Figure 1. "Hinton diagram" of the average learned hyperparameters by board position for the TAHN NORM kernel in Capture Go. Filled boxes correspond to positive weights and white boxes to negative; box area is proportional to the weight. The parameterization generated by EP-RKRL shows a significant amount of structure, biasing play towards moves that surround single stones.

To further elucidate this result, a second trial was run using the same kernel class, but with only two hyperparameters, corresponding to the positive and negative parameter settings observed above. This *translation invariant* TANH NORM kernel $k(\mathbf{x}, \mathbf{x}') = \tanh(\sum_{i=0}^{25} w_{i \bmod 2}(x_i - x'_i)^2 - 1)$ can express the same alternating positive and negative weights in a more compact form, thus trading off generality compared to the original parameterization. Under the same experimental setup, the translation invariant kernel only reaches an asymptotic performance of 88.6% wins, compared to 94.5% wins with the more general parameterization ($p < 10^{-7}$). Furthermore, the resulting dictionary size of the translation invariant kernel is 32.4, significantly larger than more general parameterization (17.4; $p < 0.001$). The general TANH NORM kernel parameterization also outperforms a variant with built-in rotational symmetry. The *rotationally symmetric* TANH NORM kernel obtains asymptotic performance of 89.3% wins ($p < 10^{-4}$). Taken together these results highlight some of the difficulties of manually building in prior knowledge.

6. Related and Future Work

This paper has presented an efficient and conceptually simple online method for selecting kernels in Bayesian RL. There is a growing body of model selection literature in machine learning and statistics, both on theory and applications, e.g. (Hastie et al., 2001; Seeger, 2001). In RL, model selection has been performed previously using regularization (Jung & Polani, 2006; Loth et al., 2007) and evolutionary methods (Whiteson & Stone, 2006). RKRL is most similar to the latter approach, differing in its use of GPs, ability to save training data across lineages, and simpler hyperparameter optimization procedure.

There are several interesting areas of future work. First, RKRL can be naturally applied to more general kernel

classes, e.g. the Matérn kernels, that admit many basic kernels as special cases (Genton, 2002). In particular, the tradeoff between kernel class complexity and performance should be explored.

Second, the learned kernel parameterizations acquired under one dictionary do not perform well under different dictionaries, indicating that the dictionaries themselves can be thought of as hyperparameters to be optimized. Developing such a theory of nonparametric sparsification in RL may lead to significantly better value function approximations.

Third, it is possible to derive a *full kernel-replacing* procedure where all covariance function evaluations share the same accumulated learning, updated after every fitness evaluation of every individual. Such an approach would further reduce the sample complexity of RKRL, and also makes possible the use of *Bayesian Model Averaging* techniques within a single learning agent, i.e. averaging over an ensemble of GP value functions weighted by their predictive likelihoods (Hastie et al., 2001).

Finally, there is a deep connection between action kernels and the concept of Relocatable Action Models (Leffler et al., 2007). It may be possible to cast the latter in terms of state-independent prior covariance functions, yielding a powerful framework for model selection.

7. Conclusion

This paper developed RKRL, a simple online procedure for improving the performance of Gaussian process temporal difference learning by automatically selecting the prior covariance function. In several empirical trials, RKRL yielded significantly higher asymptotic reward than the best hand-picked parameterizations for common covariance functions, even in cases where a large number of hyperparameters must be adapted. Furthermore, the learned covariance functions exhibit highly structured knowledge of the task that would have been difficult to build in *a priori* without significant knowledge of the domain. Overall these initial results are promising, and suggest that leveraging work in statistical model selection will significantly improve online learning.

Abstract

The dynamic hierarchical Dirichlet process (dHDP) is developed to model the time-evolving statistical properties of sequential data sets. The data collected at any time point are represented via a mixture associated with an appropriate underlying model, in the framework of HDP. The statistical properties of data collected at consecutive time points are linked via a random parameter that controls their probabilistic similarity. The sharing mechanisms of the time-evolving data are derived, and a relatively simple Markov Chain Monte Carlo sampler is developed. Experimental results are presented to demonstrate the model.

1. Introduction

The Dirichlet process (DP) mixture model (Escobar & West, 1995) has been widely used to perform density estimation and clustering, by generalizing finite mixture models to (in principle) infinite mixtures. In order to "share statistical strength" across different groups of data, the hierarchical Dirichlet process (HDP) (Teh et al., 2005) has been proposed to model the dependence among groups through sharing the same set of discrete parameters ("atoms"), and the mixture weights associated with different atoms are varied as a function of the data group. In the HDP, it is assumed that the data groups are exchangeable. However, in many real applications, such as seasonal market analysis and gene investigation for disease, data are measured in a sequential manner, and there is information in this temporal character that should ideally be exploited; this violates the aforementioned assumption of exchangeability.

Developing models for time-evolving data has recently been the focus of significant interest, and researchers have proposed various solutions directed toward specific applications. An early example is the order-based dependent DP (Griffin & Steel, 2006), in which the model is time-reversible but is not Markovian, and it requires one to specify how the mixture weights change through time. Another related work is the time-varying Dirichlet process mixture model (Caron et al., 2007) based on a modified Polya urn scheme (Blackwell & MacQueen, 1973), implemented by changing the number and locations of clusters over time. This method is easy to understand intuitively but has computational challenges for large data sets. To examine the temporal dynamics of scientific topics, latent Dirichlet allocation (Blei et al., 2003) (Griffiths & Steyvers, 2004) has been used as a generative model for analysis of documents. In order to explicitly model the dynamics of the underlying topics, Blei (Blei & Lafferty, 2006) proposed a dynamic topic model, in which the parameter at the previous time $t-1$ is the expectation for the distribution of the parameter at the next time t, and the correlation of the samples at adjacent times is controlled through adjusting the variance of the conditional distribution. Unfortunately, the non-conjugate form of the conditional distribution requires approximations in the model inference.

Recently Dunson (Dunson, 2006) proposed a Bayesian dynamic model to learn the latent trait distribution through a mixture of DPs, in which the latent variable density changes dynamically in location and shape across levels of predictors. This dynamic structure is considered in this paper to extend HDP to incorpo-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

rate time dependence, and has the following features: (*i*) two data samples drawn at proximate times have a higher probability of sharing the same underlying model parameters (atoms) than parameters drawn at disparate times; and (*ii*) there is a possibility that temporally distant data samples may also share model parameters, thereby accounting for possible distant repetition in the data.

2. Dynamic HDP

2.1. Background

A Dirichlet process is a measure on a measure G and is parameterized as $G \sim DP(\alpha_0, G_0)$, in which G_0 is a base measure and α_0 is a positive "precision" parameter. To provide an explicit form for a G drawn from $DP(\alpha_0, G_0)$, Sethuraman (Sethuraman, 1994) developed a stick-breaking construction:

$$G = \sum_{k=1}^{\infty} \pi_k \delta_{\boldsymbol{\theta}_k^*}, \quad \pi_k = \tilde{\pi}_k \prod_{i=1}^{k-1} (1 - \tilde{\pi}_i) \tag{1}$$

where $\{\boldsymbol{\theta}_k^*\}_{k=1}^{\infty}$ represent a set of atoms drawn i.i.d. from G_0 and $\{\pi_k\}_{k=1}^{\infty}$ represent a set of weights, with the constraint $\sum_{k=1}^{\infty} \pi_k = 1$; each $\tilde{\pi}_k$ is drawn i.i.d. from $Be(1, \alpha_0)$. According to the construction in (1), a draw G from a $DP(\alpha_0, G_0)$ is discrete with probability one. Based on this important property, Teh (Teh et al., 2005) proposed a hierarchical Dirichlet process (HDP) to link the group-specific Dirichlet processes, learning the models jointly across multiple data sets.

Assume we have J groups of data and the j^{th} data set (group) is denoted as $\{x_{j,i}\}_{i=1,\ldots,N_j}$. For each of these data sets, $x_{j,i}$ is drawn from the model $x_{j,i} \overset{ind}{\sim} F(\boldsymbol{\theta}_{j,i})$ with parameters $\boldsymbol{\theta}_{j,i} \overset{iid}{\sim} G_j$, and the parameters $\{\boldsymbol{\theta}_{j,i}\}_{i=1,\ldots,N_j}$ are likely to assume the atoms $\boldsymbol{\theta}_k^*$ for which the associated sticks $\pi_{j,k}$ are large, as a consequence of the form of G_j given by (1); for the J data sets, different group-specific G_j are drawn from $DP(\alpha_{j0}, G_0)$, in which G_0 is drawn from another DP. The generative model for HDP is represented as:

$$\begin{gathered} x_{j,i} \overset{ind}{\sim} F(\boldsymbol{\theta}_{j,i}) \\ \boldsymbol{\theta}_{j,i} \overset{iid}{\sim} G_j \\ G_j \overset{ind}{\sim} DP(\alpha_{j0}, G_0) \\ G_0 \sim DP(\gamma, H) \end{gathered} \tag{2}$$

where $j = 1, \ldots, J$ and $i = 1, \ldots, N_j$.

Under this hierarchical structure, not only can different observations $x_{j,i}$ and $x_{j,i'}$ in the same group share the same parameters $\boldsymbol{\theta}^*$ based on the stick weights represented by G_j, but also the observations across different groups might share parameters as a consequence of the discrete form of G_0 (all G_j are composed of the same set of atoms $\{\boldsymbol{\theta}_k^*\}_{k=1}^{\infty}$). The clusters in each group j, assumed by the set $\{\boldsymbol{\theta}_{j,i}\}_{i=1,\ldots,N_j}$, are inferred via the posterior density function on the parameters, with the likelihood function selecting the set of discrete parameters $\{\boldsymbol{\theta}_k^*\}_{k=1}^{\infty}$ most consistent with the data $\{x_{j,i}\}_{i=1,\ldots,N_j}$. Meanwhile, clusters (and, hence, associated cluster parameters $\{\boldsymbol{\theta}_k^*\}_{k=1}^{\infty}$) are shared across multiple data sets, as appropriate.

Although the HDP introduces a dependency between the J groups, the data sets are assumed exchangeable. However, in many applications, the data may be collected sequentially, and one may have a prior belief that sharing of data is more probable when the data sets are collected at similar points in time. The purpose of this paper is to extend the HDP to account for such temporal information.

