over 500 Gibbs sampling iterations.

except for maximum, the BPM performs better than the DPM, showing that the BPM is a superior model for this data set.

Lastly, we used the BPM to model images of sunsets and towers. The dataset consisted of 329 images of sunsets or towers, each of which was represented by 240 binary simple texture and color features. Partial assignments to $K = 2$ clusters were learned, and figure 8 provides the result. The top row of the figure is the three images with the most membership in the "sunset" cluster, the bottom row contains the three images with the most membership in the "tower" cluster, and the middle row shows the 3 images which have closest to 50/50 membership in each cluster ($\pi_{nk} \approx 0.5$). In this dataset, as well as all the datasets described in this section, our HMC sampler was very fast, giving reasonable results within tens of seconds.

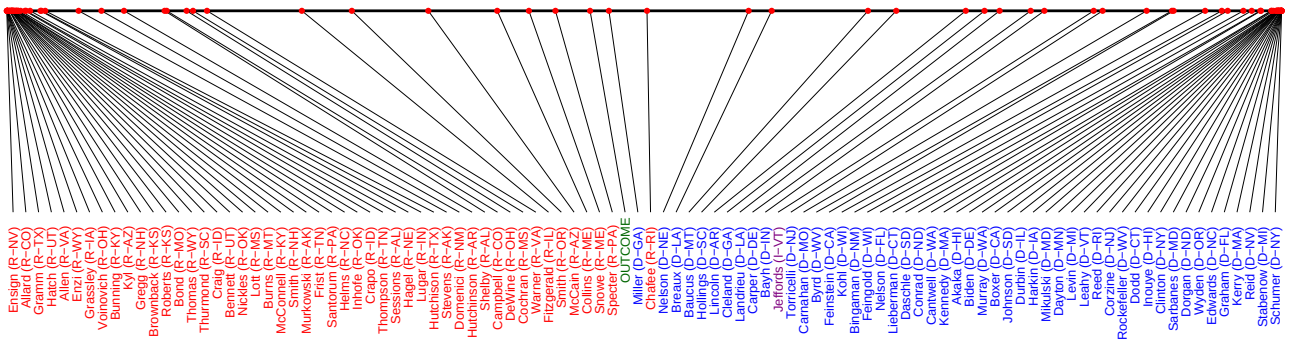

Figure 6. Analysis of the partial membership results on the Senate roll call data from 2001-2002. The line shows amount of membership in the "Democrat" cluster with the left of the line being the lowest and the right the highest.

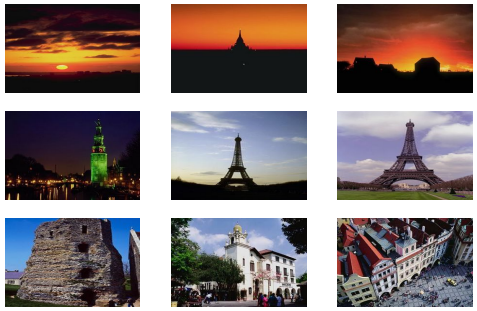

Figure 8. Tower and Sunset images. The top row are the images found to have largest membership in the "sunset" cluster, the bottom row are images found to have largest membership in the "tower" cluster, and the middle row are the images which have the most even membership in both clusters.

8. Conclusions and Future Work

In summary, we have described a fully probabilistic approach to data modelling with partial membership using continuous latent variables, which can be seen as a relaxation of clustering with finite mixture models. We employed a full Hybrid Monte Carlo algorithm for inference, and our experience with HMC has been very positive. Despite the general reputation of MCMC methods for being slow, our model using HMC seems to discover sensible partial membership structure after surprisingly few samples.

In the future we would like to develop a nonparametric version of this model. The most obvious way to try to generalize this model would be with a Hierarchical Dirichlet Process (Teh et al., 2006). However, this would involve averaging over infinitely many potential clusters, which is both computationally infeasible, and also undesirable from the point of view that each data point should have non-zero partial membership in only a few (certainly finite) number of clusters. A more promising alternative is to use an Indian Buffet Process (Griffiths & Ghahramani, 2005), where each 1 in a row in an IBP sample matrix would represent a cluster in which the data point corresponding to that row has non-zero partial membership, and then draw the continuous values for those partial memberships conditioned on that IBP matrix.