Before proceeding, it will prove useful to consider an alternative form of the HDP model, as derived in (Teh et al., 2005). Specifically, each draw G_j may be expressed as:

$$\begin{gathered} G_j = \sum_{k=1}^{\infty} \pi_{j,k} \delta_{\boldsymbol{\theta}_k^*} \\ \boldsymbol{\pi}_j \overset{ind}{\sim} DP(\alpha_{0j}, \boldsymbol{\beta}) \\ \boldsymbol{\beta} \sim Stick(\gamma) \\ \boldsymbol{\theta}_k^* \overset{iid}{\sim} H \end{gathered} \tag{3}$$

where $Stick(\gamma)$ stochastically generates an infinite set of sticks $\{\beta_1, \beta_2, \ldots\}$, based on a stick-breaking process of the form in (1), here with parameter γ, satisfying the constraint $\sum_{i=1}^{\infty} \beta_i = 1$.

2.2. Bayesian Dynamic Structure

Similar to HDP, we again consider J data sets but now using an explicit assumption that the data sets are collected sequentially, with $\{x_{1,i}\}_{i=1,\ldots,N_1}$ collected first, $\{x_{2,i}\}_{i=1,\ldots,N_2}$ collected second, and with $\{x_{J,i}\}_{i=1,\ldots,N_J}$ collected last. Since our assumption is that a time evolution exists between adjacent data groups, the distribution G_{j-1}, from which $\{\boldsymbol{\theta}_{j-1,i}\}_{i=1,\ldots,N_{j-1}}$ are drawn, is likely related to G_j, from which $\{\boldsymbol{\theta}_{j,i}\}_{i=1,\ldots,N_j}$ are drawn.

To specify explicitly the dependence between G_{j-1} and G_j, Dunson (Dunson, 2006) proposed a Bayesian dynamic mixture DP (DMDP), in which G_j shares features with G_{j-1} but some innovation may also occur. The DMDP has the drawback that mixture components can only be added over time, so that one ends up with more components at later times as an artifact of the model.

In the dHDP, we have

$$G_j = (1 - \tilde{w}_{j-1})G_{j-1} + \tilde{w}_{j-1}H_{j-1} \tag{4}$$

where $G_1 \sim DP(\alpha_{01}, G_0)$, H_{j-1} is called an innovation distribution drawn from $DP(\alpha_{0j}, G_0)$, and $\tilde{w}_{j-1} \sim Be(a_{w(j-1)}, b_{w(j-1)})$. In this way, G_j is modified from G_{j-1} by introducing a new innovation distribution H_{j-1}, and the random variable $\tilde{w}_{j-1}$ controls the probability of innovation (*i.e.*, it defines the mixture weights). As a result, the relevant atoms adjust with time, and it is probable that proximate data will share the same atoms, but with the potential for transient innovation.

Additionally, we assume that $G_0 \sim DP(\gamma, H)$ as in the HDP to enforce that G_0 is discrete, which manifests another important aspect of the dynamic HDP: the same atoms are used for *all* G_j, but with different time-evolving weights. Consequently, the model encourages sharing between temporally proximate data, but it is also possible to share between data sets widely separated in time.

Providing now more model details, the discrete base distribution drawn from $DP(\gamma, H)$ may be expressed as:

$$G_0 = \sum_{k=1}^{\infty} \beta_k \delta_{\boldsymbol{\theta}_k^*} \tag{5}$$

where $\{\boldsymbol{\theta}_k^*\}_{k=1,2,\ldots,\infty}$ are the global parameter components (atoms), drawn independently from the base distribution H and $\{\beta_k\}_{k=1,2,\ldots,\infty}$ are drawn from a stick-breaking process $\boldsymbol{\beta} \sim Stick(\gamma)$, defined as:

$$\beta_k = \tilde{\beta}_k \prod_{l<k}(1 - \tilde{\beta}_l) \qquad \tilde{\beta}_k \overset{iid}{\sim} Be(1, \gamma) \tag{6}$$

We also have J groups of data. G_j represents the prior for the mixture distribution associated with the global components in group j, H_{j-1} represents the associated prior for the innovation mixture distribution, and this yields the explicit priors used in (4):

$$\begin{gathered} G_1 = \sum_{k=1}^{\infty} \pi_{1,k} \delta_{\boldsymbol{\theta}_k^*}, H_1 = \sum_{k=1}^{\infty} \pi_{2,k} \delta_{\boldsymbol{\theta}_k^*}, \ldots, \\ H_{J-1} = \sum_{k=1}^{\infty} \pi_{J,k} \delta_{\boldsymbol{\theta}_k^*} \end{gathered} \tag{7}$$

where, analogous to the discussion at the end of Section 2.1, the different weights $\boldsymbol{\pi}_j$ are independent given $\boldsymbol{\beta}$ since $G_1, H_1, \ldots, H_{J-1}$ are independent given G_0; the relationship between $\boldsymbol{\pi}_j$ and $\boldsymbol{\beta}$ is proven (Teh et al., 2005) to be

$$\boldsymbol{\pi}_j | \alpha_{0j}, \boldsymbol{\beta} \sim DP(\alpha_{0j}, \boldsymbol{\beta}) \tag{8}$$

To further develop the dynamic relationship from G_1 to G_J, we extend the mixture structure in (4) from group to group:

$$\begin{aligned} G_j &= (1 - \tilde{w}_{j-1})G_{j-1} + \tilde{w}_{j-1}H_{j-1} \\ &= \prod_{l=1}^{j-1}(1 - \tilde{w}_l)G_1 + \sum_{l=1}^{j-1}\{\prod_{m=l+1}^{j-1}(1 - \tilde{w}_m)\}\tilde{w}_l H_l \\ &= w_{j1}G_1 + w_{j2}H_1 + \ldots + w_{jj}H_{j-1} \end{aligned} \tag{9}$$

where $w_{jl} = \tilde{w}_{l-1}\prod_{m=l}^{j-1}(1 - \tilde{w}_m)$, for $l = 1, 2, \ldots, j$, with $\tilde{w}_0 = 1$. It can be easily verified that $\sum_{l=1}^{j} w_{jl} = 1$ for each $\mathbf{w}_j$, which is the prior probability that the data in group j will be drawn from the mixture distribution: $G_1, H_1, \ldots, H_{j-1}$. If all $\tilde{w}_j = 0$, all of the groups share the same mixture distribution G_1 and the model reduces to a Dirichlet mixture model, and if all $\tilde{w}_j = 1$ the model reduces to the HDP. Therefore, the dynamic HDP is more general than both DP and HDP, with each a special case. A visual representation of the model is depicted in Figure 1.

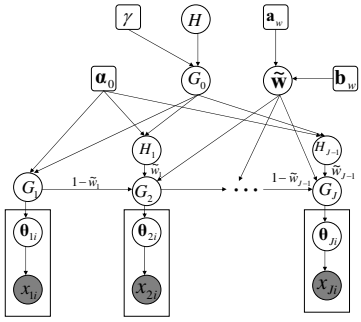

Figure 1. General graphical model for the dynamic HDP.

According to (9), the observation $x_{j,i}$ will choose a mixture distribution from $\boldsymbol{\pi}_{1:j}$ based on $Mult(\mathbf{w}_j)$ to be drawn from the global parameter components $\{\boldsymbol{\theta}_k^*\}_{k=1}^{\infty}$. We let $r_{j,i}$ be a variable to indicate which mixture distribution is taken from $\boldsymbol{\pi}_{1:j}$ to draw the observation $x_{j,i}$; $z_{j,i}$ is a parameter component indicator variable. An alternative form of the dHDP model is represented as:

$$\begin{array}{cc} \boldsymbol{\theta}_k^* | H \sim H, & \boldsymbol{\beta} | \gamma \sim Stick(\gamma) \\ \tilde{w}_j | a_{wj}, b_{wj} \sim Be(\tilde{w}_j | a_{wj}, b_{wj}), & r_{j,i} | \tilde{\mathbf{w}} \sim \mathbf{w}_j \\ \boldsymbol{\pi}_j | \alpha_{0j}, \boldsymbol{\beta} \sim DP(\alpha_{0j}, \boldsymbol{\beta}), & z_{j,i} | \boldsymbol{\pi}_{1:j}, r_{j,i} \sim \boldsymbol{\pi}_{r_{j,i}} \\ x_{j,i} | z_{j,i}, (\boldsymbol{\theta}_k^*)_{k=1}^{\infty} \sim F(\boldsymbol{\theta}_{z_{j,i}}^*), & \end{array} \tag{10}$$

and a graphical representation is shown in Figure 2, in which we add a gamma prior for γ and for the components of the vector $\boldsymbol{\alpha}_0$: $Pr(\gamma) = Ga(\gamma; \gamma_{01}, \gamma_{02})$ and $Pr(\boldsymbol{\alpha}_0) = \prod_{j=1}^{J} Ga(\alpha_{0j}; c_0, d_0)$. The form of the parametric model $F(\cdot)$ may be varied depending on the application.

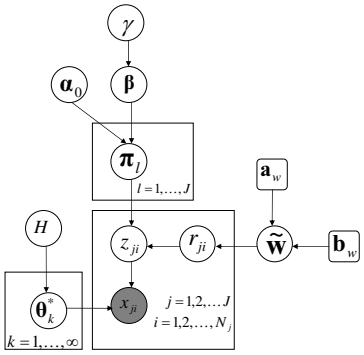

Figure 2. Graphical representation of the dHDP from a stick-breaking view.

2.3. Sharing Properties

To see the mixture structure in a discrete partition space $\mathcal{A} = (A_1, \ldots, A_K)$, we consider

$$\begin{aligned} &G_j(A_1,\ldots,A_K)|G_{j-1},\tilde{w}_{j-1} \sim \\ &(1-\tilde{w}_{j-1})G_{j-1}(A_1,\ldots,A_K)+\tilde{w}_{j-1}H_{j-1}(A_1,\ldots,A_K) \\ &\triangleq G_{j-1}(A_1,\ldots,A_K)+\triangle_j(A_1,\ldots,A_K) \end{aligned} \tag{11}$$

where $\triangle_j(A_1,\ldots,A_K) = \tilde{w}_{j-1}\{H_{j-1}(A_1,\ldots,A_K) - G_{j-1}(A_1,\ldots,A_K)\}$ is the random deviation from G_{j-1} to G_j.