Active Kernel Learning

Abstract

Identifying the appropriate kernel function/matrix for a given dataset is essential to all kernel-based learning techniques. A number of kernel learning algorithms have been proposed to learn kernel functions or matrices from side information (e.g., either labeled examples or pairwise constraints). However, most previous studies are limited to "passive" kernel learning in which side information is provided beforehand. In this paper we present a framework of *Active Kernel Learning* (**AKL**) that actively identifies the most informative pairwise constraints for kernel learning. The key challenge of active kernel learning is how to measure the informativeness of an example pair given its class label is unknown. To this end, we propose a **min-max** approach for active kernel learning that selects the example pair that results in a large classification margin regardless of its assigned class label. We furthermore approximate the related optimization problem into a convex programming problem. We evaluate the effectiveness of the proposed algorithm by comparing it to two other implementations of active kernel learning. Empirical study with nine datasets on semi-supervised data clustering shows that the proposed algorithm is more effective than its competitors.

1. Introduction

Kernel methods have attracted more and more attention of researchers in computer science and engineering due to their superior performance in data clustering, classification, and dimensionality reduction (Scholkopf & Smola, 2002; Vapnik, 1998). Kernel methods have been applied to many fields, such as data mining, pattern recognition, information retrieval, computer vision, and bioinformatics, etc. Since the choice of kernel functions or matrices is often critical to the performance of many kernel-based learning techniques, it becomes a more and more important research problem for how to automatically learn a kernel function/matrix for a given dataset. Recently, a number of kernel learning algorithms (Chapelle et al., 2003; Cristianini et al., 2002; Hoi et al., 2007; Kondor & Lafferty, 2002; Kulis et al., 2006; Lanckriet et al., 2004; Zhu et al., 2005) have been proposed to learn kernel functions or matrices from side information. The side information can be provided in two different forms: either labeled examples or pairwise constraints. In the latter case, two types of pairwise constraints are examined in the previous studies: a must-link pair where two examples should belong to the same class, and a cannot-link pair where two examples should belong to different classes. In this study, we focus on kernel learning with pairwise constraints.

Most kernel learning methods, termed as "passive kernel learning", assume that labeled data is provided beforehand. However, given the labeled data may be expensive to acquire, it is more cost effective if we are able to identify the most informative example pairs such that the kernel can be learned efficiently with only a small number of pairwise constraints. To this end, we focus on **active kernel learning** (AKL) whose goal is to identify the example pairs that are informative to the target kernels. We extends our previous work on non-parametric kernel learning (Hoi et al., 2007) to active kernel learning. As shown in (Hoi et al., 2007), the parametric approaches for kernel learning are often limited by their capacity in fitting diverse patterns of real-world data, and therefore are not as effective as the non-parametric approach for kernel learning.

The simplest approach toward active kernel learning is to measure the informativeness of an example pair by its kernel similarity. Given a pair of examples $(\mathbf{x}_i, \mathbf{x}_j)$, we assume that $K_{i,j}$, the kernel similarity between $\mathbf{x}_i$ and $\mathbf{x}_j$, is a large positive number when $\mathbf{x}_i$ and $\mathbf{x}_j$ are in the same class, and a large negative number

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

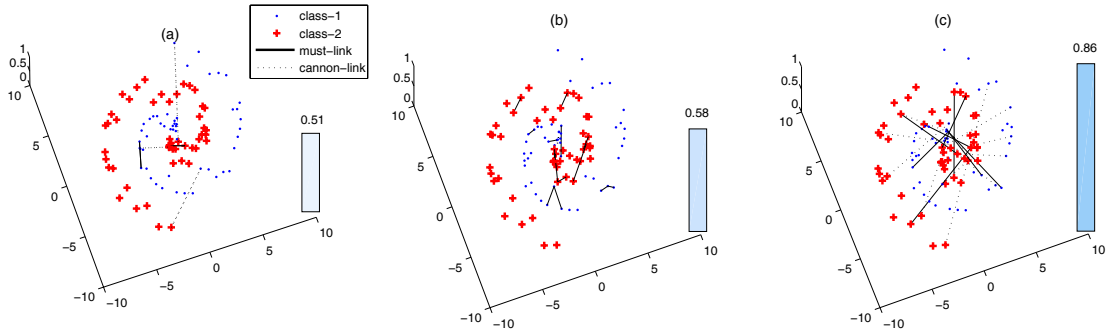

Figure 1. Examples of active kernel learning: (a) double-spiral artificial data with some given pairwise constraints, (b) AKL with the least $|K_{i,j}|$, (c) the proposed AKL method. The right bars show the resulting clustering accuracies using kernel k-means clustering methods.