Theorem 1. Given any discrete partition $\mathcal{A}$, we have:

$$\begin{aligned} &E\{\triangle_j(\mathcal{A})|G_{j-1},\tilde{w}_{j-1},H,\gamma,\alpha_{0j}\} \\ =&\tilde{w}_{j-1}\{H(\mathcal{A})-G_{j-1}(\mathcal{A})\} \end{aligned} \tag{12}$$

$$\begin{aligned} &V\{\triangle_j(\mathcal{A})|G_{j-1},\tilde{w}_{j-1},H,\gamma,\alpha_{0j}\} \\ =&\tilde{w}_{j-1}^2\frac{(1+\gamma+\alpha_{0j})H(\mathcal{A})(1-H(\mathcal{A}))}{(1+\alpha_{0j})(1+\gamma)} \end{aligned} \tag{13}$$

According to Theorem 1, given the previous mixture distribution G_{j-1}, the expectation of the deviation from G_{j-1} to G_j is controlled by $\tilde{w}_{j-1}$. Meanwhile, the variance of the deviation is both related with $\tilde{w}_{j-1}$ and the precision parameters γ, α_{0j}. To consider limiting cases, we observe the following:

- if $\tilde{w}_{j-1} \to 0$, $G_j = G_{j-1}$;
- if $G_{j-1} \to H$, $E(G_j(\mathcal{A})|G_{j-1},\tilde{w}_{j-1},H,\gamma,\alpha_{0j}) = G_{j-1}(\mathcal{A})$;
- if $\gamma \to \infty$ and $\alpha_{0j} \to \infty$, $V(\triangle_j(\mathcal{A})|G_{j-1},\tilde{w}_{j-1},H,\gamma,\alpha_{0j}) \to 0$.

These limiting cases yield insights on the underlying dependence between adjacent groups.

Theorem 2. The correlation coefficient of the distributions between two adjacent groups G_{j-1} and G_j for $j = 2,\ldots,J$ is

$$\begin{aligned} &Corr(G_{j-1},G_j) \\ =&\frac{E\{G_j(\mathcal{A})G_{j-1}(\mathcal{A})\}-E\{G_j(\mathcal{A})\}E\{G_{j-1}(\mathcal{A})\}}{[V\{G_j(\mathcal{A})\}V\{G_{j-1}(\mathcal{A})\}]^{1/2}} \\ =&\frac{\sum_{l=1}^{j-1}\frac{w_{jl}w_{j-1,l}}{1+\alpha_{0l}}\cdot\frac{\alpha_{0l}+\gamma+1}{\gamma+1}}{[\sum_{l=1}^{j}\frac{w_{jl}^2}{1+\alpha_{0l}}\cdot\frac{\alpha_{0l}+\gamma+1}{\gamma+1}]^{1/2}[\sum_{l=1}^{j-1}\frac{w_{j-1,l}^2}{1+\alpha_{0l}}\cdot\frac{\alpha_{0l}+\gamma+1}{\gamma+1}]^{1/2}} \end{aligned} \tag{14}$$

To compare the similarity of two data groups, the correlation coefficient defined in Theorem 2 can be calculated from the posterior expectation of $\mathbf{w}$, $\boldsymbol{\alpha}_0$ and γ as a local similarity measure.

2.4. Posterior Computation

A modification of the block Gibbs sampler (Ishwaran & James, 2001) is proposed for dHDP inference. Since in practice the $\{\pi_k\}_{k=1}^{\infty}$ in (1) diminish quickly with increasing k, a truncated stick-breaking process (Ishwaran & James, 2001) is employed here, with a large truncation level K, to approximate the infinite stick breaking process. In the dHDP, the second level of DPs associated with the dynamic structure is the only part different from HDP (see Figure 2). Due to the limited space, we only give the conditional posterior distributions for $\tilde{\mathbf{w}}$, $\tilde{\boldsymbol{\pi}}$, $\mathbf{r}$ and $\mathbf{z}$.

The conditional distribution of $\tilde{w}_l$, for $l = 1,\ldots,J-1$ has the simple form:

$$(\tilde{w}_l|\cdots) \sim Be(a_w + \sum_{j=l+1}^{J} n_{j,l+1}, b_w + \sum_{j=l+1}^{J}\sum_{h=1}^{l} n_{jh}) \tag{15}$$

where $n_{jh} = \sum_{i=1}^{N_j}\delta(r_{ji} = h)$. In (15) and in the results that follow, for simplicity, the distributions $Be(a_{wj}, b_{wj})$ are set with fixed parameters $a_{wj} = a_w$ and $b_{wj} = b_w$ for all time samples.

The conditional distribution of $\tilde{\pi}_{lk}$, for $l = 1,\ldots,J$ and $k = 1,\ldots,K$, is updated under the conjugate prior: $\tilde{\pi}_{lk} \sim Be(\alpha_{0,l}\beta_k, \alpha_{0,l}(1-\sum_{m=1}^{k}\beta_m))$, which is specified in (Teh et al., 2005). Then the conditional posterior of $\tilde{\pi}_{lk}$ has the form

$$\begin{aligned} &(\tilde{\pi}_{lk}|\cdots) \sim Be(\alpha_{0l}\beta_k + \sum_{j=1}^{J}\sum_{i=1}^{N_j}\delta(r_{ji}=l,z_{ji}=k), \\ &\alpha_{0l}(1-\sum_{l=1}^{k}\beta_l) + \sum_{j=1}^{J}\sum_{i=1}^{N_j}\sum_{k'=k+1}^{K}\delta(r_{ji}=l,z_{ji}=k')) \end{aligned} \tag{16}$$

The update of the indicator variables r_{ji} and z_{ji}, for $j = 1,\ldots,J$ and $i = 1,\ldots,N_j$ are completed by generating samples from multinomial distributions with

entries as follows:

$$Pr(r_{ji} = l|\cdots) \propto \tilde{w}_{l-1} \prod_{m=l}^{j-1}(1-\tilde{w}_m) \cdot \tilde{\pi}_{lz_{ji}} \prod_{q=1}^{z_{ji}-1}(1-\tilde{\pi}_{lq}) \cdot Pr(x_{ji}|\boldsymbol{\theta}^*_{z_{ji}}) \tag{17}$$

where $l = 1, \ldots, j$. The posterior probability $Pr(r_{ji} = l)$ is normalized so that $\sum_{l=1}^{j} Pr(r_{ji} = l) = 1$.

$$Pr(z_{ji} = k|\cdots) \propto \tilde{\pi}_{r_{ji}k} \prod_{k'=1}^{k-1}(1-\tilde{\pi}_{r_{ji}k'}) \cdot Pr(x_{ji}|\boldsymbol{\theta}^*_k) \tag{18}$$

where $k = 1, \ldots, K$ and the posterior is also normalized by a constant $\sum_{k=1}^{K} Pr(z_{ji} = k)$.

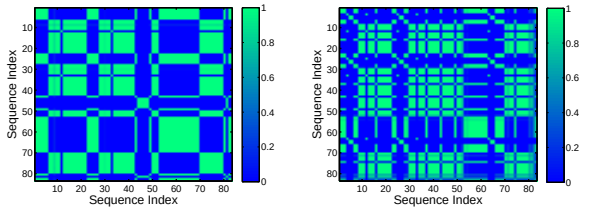
The remaining variables specified in (10) are sampled in the same ways as in HDP (Teh et al., 2005). The component parameters $\boldsymbol{\theta}^*_k$ for $k = 1, \ldots, K$ are considered for different model forms depending on the specific applications. For the results that follow, it is of interest to consider a hidden Markov model (HMM) mixture (Qi et al., 2007) and Gaussian mixture model (GMM), in which $\boldsymbol{\theta}^*_k$ respectively represent the state-transition matrix, the observation matrix, the initial-state distribution for the HMM and the mean vector and covariance matrix for GMM. For more details about sampling for such models, see (Qi et al., 2007) and (Escobar & West, 1995). The Gibbs sampling algorithm was tested carefully under different initializations and the diagnostic method in (Raftery & Lewis, 1992) is used to demonstrate rapid convergence and good mixing (for the results considered, convergence based on this method was observed for a burn-in of 200 samples, followed by a subsequent 4000 samples).

3. Experimental Results

3.1. Music Segmentation

It is of interest to segment music, to infer inter-relationships between different parts of a given piece, as well as between different pieces. Here we consider segmentation of music, where a given piece is divided into contiguous subsequences, with each subsequence modeled via a hidden Markov model (HMM). The dHDP model is useful in this application in enforcing the idea that contiguous subsequences are likely to be within the same music segment, and therefore are likely to share HMM parameters. However, when the segment changes, these changes are detected via innovation within the dHDP.

The music under consideration is the first movement "Largo - Allegro" from the Beethoven piano Sonata No. 17 (Newman, 1972). As is widely employed for analysis of such audio data, MFCC features are extracted and discretized with vector quatization (Qi et al., 2007); each of the aforementioned subsequences corresponds to a sequence of codewords (we here employ a discrete HMM). The basic form of the Bayesian representation of a discrete HMM is as discussed in (Qi et al., 2007). The piece is transformed into 4980 discrete symbols, divided into 83 subsequences of equal length (the codebook has 16 codes, and 8 states are employed for each HMM); each subsequence corresponds to 6 secs in the music. To model the time dependence between adjacent subsequences, each subsequence corresponds to one group in the dHDP HMM mixture and will choose one set of HMM parameters according to the corresponding mixture weights. In the dHDP framework, one subsequence can share the old DP mixture distributions with the previous ones or it might be drawn from an innovation DP mixture, which may be also shared by the following time series in a similar manner. To encourage that adjacent subsequences be shared, the prior for $\tilde{\mathbf{w}}$ is specified as $E(\tilde{\mathbf{w}}) < 0.5$. The product of most interest here is the segmentation of the music, with the specific HMM parameters of secondary importance.



(a) (b)

Figure 3. Similarity matrix $E(z'z)$ from HMM mixture modeling of the Sonata. (a) dHDP-HMM, (b) HDP-HMMs.

To represent the time dependence of the piece, the similarity measure $E(\mathbf{z}'\mathbf{z})$ (see $\mathbf{z}$ in Eq. (18)) is computed across each pair of subsequences, as shown in Figure 3, in which larger values represent higher probability of the two corresponding subsequences being shared during parameter inference. Based upon a discussion in (Newman, 1972), the movement alternates seeming peacefulness with sudden turmoil (1st-6th subsequences), after some time expanding into a haunting "storm" in which the peacefulness is lost (7th-21st subsequences). After the recurrence of the same pattern (22nd-42nd subsequences) and a small transition, the movement starts a long recitative section in a slow tone (53rd-69th subsequences). Then through the crescendo, previous disturbed tones come back again until the music goes to the peaceful epilogue

(after the 70th subsequence). See (Newman, 1972) for more details on the Sonata. This is deemed to be an interesting piece for study because it is well characterized in the music literature, as briefly summarized above, and because it is anticipated to have repeated segments over the length of the piece. In Figures 3(a) and (b) we compare the dHDP and HDP, respectively, the latter computed by fixing all $\tilde{\boldsymbol{w}} = 1$ in the dHDP model. The dHDP and HDP yield related results, but the former yields a smoother segmentation, in good agreement with the music theory discussed above.