when they are in different classes. Thus, by following the uncertainty principle of active learning (Tong & Koller, 2000; Hoi et al., 2006), the most informative example pairs should be the ones whose kernel similarities are closest to zero. In other words, the criterion is to select the example pair with the least absolute kernel similarity (i.e., $|K_{i,j}|$). Unfortunately, this simple approach may not always be effective in obtaining informative pairwise constraints for kernel learning. Figure 1 illustrates an example of active kernel learning for data clustering. In this example, Figure 1(a) shows an artificial dataset of two classes together with a few pairwise constraints. Figure 1(b) shows the pairwise constraints with the least $|K_{i,j}|$. We observe that most of them are must-link pairs with two data points separated by a modest distance. Since must-link constraints are not informative to the clustering boundary, a relatively small improvement is observed in clustering accuracy (from 51% to 58%) when using the kernel learned by this simple approach. In contrast, as shown in Figure 1(c), the proposed approach for active kernel learning is able to identify a pool of diverse pairwise constraints, including both must-links and cannot-links. The clustering accuracy is increased significantly, from 51% to 86%, by using the proposed active kernel learning.

The rest of this paper is organized as follows. Section 2 presents the min-max framework for our active kernel learning method, in which the problem is formulated into a convex optimization problem. Section 3 describes the results of the experimental evaluation. Section 4 concludes this work.

2. Active Kernel Learning

Our work extends the previous work on non-parametric kernel learning (Hoi et al., 2007) by introducing the component of actively identifying the example pairs that are most informative to the target kernel. In this section, we will first briefly review the non-parametric approach for kernel learning in (Hoi et al., 2007), followed by the description of the min-max framework for active kernel learning.

2.1. Non-parametric Kernel Learning

Let the entire data collection be denoted by $\mathcal{U} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N)$ where each data point $\mathbf{x}_i \in \mathbb{R}^d$ is a vector of d elements. Let $S \in \mathbb{R}^{N \times N}$ be a symmetric matrix where each $S_{i,j} \geq 0$ represents the similarity between $\mathbf{x}_i$ and $\mathbf{x}_j$. Unlike the kernel similarity matrix, S does not have to be positive semi-definite. For the convenience of presentation, we set $S_{i,i} = 0$ for all the examples. Then, according to (Hoi et al., 2007), a normalized graph Laplacian L is constructed using the similarity matrix S as follows:

$$L = (1+\delta)I - D^{-1/2} S D^{-1/2}$$

where $D = \text{diag}(d_1, d_2, \ldots, d_N)$ is a diagonal matrix with $d_i = \sum_{j=1}^{N} f(\mathbf{x}_i, \mathbf{x}_j)$. A small $\delta > 0$ is introduced to prevent L from being singular. Let's denote by $\mathcal{T}$ the set of pairwise constraints. We construct a matrix $T \in \mathbb{R}^{N \times N}$ to represent the pairwise constraints in $\mathcal{T}$, i.e.,

$$T_{i,j} = \begin{cases} +1 & (\mathbf{x}_i, \mathbf{x}_j) \text{ is a must-link pair in } \mathcal{T} \\ -1 & (\mathbf{x}_i, \mathbf{x}_j) \text{ is a cannot-link pair in } \mathcal{T} \\ 0 & \text{otherwise} \end{cases}$$

Given the similarity matrix S and the pairwise constraints in $\mathcal{T}$, the goal of kernel learning is to identify a kernel matrix $Z \in \mathbb{R}^{N \times N}$ that is consistent with both $\mathcal{T}$ and S. Following (Hoi et al., 2007), we formulate it

into the following convex optimization problem:

$$\begin{aligned} \arg\min_{Z,\varepsilon} \quad & \mathrm{tr}(LZ) + \frac{c}{2}\sum_{(i,j)\in\mathcal{T}} \varepsilon_{i,j}^2 \qquad (1) \\ \text{s. t.} \quad & \forall (i,j)\in\mathcal{T},\ Z_{i,j}T_{i,j} \geq 1-\varepsilon_{i,j},\ \varepsilon_{i,j}\geq 0 \\ & Z \succeq 0 \end{aligned}$$