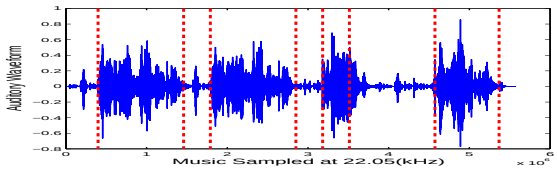


Figure 4. Segmentation of the Beethoven piano music from the dHDP HMMs (red dash lines represent segment positions and blue curves represent the auditory waveform).

Based on the results from the dHDP HMM, which effectively yields a model with smoothly time-evolving statistics, we segment the music and present the associated auditory waveform in Figure 4. By examining the waveform and the results in Figure 3, we note that the dHDP segments the music into dominant auditory phenomena, but it is less sensitive to noticeable but temporally localized events in the music, yielding a segmentation that is consistent with the music theory. By contrast, the HDP results in Figure 3(b) are evidently more sensitive to these local temporal bursts in the waveform.

3.2. Gene Expression Data

As a second example, we consider the time-evolving characteristics of gene-expression data, here for a Dengue virus study (Hibberd et al., 2006). Concerning a model for the gene-expression data at one time snapshot, Dunson (Dunson, 2006) proposed a latent response model based on a linear regression structure; we extend this model for time-evolving gene-expression data via dHDP (with comparison as well to HDP).

Assume $\mathbf{y}_{ji}$ is a feature vector with dimension p for $j = 1, \ldots, J$ and $i = 1, \ldots, N_j$ (index j corresponds to time, i represents a particular cell from which a sample is collected, and p denotes the number of genes being modeled). Each $\mathbf{y}_{ji}$ is represented as

$$\mathbf{y}_{ji} = \boldsymbol{\mu} + \boldsymbol{\lambda}\eta_{ji} + \boldsymbol{\varepsilon}_{ji} \tag{19}$$

where $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_p)'$ is the intercept vector and $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_p)'$ represents factor loadings. We define a hidden variable η_{ji} underlying the observation $\mathbf{y}_{ji}$ to be associated with the i^{th} sample at time t_j. The error term $\boldsymbol{\varepsilon}_{ji}$ is also a vector of dimension p and each coefficient $\varepsilon_{ji,d}$ is independently drawn from a Student-t distribution. To eliminate the problem of model identifiability, we incorporate the constraints that $\mu_1 = 0$ and $\lambda_1 = 1$, as (Dunson, 2006) discusses. In the present model, one cannot explicitly associate $\boldsymbol{\eta}$ exclusively with the virus; however, since these are cell data, it is anticipated that the virus represents the dominant phenomena.

We have access to expressions of thousands of genes from each sample (cell) for multiple consecutive times $t_1, t_2, \ldots, t_J$. For each time t_j, there are N_j samples measured from different cells (Hibberd et al., 2006). Although these samples may have different observations in gene expressions at the same time, due to individual diversity, the hidden variable $\boldsymbol{\eta}$ (see (19)) underlying the observations may have similar characteristics. Based on this consideration, the $\boldsymbol{\eta}$ underlying the observations in one group corresponding to one time are assumed to be drawn from a Gaussian mixture model. They may also share the same mixture distribution for proximate time points, under the assumption of the dHDP model.

The Dengue gene expression data (Hibberd et al., 2006) are divided into six groups of samples measured at different times and the number of samples in each group are 10, 12, 12, 10, 12, 9 (the specific time points associated with these data are respectively 3, 6, 12, 24, 48 and 72 hours); each sample has 19,143 genes. To deal with such high-dimensional data, the Fisher score (Duda & Hart, 1973) is used to preliminarily select $p = 5000$ genes as being the most relevant (variable across time and cell), and then we use the dHDP mixture model discussed above to analyze the time evolution existing in these gene samples.

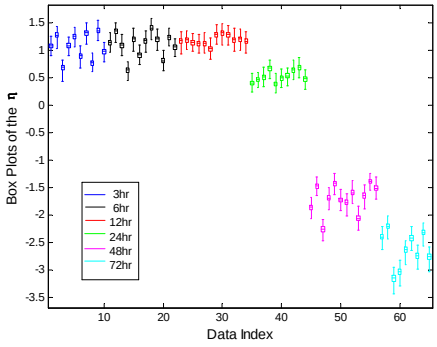

Figure 5. Median values and associated uncertainty based on posterior distributions of the hidden variables $\boldsymbol{\eta}$.

Based on the samples collected from the Gibbs sampling after burn-in, the posterior distributions (includ-

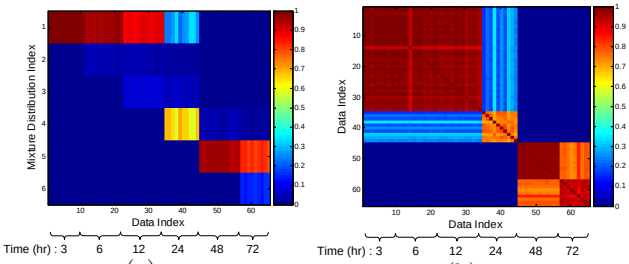

Figure 6. The dHDP GMM modeling for the gene expression data. (a) The posterior distribution of $\mathbf{r}$. (b) The similarity matrix $E[z'z]$.

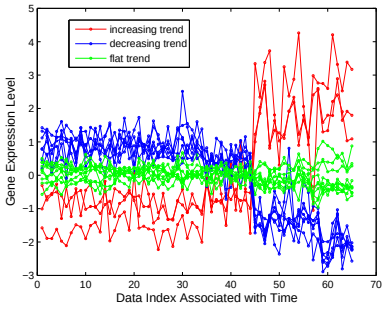

Figure 7. The first ten inferred important genes (color red and blue) and the relatively unrelated genes (color green).

ing the minimum, median, maximum, 25th and 75th percentiles of the values) for all components of $\boldsymbol{\eta}$ underlying these samples at different times are shown in Figure 5. Time points 3hr, 6hr and 12hr appear to share a similar pattern, but the $\boldsymbol{\eta}_{t=12}$ seem to have smaller diversity among different samples. From 24hrs, $\boldsymbol{\eta}$ drops slightly to a new pattern and they drop significantly again at 48hr. The posterior of indicator $\mathbf{r}$ is plotted in Figure 6(a) to show the mixture-distribution sharing relationship across different groups. Figure 6(b) shows the similarity measure $E(\mathbf{z}'\mathbf{z})$ across every pair of samples; here z_{ji} is the indicator variable for the η_{ji} associated with time t_j (see Eq. (18)).

Consider the factor loadings vector $\boldsymbol{\lambda}$, which has components linked to the p genes under consideration. The larger the value of $|\lambda_d|$, the more influence the pattern contained in $\boldsymbol{\eta}$ has on the corresponding gene at the d^{th} dimension. Therefore, according to the posterior mean of $|\lambda_d|$ for all d from the Gibbs sampling we rank the genes based on their importance.

In Figure 7 we plot the expression levels over time for the 10 most important and 10 least important genes. The red and blue curves show two different time patterns and their values have either an increasing or a decreasing trend with time, depending on whether the associated λ is positive or negative. The green curves represent the genes with no apparent relation to the virus (as determined by the analysis) due to the lack of a systematic trend over time.

As discussed in Section 2.2, if all $\tilde{w}_j$ are set to one for $j = 1, \ldots, J-1$, the dHDP reduces to HDP and all the temporal groups are conditionally exchangeable. It is of interest to compare the dHDP with HDP both in the sharing mechanism and parameter estimation. In practice, acquisition of the gene-expression data is expensive, and it is desirable to reduce the number of samples required. To consider this issue, we reduced the samples size to four at each time point, and plot the data similarity matrix $E[\boldsymbol{z}'\boldsymbol{z}]$ for HDP and dHDP respectively in Figures 8(a) and (b).

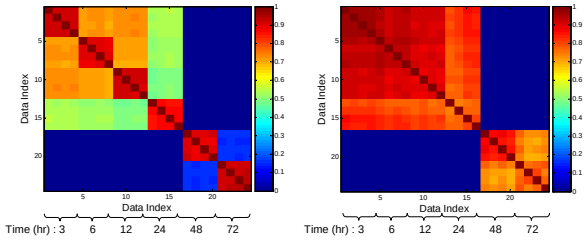

Figure 8. Similarity matrix $E[z'z]$ with four samples for each temporal group. (a) HDP, (b) dHDP.

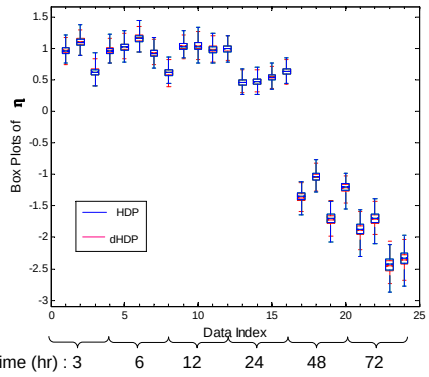

Figure 9. Comparison of dHDP and HDP with box plots of the hidden variables $\boldsymbol{\eta}$ as the sample size is reduced to four for each temporal group (the standard deviation based on dHDP is 12.1% reduced on average relative to HDP; the means are very similar).

Compared with HDP, dHDP has more sharing between the related groups (as expected from model construction), and despite the reduced data samples the dHDP yields an inter-relationship between the different times that is consistent with that in Figure 6(b) which employs all of the available data. In Figure 9 we compare dHDP and HDP estimation of $\boldsymbol{\eta}$ based on four samples per time point. These results show that dHDP has a smaller estimation uncertainty for most $\boldsymbol{\eta}$ relative to HDP, which is attributed to proper temporal

sharing explicitly imposed by dHDP. As the sample size is increased, the differences between dHDP and HDP diminish.

Finally, correlation coefficients between two groups are calculated from the samples drawn from the Gibbs sampler, according to (14) and plotted as a matrix in Figure 10; this representation is an additional benefit of the dynamic structure explicitly imposed within dHDP (of potential biological interest). The size of each small block at the i^{th} row and j^{th} column is proportional to the value of the correlation coefficient associated with group i and group j. We note based on Figure 10 that such inference appears to be accurate (or at least consistent) even with diminished sample size.