The first term in the above objective function plays a similar role as the manifold regularization (Belkin & andd P. Niyogi, 2004), where the graph Laplacian is used to regularize the classification results. The second term in the above measures the inconsistency between the learned kernel matrix Z and the given pairwise constraints. Note that unlike the formulation in (Hoi et al., 2007), we change $\varepsilon_{i,j}$ in the loss function to $\varepsilon_{i,j}^2$. This modification is specifically designed for active kernel learning, and the reason will be clear later. It is not difficult to see that the problem in (1) is a semi-definite programming problem, and therefore can be solved by the standard software package, such as SeDuMi (Sturm, 1999).

2.2. Min-max Framework for Active Kernel Learning

The simplest approach toward active kernel learning is to follow the uncertainty principle of active learning, and to select the example pair $(\mathbf{x}_i, \mathbf{x}_j)$ with the least $|Z_{i,j}|$ [1]. However, as already discussed in the introduction section, the key problem with this simple approach is that the example pairs with the least $|Z_{i,j}|$ may not necessarily be the the most informative ones, and therefore may not result in an efficient learning of the kernel matrix. To address this problem, we propose a min-max framework for active kernel learning that measures the informativeness of an example pair by how significantly the selected example pair will affect the target kernel matrix.

Consider an unlabeled example pair $(\mathbf{x}_k, \mathbf{x}_l) \notin \mathcal{T}$. To measure how this example will affect the kernel matrix, we consider the kernel learning problem with the additional example pair $(\mathbf{x}_k, \mathbf{x}_l)$ labeled by $y \in \{-1, +1\}$, i.e.,

$$\begin{aligned} \min_{Z,\varepsilon} \quad & \mathrm{tr}(LZ) + \frac{c}{2}\sum_{(i,j)\in\mathcal{T}} \varepsilon_{i,j}^2 + \frac{c}{2}\varepsilon_{k,l}^2 \qquad (2) \\ \text{s. t.} \quad & T_{i,j}Z_{i,j} \geq 1-\varepsilon_{i,j},\ \forall (i,j)\in\mathcal{T} \\ & yZ_{k,l} \geq 1-\varepsilon_{k,l},\ Z\succeq 0 \end{aligned}$$

Let us denote by $\omega((k,l),y)$ the optimal value of the above optimization problem. Intuitively, $\omega((k,l),y)$ measures the overall classification accuracy with the additional example pair $(\mathbf{x}_k, \mathbf{x}_l)$ labeled by y. To further measure the informativeness of example pair $(\mathbf{x}_k, \mathbf{x}_l)$, we introduce the quantity $\kappa(k,l)$ as follows

$$\kappa(k,l) = \max_{y\in\{-1,+1\}} \omega((k,l),y) \qquad (3)$$

Clearly, $\kappa(k,l)$ measures the worst classification error with the addition of example pair $(\mathbf{x}_k, \mathbf{x}_l)$. Overall, $\kappa(k,l)$ measures how the example pair $(\mathbf{x}_k, \mathbf{x}_l)$ will affect the overall objective function, which indirectly measures the impact of the example pair on the target kernel matrix. To see this, consider an example pair $(\mathbf{x}_k, \mathbf{x}_l)$ that is highly consistent with the current kernel Z with label y (i.e., $Z_{k,l}y \geq 1$). According to the definition $\kappa(k,l)$, we would expect a large $\kappa(k,l)$ for pair $(\mathbf{x}_k, \mathbf{x}_l)$. This is because by assigning a label $-y$ to example pair $(\mathbf{x}_k, \mathbf{x}_l)$, we expect a large classification error and therefore large $\kappa(k,l)$. Hence, we use $\kappa(k,l)$ to measure the *uninformativeness* of example pairs, i.e., the smaller $\kappa(k,l)$, the less informative the example pair is. Therefore, the most informative example pair is found by minimizing $\kappa(k,l)$, i.e.,

$$(k,l)^* = \arg\min_{(k,l)\notin\mathcal{T}} \max_{t\in\{-1,+1\}} \omega((k,l),t) \qquad (4)$$

Directly solving the min-max optimization problem in (4) is challenging because function $\omega((k,l),t)$ is defined implicitly by the optimization problem in (2). The following theorem allows us to significantly simplify the optimization problem in (4)

Theorem 1. *The optimization problem in (4) is equivalent to the following optimization problem*

$$\begin{aligned} \min_{Z,\varepsilon,(k,l)\notin\mathcal{T}} \quad & \mathrm{tr}(LZ) + \frac{c}{2}\sum_{(i,j)\in\mathcal{T}} \varepsilon_{i,j}^2 + \frac{c}{2}\varepsilon_{k,l}^2 \qquad (5) \\ s.\ t. \quad & T_{i,j}Z_{i,j} \geq 1-\varepsilon_{i,j}, \varepsilon_{i,j}\geq 0,\ \forall (i,j)\in\mathcal{T} \\ & \varepsilon_{k,l} \geq 1+|Z_{k,l}|,\ Z\succeq 0 \end{aligned}$$

Proof. The above theorem follows the fact that the solution $y^* \in \{-1,+1\}$ maximizing $\omega((k,l),y)$ is $y^* = -\mathrm{sign}(Z_{k,l})$. This fact allows us to remove the maximization within (4) and obtain the result in the theorem. □

The following corollary shows that the approach of selecting the example pair with the least $|Z_{k,l}|$ indeed corresponds to a special solution for the problem in (5).

Corollary 2. *The optimal solution to (5) with fixed kernel matrix Z is the example pair with the least $|Z_{k,l}|$, i.e.,*

$$(k,l)^* = \arg\min_{(k,l)\notin\mathcal{T}} |Z_{k,l}|$$

[1] Here we assume that $Z_{i,j} > 0$ when $\mathbf{x}_i$ and $\mathbf{x}_j$ are likely to share the same class, and $Z_{i,j} < 0$ when $\mathbf{x}_i$ and $\mathbf{x}_j$ are likely to be assigned to different classes

Proof. By fixing Z, the problem in (5) is simplified as

$$\min_{(k,l)\notin\mathcal{T}} \quad \varepsilon_{k,l}^2 \quad \text{s. t.} \quad \varepsilon_{k,l} \geq 1 + |Z_{k,l}|$$

It is easy to see that the optimal solution to the above problem is the example pair with the least $|Z_{k,l}|$. □

Note that a similar observation is described in the study (Chen & Jin, 2007) for standard active learning.

2.3. Algorithm

The straightforward approach toward the optimization problem in (5) is to try out every example pair $(\mathbf{x}_k, \mathbf{x}_l) \notin \mathcal{T}$. Evidently, this approach will not scale well when the number of example pairs is large.

Our first attempt toward solving the problem (5) is to turn it into a continuous optimization problem. To this purpose, we introduce variable $p_{k,l} \geq 0$ to represent the probability of selecting the example pair $(k,l) \notin \mathcal{T}$. Using this notation, we have the optimization problem in (5) rewritten as

$$\begin{aligned} \min_{Z\succeq 0, p, \varepsilon} \quad & \mathrm{tr}(LZ) + \frac{c}{2}\sum_{(i,j)\in\mathcal{T}} \varepsilon_{i,j}^2 + \frac{c}{2}\sum_{(k,l)\notin\mathcal{T}} p_{k,l}\varepsilon_{k,l}^2 \quad (6) \\ \text{s. t.} \quad & T_{i,j}Z_{i,j} \geq 1 - \varepsilon_{i,j},\ \forall (i,j) \in \mathcal{T} \\ & \varepsilon_{k,l} - 1 \geq Z_{k,l} \geq 1 - \varepsilon_{k,l}, \forall (k,l) \notin \mathcal{T} \\ & \sum_{(k,l)\notin\mathcal{T}} p_{k,l} \geq 1,\ p_{k,l} \geq 0, \forall (k,l) \notin \mathcal{T} \end{aligned}$$

The following theorem shows the relationship between (6) and (5).

Theorem 3. *Any global optimal solution to (5) is also a global optimal solution to (6).*

The proof of the above theorem can be found in Appendix A.