4. Conclusions

The proposed dynamic hierarchical Dirichlet process (dHDP) extends the HDP (Teh et al., 2005), imposing a dynamic time dependence so that the initial mixture model and the subsequent time-dependent mixtures share the same set of components (atoms). The experiments indicate that the dHDP is an effective model for analysis of time-evolving data. Concerning future research, more efficient inference methods will be considered, such as collapsed sampling (Welling et al., 2007) and variational Bayesian inference (Blei & Jordan, 2004).

Abstract

We propose a family of supervised dimensionality reduction (SDR) algorithms that combine feature extraction (dimensionality reduction) with learning a predictive model in a unified optimization framework, using data- and class-appropriate generalized linear models (GLMs), and handling both classification and regression problems. Our approach uses simple closed-form update rules and is provably convergent. Promising empirical results are demonstrated on a variety of high-dimensional datasets.

1. Introduction

Dimensionality reduction (DR) is a popular data-processing technique that serves the following two main purposes: it helps to provide a meaningful interpretation and visualization of the data, and it also helps to prevent overfitting when the number of dimensions greatly exceeds the number of samples, thus working as a form of regularization.

When our goal is prediction rather than an (unsupervised) exploratory data analysis, *supervised* dimensionality reduction (SDR) that combines DR with *simultaneously* learning a predictor can significantly outperform a simple combination of unsupervised DR with a subsequent learning of a predictor on the resulting low-dimensional representation (Pereira & Gordon, 2006; Sajama and Alon Orlitsky, 2005). The problem of supervised dimensionality reduction can be viewed as finding a *predictive structure*, such as a low-dimensional representation, which captures the information about the class label contained in the high-dimensional feature vector while ignoring the "noise".

However, existing SDR approaches are often restricted to specific settings, and can be viewed as jointly learning a *particular mapping* (most commonly, a linear one) from the feature space to a low-dimensional hidden-variable space, together with a *particular predictor* that maps the hidden variables to the class label. For example, SVDM (Pereira & Gordon, 2006) learns a linear mapping from observed to hidden variables, effectively assuming Gaussian features when minimizing sum-squared reconstruction loss; on the prediction side, it focuses on SVM-like binary classification using hinge loss. SDR-MM method of (Sajama and Alon Orlitsky, 2005) treats various types of features (e.g., binary and real-valued) but is limited to discrete classification problems, i.e. is not suitable for regression. Recent work on distance metric learning (Weinberger et al., 2005; Weinberger & Tesauro, 2007) treats both classification and regression settings, but is limited, like SVDM, to Gaussian features and linear mappings when learning Mahalanobis distances.

This paper approaches SDR in a more general framework that views both features and class labels as exponential-family random variables, and allows to mix-and-match data- and label-appropriate *generalized linear models*, thus handling both classification and regression, with both discrete and real-valued data[1]. It can be viewed as a discriminative learn-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] In other words, the proposed framework provides nonlinear dimensionality reduction methods based on minimizing Bregman divergences that correspond to particular

ing based on minimization of conditional probability of class given the hidden variables, while using as a regularizer the conditional probability of the features given the low-dimensional hidden-variable "predictive" representation.

The main advantage of our approach, besides being more general, is using simple *closed-form* update rules when performing its alternate minimization procedure. This method yields a short Matlab code, fast performance, and is guaranteed to converge. The convergence property, as well as closed form update rules, result from using appropriate auxiliary functions bounding each part of the objective function (i.e., reconstruction and prediction losses). We exploit the additive property of auxiliary functions in order to combine bounds on multiple loss functions.

We perform a variety of experiments, both on simulated and real-life problems. Results on simulated datasets convincingly demonstrate that our SDR approach can discover underlying low-dimensional structure in high-dimensional noisy data, while outperforming SVM and SVDM, often by far, and practically always beating the unsupervised DR followed by learning a predictor. On real-life datasets, SDR approaches continue to beat the unsupervised DR by far, while often matching or somewhat outperforming SVM and SVDM.

2. SDR-GLM: Hidden-Variable Model

Let X be an $N \times D$ data matrix with entries denoted X_{nd} where N is the number of i.i.d. samples, and n-th sample is a D-dimensional row vector denoted $\mathbf{x}_n$. Let Y be an $N \times K$ matrix of class labels for K separate prediction problems (generally, we will consider $K > 1$), where j-th column, $1 \leq j \leq K$, provides a set of class labels for the j-th prediction problem. Our supervised dimensionality approach relies on the assumption that each data point $\mathbf{x}_n$, $n = 1, ..., N$, is a noisy version of some "true" data point $\theta_\mathbf{n}$ which lives in a low-dimensional space, and that this hidden representation of the noisy data is actually predictive about the class label.

We will also assume, following ePCA (Collins et al., 2001), $(GL)^2M$(Gordon, 2002), logistic PCA (Schein et al., 2003) and related extensions of PCA, that noise in the features follows exponential-family distributions with natural parameters $\theta_\mathbf{n}$, with different members of the exponential family used for different dimensions[2], and that the noise is applied independently to each coordinate of $\mathbf{x}_n$. Namely, it is assumed that $N \times D$ parameter matrix Θ can be represented by a linear model in an L-dimensional ($L < D$) space:

$$\Theta_{nd} = \sum_{l=1}^{L} U_{nl} V_{ld} + \Delta_{X_d},$$

where the rows of the $L \times D$ matrix V correspond to the basis vectors, the columns of the $N \times L$ matrix U correspond to the coordinates of the "true points" θ_n, $n = 1, ...N$ in the L-dimensional space spanned by those basis vectors, and Δ_X is the bias vector (corresponding to the empirical mean in PCA). However, to simplify the notation, we will include Δ_X as the $(L+1)$'s row of the matrix V (i.e., $V_{L+1} = \Delta_X$), and add the $(L+1)$'s column of 1's to U, so that we can write Θ_X as a product of two matrices, $\Theta_{X_{nd}} = (UV)_{nd} = \sum_{l=1}^{L+1} U_{nl} V_{ld}$.

Given the natural parameter Θ_{nd}, an exponential-family noise distribution is defined for each X_{nd} by

$$\log P(X_{nd}|\Theta_{X_{nd}}) = X_{nd}\Theta_{X_{nd}} - G(\Theta_{X_{nd}}) + \log P_0(X_{nd}),$$

where $G_x(\Theta_{nd})$ is the *cumulant* or *log-partition* function that ensures that $P(X_{nd}|\Theta_{nd})$ sums (or integrates) to 1 over the domain of X_{nd}. This function uniquely defines a particular member of the exponential family, e.g., Gaussian, multinomial, Poisson, etc.

We can now view each row U_n as a "compressed" representation of the corresponding data sample $\mathbf{x}_n$ that will be used to predict the class labels. We will again assume a noisy linear model for each class label Y_k (column-vector in Y) where the natural parameter is represented by linear combination

$$\Theta_{Y_{nk}} = \sum_{l=1}^{L} U_{nl} W_{lk} + \Delta_{Y_k}$$

with linear coefficients $\mathbf{w} = (w_1, ..., w_L)$ and K-dimensional bias vector Δ_Y. As for $\Theta_{X_{nd}}$, we will simplify the notation by including Δ_Y as the $(L+1)$'s row of the matrix W, and write $\Theta_{Y_{nk}} = (UW)_{nk} = \sum_{l=1}^{L+1} U_{nl} W_{lk}$. Using an appropriate type of exponential-family noise $P(Y_{nk}|\Theta_{Y_{nk}})$, we can handle both classification and regression problems. For

members of the exponential family of distribution, including linear (PCA-like) dimensionality reduction as a particular case for Gaussian variables.

[2] It is important to note that in case of standard (linear) PCA corresponding to Gaussian noise the parameters θ_n live in a linear subspace in the original data space, but for other types of exponential-family noise the low-dimensional space of parameters is typically a nonlinear surface in the original data space.

example, in case of binary classification, we can model Y_{nk} as a Bernoulli variable with parameter p_{nk} and the corresponding natural parameter $\Theta_{nk} = \log(\frac{p_{nk}}{1-p_{nk}})$, and use logistic function $\sigma(x) = \frac{1}{1+e^{-x}}$ to write the Bernoulli distribution for Y_{nk} as

$$P(Y_{nk}|\Theta_{Y_{nk}}) = \sigma(\Theta_{Y_{nk}})^{Y_{nk}}\sigma(-\Theta_{Y_{nk}})^{1-Y_{nk}}.$$

In case of regression, Y_{nk} will be a Gaussian variable with the expectation parameter coinciding with the natural parameter $\Theta_{Y_{nk}}$.

In other words, we will use a *generalized linear model (GLM)* $E(X_d) = f_d^{-1}(UV_d)$ for each feature X_d (d-th column in X, $1 \le d \le D$), and yet another set of GLMs $E(Y_k) = f_k^{-1}(UW)$ for each class label Y_k (k-th column in Y, $1 \le k \le K$), with possibly different *link functions* f_d and f_k (e.g., the logit link function $f(\mu) = \ln\frac{\mu}{1-\mu} = \sigma^{-1}(\theta)$ is used for binary classification, and identity link function $f(\mu) = \mu$ is used for real-valued regression with Gaussian output).

SDR-GLM optimization problem. We formulate SDR as joint optimization of two objective functions corresponding to the reconstruction accuracy (data likelihood) and the prediction accuracy (class likelihood):

$$\mathcal{L}_X(\Theta_X) = \sum_{nd} \log P(X_{nd}|\Theta_{X_{nd}}), \quad (1)$$

$$\mathcal{L}_Y(\Theta_Y) = \sum_{nk} \log P(Y_{nk}|\Theta_{Y_{nk}}), \quad (2)$$

where $\Theta_X = UV$, $\Theta_Y = UW$, and the likelihoods above correspond to particular members of exponential family. Then the SDR optimization problem is

$$\max_{U,V,W} \alpha\mathcal{L}_X(UV) + \mathcal{L}_Y(UW) \quad (3)$$

where the data likelihood can be viewed as a regularization added on top of the class likelihood maximization objective, with the regularization constant α controlling the trade-off between the two likelihoods [3].

Comparison with SVDM. Note that the idea of combining loss functions for SDR was also proposed before in SVDM (Pereira & Gordon, 2006), where, similarly to SVD, quadratic loss $||X - UV||_2^2$ was used for data reconstruction part of the objective, while the hinge loss was used for the prediction part (using U as the new data matrix). Herein, we generalize SVDM's sum-squared reconstruction loss to log-likelihoods of exponential family, similarly to ePCA(Collins et al., 2001) and G^2L^2M(Gordon, 2002), replace hinge loss by the loglikelihoods corresponding to exponential-family class variables, and provide closed-form update rules rather than perform optimization at each iteration, which results into a significant speed up when compared with SVDM.