Unfortunately, the optimization problem in (6) is non-convex because of the term $p_{k,l}\varepsilon_{k,l}^2$. It is therefore difficult to find the global optimal solution for (6). In order to turn (6) into a convex optimization problem, we view the constraint $\sum_{(k,l)\notin\mathcal{T}} p_{k,l} \geq 1$ as a bound for the arithmetic mean of $p_{k,l}$, i.e.,

$$\frac{1}{m}\sum_{(k,l)\notin\mathcal{T}} p_{k,l} \geq \frac{1}{m}$$

where $m = |\{(k,l)|(k,l) \notin \mathcal{T}\}|$. We then relax this constraint by the harmonic mean of $p_{k,l}$, i.e.,

$$\frac{m}{\sum_{(k,l)\notin\mathcal{T}} p_{k,l}^{-1}} \geq \frac{1}{m}, \text{ or } \sum_{(k,l)\notin\mathcal{T}} p_{k,l}^{-1} \leq m^2$$

The above relaxation is based on the property that a harmonic mean is no larger than an arithmetic mean. By replacing the constraint $\sum_{(k,l)\notin\mathcal{T}} p_{k,l} \leq 1$ with (7), we have (6) relaxed into the following optimization problem

$$\begin{aligned} \min_{Z\succeq 0, p, \varepsilon} \quad & \mathrm{tr}(LZ) + \frac{c}{2}\sum_{(i,j)\in\mathcal{T}} \varepsilon_{i,j}^2 + \frac{c}{2}\sum_{(k,l)\notin\mathcal{T}} p_{k,l}\varepsilon_{k,l}^2 \quad (7) \\ \text{s. t.} \quad & T_{i,j}Z_{i,j} \geq 1 - \varepsilon_{i,j}, \varepsilon_{i,j} \geq 0,\ \forall (i,j) \in \mathcal{T} \\ & \varepsilon_{k,l} - 1 \geq Z_{k,l} \geq 1 - \varepsilon_{k,l}, \forall (k,l) \notin \mathcal{T} \\ & \sum_{(k,l)\notin\mathcal{T}} p_{k,l}^{-1} \leq m^2,\ 0 \leq p_{k,l} \leq 1, \forall (k,l) \notin \mathcal{T} \end{aligned}$$

By defining variable $h_{k,l} = p_{k,l}^{-1}$, we have

$$\begin{aligned} \min_{Z\succeq 0, h, \varepsilon} \quad & \mathrm{tr}(LZ) + \frac{c}{2}\sum_{(i,j)\in\mathcal{T}} \varepsilon_{i,j}^2 + \frac{c}{2}\sum_{(k,l)\notin\mathcal{T}} \frac{\varepsilon_{k,l}^2}{h_{k,l}} \quad (8) \\ \text{s. t.} \quad & T_{i,j}Z_{i,j} \geq 1 - \varepsilon_{i,j}, \varepsilon_{i,j} \geq 0,\ \forall (i,j) \in \mathcal{T} \\ & \varepsilon_{k,l} - 1 \geq Z_{k,l} \geq 1 - \varepsilon_{k,l}, \forall (k,l) \notin \mathcal{T} \\ & \sum_{(k,l)\notin\mathcal{T}} h_{k,l} \leq m^2,\ h_{k,l} \geq 1, \forall (k,l) \notin \mathcal{T} \end{aligned}$$

Notice that constraint $0 \leq p_{k,l} \leq 1$ is transferred into $h_{k,l} \geq 1$. The following theorem shows the property of the formulation in (8)

Theorem 4. *We have the following properties for (8)*

- *(8) is a semi-definite programming (SDP) problem.*
- *Any feasible solution to (8) is also a feasible solution to (5) with $p_{k,l} = h_{k,l}^{-1}$, and the optimal value for (6) is upper bounded by that for (8).*

The proof is provided in Appendix B. Note that using $\varepsilon_{i,j}^2$ instead of $\varepsilon_{i,j}$ for the loss function is key to turning (6) into a convex optimization problem. The second property stated in Theorem 4 indicates that by minimizing (8), we guarantee a small value for the objective function in (6).

The following theorem shows the dual problem of (8), which is the key to the efficient computation.