[3] In our implementation, an L_2-norm regularization was also added on all matrices U, V, W with small regularization constants (0.01), effectively corresponding to assuming Gaussian priors on those matrices.

3. Combining Auxiliary Functions

Since the above problem (eq. 3) is not jointly convex in all parameters, finding a globally optimal solution is nontrivial. Instead, we can employ the auxiliary function approach commonly used in EM-style algorithms, and using auxiliary function of a particular form, derive *closed-form* iterative update rules that are guaranteed to converge to a local minimum. We show that an auxiliary function for the objective in eq. 3 can be easily derived for an arbitrary pair of $\mathcal{L}_X$ and $\mathcal{L}_Y$ provided that we know their corresponding auxiliary functions.

Auxiliary functions. Given a function $\mathcal{L}(\theta)$ to be maximized, a function $Q(\hat{\theta}, \theta)$ is called an *auxiliary function* for $\mathcal{L}(\theta)$ if $\mathcal{L}(\theta) = Q(\theta, \theta)$ and $\mathcal{L}(\hat{\theta}) \ge Q(\hat{\theta}, \theta)$ for all $\hat{\theta}$. It is easy to see that $\mathcal{L}(\theta)$ is non-decreasing under the update

$$\theta^{t+1} = \arg\max_{\hat{\theta}} Q(\hat{\theta}, \theta^t),$$

i.e., $\mathcal{L}(\theta^{t+1}) \ge \mathcal{L}(\theta^t)$, and thus an iterative application of such updates is guaranteed to converge to a local maximum of $\mathcal{L}$ under mild conditions on $\mathcal{L}$ and Q.

We will make use of the following properties of auxiliary functions:

Lemma 1 *Let $Q_1(\hat{\theta}, \theta)$ and $Q_2(\hat{\theta}, \theta)$ be auxiliary functions for $\mathcal{L}_1(\theta)$ and $\mathcal{L}_2(\theta)$, respectively. Then*

$$Q(\hat{\theta}, \theta) = \alpha_1 Q_1(\hat{\theta}, \theta) + \alpha_2 Q_2(\hat{\theta}, \theta) \quad (4)$$

is an auxiliary function for $\mathcal{L}(\theta) = \alpha_1\mathcal{L}_1(\theta) + \alpha_2\mathcal{L}_2(\theta)$, where $\alpha_i > 0$ for $i = 1, 2$.

Proof. $Q(\hat{\theta}, \theta) = \alpha_1 Q_1(\hat{\theta}, \theta) + \alpha_2 Q_2(\hat{\theta}, \theta) \le \alpha_1\mathcal{L}_1(\hat{\theta}) + \alpha_2\mathcal{L}_2(\hat{\theta}) = \mathcal{L}(\hat{\theta})$, and $Q(\theta, \theta) = \alpha_1 Q_1(\theta, \theta) + \alpha_2 Q_2(\theta, \theta) = \alpha_1\mathcal{L}_1(\theta) + \alpha_2\mathcal{L}_2(\theta) = \mathcal{L}(\theta)$. ■

Also, it is obvious that a function is an auxiliary for itself, i.e. $Q(\hat{\theta}, \theta) = \mathcal{L}(\hat{\theta})$ is an auxiliary function for $\mathcal{L}(\theta)$. This observations allows us to combine various dimensionality reduction approaches with appropriate predictive loss functions, given appropriate auxiliary functions for both (next section discusses two such combinations). When optimization of an auxiliary functions yields an analytical solution (e.g., for

quadratic functions), it is easy to obtain closed-form update rules for alternating minimization.

4. Iterative Update Rules

Recall that natural parameters for X_{nd} and Y_{nk} variables are represented by $\Theta_{X_{nd}} = \sum_{l=1}^{L+1} U_{nl}V_{ld}$ and $\Theta_{Y_{nk}} = \sum_{l=1}^{L+1} U_{nl}W_{lk}$. Let $Q_X(\hat{\Theta}_X, \Theta_X)$ and $Q_Y(\hat{\Theta}_Y, \Theta_Y)$ be the auxiliary functions for the corresponding loglikelihoods in eq. 2, then $Q(\hat{\Theta}_X, \Theta_X, \hat{\Theta}_Y, \Theta_Y) =$

$$= \alpha Q_X(\hat{\Theta}_X, \Theta_X) + Q_Y(\hat{\Theta}_Y, \Theta_Y) \quad (5)$$

is an auxiliary function for the combined log-likelihood in eq. 3 when we fix two out of three parameters and optimize over the remaining one. The update rules for $\hat{U}_{nl}$, $\hat{V}_{ld}$ and $\hat{W}_{nk}$ are obtained by solving

$$\frac{\partial Q}{\partial \hat{U}_{nl}} = 0,\ \frac{\partial Q_X}{\partial \hat{V}_{ld}} = 0,\ \frac{\partial Q_Y}{\partial \hat{W}_{nk}} = 0,\ where$$

$$\frac{\partial Q}{\partial \hat{U}_{nl}} = \alpha \sum_d \frac{\partial Q}{\partial \hat{\Theta}_{X_{nd}}} \frac{\hat{\Theta}_{X_{nd}}}{\partial \hat{U}_{nl}} + \sum_k \frac{\partial Q}{\partial \hat{\Theta}_{Y_{nk}}} \frac{\hat{\Theta}_{Y_{nk}}}{\partial \hat{U}_{nl}}.$$

Note that we get simpler expressions for V and W since they appear only in Q_X or only in Q_Y parts of eq. 5, respectively.

Auxiliary functions for Bernoulli and Gaussian log-likelihoods. For a Bernoulli variable s with natural (log odds) parameter θ we use the variational bound on log-likelihood $\mathcal{L}(\theta) = \log P(s|\theta)$ proposed by (Jaakkola & Jordan, 1997) and used later by (Schein et al., 2003)

$$\mathcal{L}(\hat{\theta}) \geq Q(\hat{\theta}, \theta) = \log 2 - \log\cosh(\theta/2) + + \frac{T\theta^2}{4} + \frac{(2s-1)\hat{\theta}}{2} - \frac{T\hat{\theta}^2}{4}, \quad (6)$$

where $T = \frac{tanh(\theta/2)}{\theta}$. Note that the auxiliary function is quadratic in θ and taking its derivatives leads to simple closed-form iterative update rules for U, V and W. For multinomial variables, one can use a recent extension of the above bound to multinomial logistic regression proposed by (Bouchard, 2007).

For a Gaussian variable s with natural parameter θ that coincides with the mean parameter (identity link function) we do not really have to construct an auxiliary function, since we can simply use the negative squared loss proportional to the Gaussian loglikelihood as an auxiliary function itself, i.e.

$$\mathcal{L}(\hat{\theta}) = Q(\hat{\theta}, \theta) = -c(s-\theta)^2, \quad (7)$$

where $c = (2\sigma)^{-1}$ is a constant, assuming a fixed standard deviation that will not be a part of our estimation procedure here, similarly to the approach of (Collins et al., 2001) and related work; c can be ignored since it will be subsumed by the parameter α.

Using the above auxiliary functions, we can combine them into joint auxiliary functions as in eq. 5 for various combinations of Bernoulli and Gaussian variables X_{nd} and Y_{nk}. Namely, assuming all X_{nd} are Bernoulli, we get (Schein et al., 2003):

$$Q_X^{Ber}(\hat{\Theta}_{X_{nd}}, \Theta_{X_{nd}}) = \sum_{nd} \log\cosh(\Theta_{X_{nd}}/2) + + \frac{T\Theta_{X_{nd}}^2}{4} + \frac{(2X_{nd}-1)\hat{\Theta}_{X_{nd}}}{2} - \frac{T\hat{\Theta}_{X_{nd}}^2}{4}, \quad (8)$$

while assuming all X_{nd} are Gaussian, we get

$$Q_X^{Gauss}(\hat{\Theta}_{X_{nd}}, \Theta_{X_{nd}}) = -\sum_{nd}(X_{nd} - \hat{\Theta}_{X_{nd}})^2. \quad (9)$$

Note that $Q_Y(\hat{\Theta}_{Y_{nk}}, \Theta_{Y_{nk}})$ for all-Bernoulli or all-Gaussian Y_{nk} is obtained by replacing X with Y, V with W, and d with k in eq. 8 and 9, respectively.

Due to lack of space, we omit the derivation of the iterative update rules for the four versions of SDR-GLM that we experimented with (for more detail, see (Rish et al., 2008)): *Gaussian-SDR*, that assumes Gaussian X_{nd} and Bernoulli Y_{nk}, *Bernoulli-SDR* in case of Bernoulli X_{nd} and Bernoulli Y_{nk}, *Gaussian-SDR-Regression* and *Bernoulli-SDR-Regression* in case of Gaussian Y_{nk} (appropriate for real-valued label, i.e. for the regression problem).

Prediction step. Once we learn the parameters U, V and W, and thus Θ_X and Θ_Y, we can use them on test data in order to predict labels for previously unseen data. Given the test data X^{test}, we only need to find the corresponding low-dimensional representation U^{test} by performing the corresponding iterative updates only with respect to U, keeping V and W fixed. Once U^{test} is found, we predict the class labels as $Y^{test} = U^{test}W$.

5. Empirical Evaluation

We evaluated our SDR-GLM methods on both simulated and real-life datasets, in both classification and regression settings. We varied the low-dimensionality parameter L from 2 to 10, and evaluated a range of regularization parameters $\alpha = 0.0001, 0.001, 0.01, 0.1, 1, 10, 100$, selecting those giving the best average error among several dimensions[4].

[4]Selecting the best α separately for each dimension can only improve the results, but would be more computationally intensive.

5.1. Classification Problems

In the classification setting, we compared *Bernoulli-SDR* and *Gaussian-SDR* versus linear SVM[5] and versus unsupervised dimensionality reduction followed by SVM and by logistic regression, which we refer to as SVM-UDR and *Logistic-UDR*, respectively. In both cases, unsupervised dimensionality reduction is performed first using the data-appropriate DR method (i.e., PCA for real-valued data and Logistic-PCA for binary data; this is equivalent to removing the prediction loss in eq. 3); then SVM or logistic regression are performed on the low-dimensional data representation U. For datasets with real-valued features, we also compared the above methods to SVDM (Pereira & Gordon, 2006). We performed k-fold cross-validation with $k = 10$ on the datasets with less than 1000 dimensions, and with $k = 5$ otherwise.

Simulated data. In order to test our methods first on the data with controllable low-dimensional structure, we simulated high-dimensional datasets that indeed were noisy versions of some underlying easily-separable low-dimensional data. Particularly, a set of $N = 100$ samples from two classes was generated randomly in two-dimensional space so that the samples were linearly separable with a large margin.

Next, we simulated two sets of exponential-family random variables X_{nd}, a Bernoulli set and a Gaussian set, using the coordinates of the above points for natural parameters Θ_{nd}, where the number of samples was $N = 100$ and the dimensionality of a "noisy" dataset varied from $D = 100$ to $D = 1000$. We then combined the data with the labels generated in the low-dimensional space and provided them as an input to our algorithms.

Simulated data: Bernoulli noise. Figures 1a summarize the results for Bernoulli-noise dataset. Supervised DR methods (Bernoulli-SDR and Gaussian-SDR) versus SVM and versus unsupervised DR followed by learning a predictor (Logistic-UDR and SVM-UDR); the reduced dimensionality parameters is set to $L = 2$ and the regularization constant is $\alpha = 0.0001$ (the choice of those parameters is discussed below). We can see that Bernoulli-SDR significantly outperforms all other methods, including SVM, and both Bernoulli-SDR and Gaussian-SDR also outperform the unsupervised DR followed by either logistic regression or SVM. Apparently, Bernoulli-SDR is able to reconstruct correctly the underlying separable two-dimensional dataset and is robust to noise, as its error remains zero for up to 700 dimensions, and only increases slightly up to 0.05 for 1000 dimensions. On the other hand, SVM has zero-error prediction only in the lowest-dimensional case ($D = 100$), and is much more sensitive to noise when the dimensionality of the data increases, making incorrect predictions in up to 14% to 21% cases when the dimensionality increases above $D = 300$. Apparently, SVM was not able to exploit the underlying separable low-dimensional structure disturbed by high-dimensional noise, while supervised dimensionality reduction easily detected this structure.

Also, using the Bernoulli model instead of Gaussian when features are binary is clearly beneficial, and thus, as noted previously, proper extensions of PCA to exponential-family data must be used (Collins et al., 2001; Schein et al., 2003). However, previous work on logistic PCA by (Schein et al., 2003) demonstrated advantages of using the Bernoulli vs Gaussian assumption only for *reconstruction* of the original data, while this paper investigates the impact of such assumptions on the *generalization* error in supervised learning case. This is less obvious, since a good fit to the training data does not necessarily imply a good generalization ability, as shown by our experiments with unsupervised dimensionality reduction followed by learning a classifier.

Regarding the choice of the regularization parameter α, we experimented with a range of values from 0.0001 to 10, and concluded that the smallest value was the most beneficial for both SDR algorithms; this is intuitive since it effectively puts most of the weight on the predictive loss. There is a clear trend (Figure 1b) in error decrease with the parameter decrease, where sufficiently low values of $\alpha \leq 0.1$ yield quite similar low errors, but increasing α further, especially above 1, leads to a drastic increase in the classification error, especially in higher-dimensional cases. Note, however, that such tendency is not present in the other datasets we experimented with, where the effect of regularization constant can be non-monotonic, and thus underscores the importance of using cross-validation or other parameter-tuning approaches[6].

Regarding the choice of the reduced-dimensionality parameter L, for low values of α, we did not observe any significant variation in the results with increasing this parameter up to $L = 10$, e.g. the results for different L were practically identical when $\alpha \leq 0.1$, while for higher values variance was more significant.

[5]We used the SVM code by A. Schwaighofer available at http://ida.first.fraunhofer.de/~anton/software.html.

[6]Bayesian approach to selecting regularization parameter may prove beneficial, as shown, for example, in (Y. Lin and D. Lee, 2006)

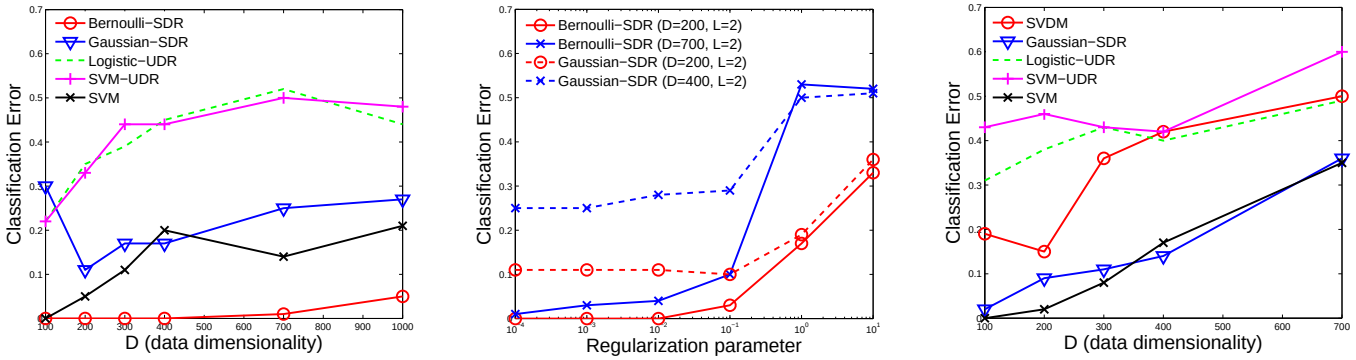

Figure 1. (a) Results for Bernoulli noise. (b) Effects of the regularization parameter α (the weight on the data reconstruction loss) - Bernoulli noise. (c) Results for Gaussian noise.

Simulated data: Gaussian noise. Figure 1c shows the results for the Gaussian noise: supervised dimensionality reduction provides a clear advantage over unsupervised ones, although the performance of SDR versus SVM is somewhat less impressive, as Gaussian-SDR is comparable to SVM. However, Gaussian-SDR seems to outperform considerably another supervised dimensionality method, SVDM, proposed by (Pereira & Gordon, 2006). SVDM was used with its regularization constant set to 100 since it provided the best SVDM performance among the same values of α as before. Interestingly, the performance of SVDM does not show any monotonic dependence on this parameter.

Real-life datasets. First, we considered several datasets with *binary features*, such as a 41-dimensional *Sensor network* dataset where the data represent connectivity (0 or 1) between all pairs of sensor nodes in a network of 41 light sensors (see Table 1). Note that Bernoulli-SDR with $L = 10$ and regularization parameter $\alpha = 0.1$ outperformed SVM, Gaussian-SDR with $L = 8, 10$ and same $\alpha = 0.1$ matched SVM performance, while both the unsupervised dimensionality reduction methods followed by SVM and logistic regression - *SVM-UDR* and *Logistic-UDR*, respectively - performed worse. (Best results for each method are shown in the boldface.) Also, using the Bernoulli model for binary data instead of Gaussian seems to pay off: Bernoulli-SDR performs somewhat better than Gaussian-SDR. It is interesting to note that for really low dimensionality $L = 2$, all of the above methods have same error of 0.2, while increasing the dimensionality allows for much better performance, although this effect is non-monotonic.

Another dataset related to network performance management, of somewhat larger dimensionality ($N = 169$, $D = 168$), contains pairwise end-to-end network latency (ping round-trip times) collected by the PlanetLab measurement project (http://www.pdos.lcs.mit.edu/∼simstrib/pl_app) discretized by applying a threshold as follows: above the average latency is considered "bad" (1) while the below-average latency is considered "good" (0). We selected the first column (latencies of all 169 nodes towards the node 1) as the label, and predicted them given the remaining data. The results are shown in Table 2. The regularization parameters α selected by cross-validation were different here for different SDR methods: for Bernoulli-SDR, $\alpha = 100$ turned out to be the best, while Gaussian-SDR performed better with $\alpha = 1$. Overall, the results for different methods and

varying dimensions L were surprisingly similar to each other, with both SDR methods achieving the lowest error of 0.07 for $L = 4$ and $L = 8$, respectively, that was also achieved by SVM-UDR at $L = 10$, slightly outperforming SVM (0.10 error). Very similar results (not shown here due to lack of space) were also obtained on the *Advertisement* dataset from UCI ML repository.

We experimented next with several extremely high-dimensional datasets from biological experiments that had *real-valued features*. The first dataset, called here *Proteomics data*, containing mass-spectrometry data for $D = 38573$ proteins (features), showing their "expression levels" in $N = 50$ female subjects (examples), 25 of which were pregnant (class 1), and the others were not (class 0). The results are shown in Table 3, comparing Gaussian-SDR with $\alpha = 0.001$ (that yields lowest average SVDM error (among all dimensions) on this dataset) versus SVM, Logistic-UDR, SVM-UDR (both using the Gaussian assumption, i.e. PCA, for dimensionality reduction), and SVDM with its best-performing parameter 0.01. Despite its very high dimensionality, this dataset turned out to be easy: both SVM and Gaussian-SDR achieved an error of 0.02, and Gaussian-SDR used only $L = 4$ dimensions to achieve it. On the contrary, unsupervised DR followed by predictor learning (Logistic-UDR and SVM-UDR), suffered from really high errors at low dimensions, and only managed to achieve same low error at $L = 10$. SVDM was able to reach its lowest error (same 0.02) a bit earlier ($L = 6$), although for $L = 2$ it incurred a huge error of 0.42, while Gaussian-SDR had 0.04 error at that same level of reduced dimensionality.

Another truly high-dimensional dataset we used contained the fMRI recordings of subject's brain activity (measured using changes in the brain oxygenation levels) while the subject was observing on a screen words of two types, representing tools or buildings (see (Pereira & Gordon, 2006) for details). The task was to learn a mind-reading classifier that would predict, given the fMRI data, what type of the word the subject was looking at. The features here correspond to fMRI voxels ($D = 14043$ voxels were selected after some preprocessing of the data, as described in (Pereira & Gordon, 2006)), and there are $N = 84$ samples (i.e., word instances presented to a subject). This dataset was clearly more challenging then the previous one (both SVM's and SDR's errors were around 0.2).

The results for all methods are shown in Table 4; for Gaussian-SDR we used $\alpha = 0.0001$, while SVDM was best at 0.001 (as before, we used the average error over all dimensions to select best α). For those values of α parameter, Gaussian-SDR matches SVM's errors of 0.21 using just five dimensions ($L = 5$), while SVDM reaches same error at $L = 15$ dimensions. Again, learning a predictor on "compressed" data obtained via *unsupervised* dimensionality reduction was consistently worse than both supervised methods.

5.2. Regression Problems

Finally, we did some preliminary experiments with the regression version of our SDR approach that makes Gaussian assumption about the label (response variable) Y and thus uses sum-squared predictive $\mathcal{L}_Y(UW)$ loss in equation 3, comparing it with the state-of-art sparse-regression technique called the *Elastic Net*, which was shown to improve over both *Lasso* and *ridge* regression using a convex combination of the $L1$- and $L2$-norm regularization terms (Zou & Hastie, 2005).

We used the fMRI data from the 2007 Pittsburgh Brain Activity Interpretation Competition (PBAIC)(Pittsburgh EBC Group, 2007), where the fMRI data were recorded while subjects were playing a videogame, and the task was to predict several real-valued response variables, such as level of anxiety the subject was experiencing etc. We used the data for the two runs (games) by the first subject, and for the *Instructions* response variable, learning from run 1 and predicting on run 2. The dataset contained $N = 704$ samples (measurements over time) and approximately $D = 33,000$ features (voxels). Figure 2 compares the performance of Elastic Net and Gaussian-SDR-Regression, where the L parameter denotes the number of active variables (voxels selected)

by the sparse EN regression. We can see that SDR regression is comparable with the state-of-the art EN (or even slightly better) when the number of hidden dimensions is not too low.

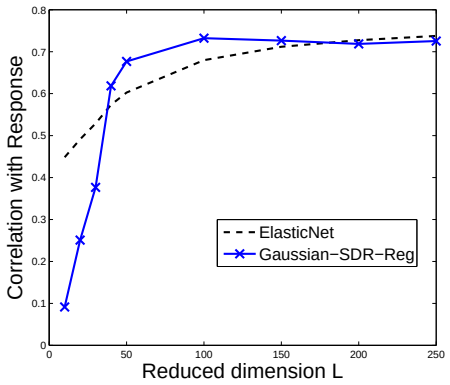

Figure 2. Results for the fMRI dataset from PBAIC. Performance is measured by correlation between the actual and predicted response variable (*Instructions*, in this case).

6. Conclusions and Future Work

This paper proposes a family of SDR algorithms that use generalized linear models to handle various types of features and labels, thus generalizing previous approaches in a unifying framework. Our SDR-GLM approach is fast and simple: it uses closed-form update rules at each iteration of alternating minimization procedure, and is always guaranteed to converge. Experiments on a variety of datasets show that this approach is clearly promising, although more empirical investigation is needed in case of SDR-regression.

Although we only tested our approach with Gaussian and Bernoulli variables, it can be easily extended to multinomial variables (and thus to multiclass classification) using a recent extension of the variational bound proposed in (Jaakkola & Jordan, 1997) to multinomial logistic regression (soft-max)(Bouchard, 2007). Deriving closed-form update rules for other members of the exponential family (e.g., Poisson) remains a direction of future work. Another possible extension is to obtain closed-form SDR update rules for alternative DR methods, such as non-negative matrix factorization (NMF)(Lee & Seung, 2000), simply plugging in NMF's auxiliary function instead of (unconstrained) PCA-like quadratic-loss.

Other potential applications of our approach include dimensionality reduction on mixed-type data, weighted dimensionality reduction schemes (e.g., assigning different weight to reconstruction error of different coordinates in PCA and similar DR techniques), multitask learning, as well as semi-supervised learning, including only the reconstruction loss part of the objective for unlabeled date, while keeping both reconstruction and prediction losses for the labeled ones. Finally, a more principled selection of the regularization constant α (e.g., using Bayesian approaches) is another open research direction.

Bi-Level Path Following for Cross Validated Solution of Kernel Quantile Regression

Saharon Rosset SAHARON@POST.TAU.AC.IL
Department of Statistics and Operations Research, The Raymond and Beverly Sackler School of Mathematical Sciences, Tel Aviv University, Israel

Abstract

Modeling of conditional quantiles requires specification of the quantile being estimated and can thus be viewed as a parameterized predictive modeling problem. Quantile loss is typically used, and it is indeed parameterized by a quantile parameter. In this paper we show how to follow the path of cross validated solutions to regularized kernel quantile regression. Even though the bi-level optimization problem we encounter for every quantile is non-convex, the manner in which the optimal cross-validated solution evolves with the parameter of the loss function allows tracking of this solution. We prove this property, construct the resulting algorithm, and demonstrate it on data. This algorithm allows us to efficiently solve the whole family of bi-level problems.

1. Introduction

In the standard predictive modeling setting, we are given a *training sample* of n examples $\{\mathbf{x}_1, y_1\}, ..., \{\mathbf{x}_n, y_n\}$ drawn i.i.d from a joint distribution $P(X, Y)$, with $\mathbf{x}_i \in \mathbb{R}^p$ and $y_i \in \mathbb{R}$ for regression, $y_i \in \{0, 1\}$ for two-class classification. We aim to utilize these data to build a model $\hat{Y} = \hat{f}(X)$ to describe the relationship between X and Y, and later use it to predict the value of Y given new X values. This is often done by defining a family of models $\mathcal{F}$ and finding (exactly or approximately) the model $f \in \mathcal{F}$ which minimizes an *empirical loss function*: $\sum_{i=1}^{n} L(y_i, f(\mathbf{x}_i))$. Examples of such algorithms include linear and logistic regression, empirical risk minimization in classification and others.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

If $\mathcal{F}$ is complex, it is often desirable to add *regularization* to control model complexity and overfitting. The generic regularized optimization problem can be written as:

$$\hat{f} = \arg\min_{f \in \mathcal{F}} \sum_{i=1}^{n} L(y_i, f(\mathbf{x}_i)) + \lambda J(f)$$

where $J(f)$ is an appropriate model complexity penalty and λ is the regularization parameter. Given a loss and a penalty, selection of a good value of λ is a *model selection* problem. Popular approaches that can be formulated as regularized optimization problems include all versions of support vector machines, ridge regression, the Lasso and many others. For an overview of predictive modeling, regularized optimization and the algorithms mentioned above, see for example Hastie et al. (2001).

In this paper we are interested in a specific setup where we have a family of regularized optimization problems, defined by a parameterized loss function and a regularization term. A major motivating example for this setting is regularized quantile regression (Koenker, 2005):

$$\hat{\beta}(\tau, \lambda) = \arg\min_{\beta} \sum_{i=1}^{n} L_\tau(y_i - \beta^\mathsf{T} \mathbf{x}_i) + \lambda \|\beta\|_q^q \quad (1)$$
$$\text{for } 0 < \tau < 1,\ 0 \leq \lambda < \infty$$

where L_τ, the parameterized quantile loss function, has the form:

$$L_\tau(r) = \begin{cases} r\tau & r \geq 0 \\ -r(1-\tau) & r < 0 \end{cases}$$

and is termed *τ-quantile loss* because its population optimizer is the appropriate quantile (Koenker, 2005):

$$\arg\min_{c} E(L_\tau(Y - c)|X) = \text{quantile } \tau \text{ of } P(Y|X) \quad (2)$$

Because quantile loss has this optimizer, the solution of the quantile regression problems for the whole range

$0 < \tau < 1$ has often been advocated as an approach to estimating the full conditional probability of $P(Y|X)$ (Koenker, 2005; Perlich et al., 2007). Much of the interesting information about the behavior of $Y|X$ may lie in the details of this conditional distribution, and if it is not *nicely behaved* (i.i.d Gaussian noise being the most commonly used concept of nice behavior), just estimating a conditional mean or median is often not sufficient to properly understand and model the mechanisms generating Y. The importance of estimating a complete conditional distribution, and not just a central quantity like the conditional mean, has long been noted and addressed in various communities, like Econometrics, Education and Finance (Koenker, 2005; Buchinsky, 1994; Eide & Showalter, 1998). There has also been a surge of interest in the Machine Learning community in conditional quantile estimation in recent years (Meinshausen, 2006; Takeuchi et al., 2006). Figure 1 shows a graphical representation of L_τ for several values of τ, and a demonstration of the conditional quantile curves in a univariate regression setting, where the linear model is correct for the median, but the noise has a non-homoscedastic distribution.

On the penalty side, we typically use the ℓ_q norm of the parameters with $q \in \{1, 2\}$. Adding a penalty can be thought of as shrinkage, complexity control or putting a prior to express our expectation that the β's should be small.

As has been noted in the literature (Rosset & Zhu, 2007; Hastie et al., 2004; Li et al., 2007) if $q \in \{1, 2\}$ and if we fix $\tau = \tau_0$, we can devise *path following* (AKA parametric programming) algorithms to efficiently generate the 1-dimensional curve of solutions $\{\hat{\beta}(\tau_0, \lambda) \ : \ 0 \le \lambda < \infty\}$. Although it has not been explicitly noted by most of these authors, it naturally follows that similar algorithms exist for the case that we fix $\lambda = \lambda_0$ and are interested in generating the curve $\{\hat{\beta}(\tau, \lambda_0) \ : \ 0 < \tau < 1\}$.

In addition to parameterized quantile regression, there are other modeling problems in the literature which combine a parameterized loss function problem with the existence of efficient path following algorithms. These include Support vector regression (SVR, Smola and Schölkopf (2004), see Gunther and Zhu (2005) for path following algorithm) with ℓ_1 or ℓ_2 regularization, where the parameter ϵ determines the width of the *don't care* region around 0.

An important extension of the ℓ_2-regularized optimization problem is to *non-linear* fitting through kernel embedding (Schölkopf & Smola, 2002). The kernelized version of problem (1) is:

$$\hat{f}(\tau, \lambda) = \arg\min_f \sum_i L_\tau(y_i - f(\mathbf{x}_i)) + \frac{\lambda}{2}\|f\|^2_{\mathcal{H}_K} \quad (3)$$

where $\|\cdot\|_{\mathcal{H}_K}$ is the norm induced by the positive-definite kernel K in the Reproducing Kernel Hilbert Space (RKHS) it generates. The well known *representer theorem* (Kimeldorf & Wahba, 1971) implies that the solution of problem (3) lies in a low dimensional subspace spanned by the representer functions $\{K(\cdot, \mathbf{x}_i), i \in 1, ..., n\}$. Following the ideas of Hastie et al. (2004) for the support vector machine, Li et al. (2007) have shown that λ-path of solutions to problem (3) when τ is fixed can also be efficiently generated.

It is important to note the difference in the roles of the two parameters τ, λ. The former defines a family of loss functions, in our case leading to estimation of different quantiles. Thus we would typically want to build and use a model for every value of τ. The latter is a regularization parameter, controlling model complexity with the aim of generating a better model and avoiding overfitting, and is not part of the prediction objective (at least as long as we avoid the Bayesian view). We would therefore typically want to generate a set of models $\beta^*(\tau)$ (or $f^*(\tau)$ in the kernel case), by selecting a good regularization parameter $\lambda^*(\tau)$ for every value of τ, thus obtaining a family of good models for estimating the range of conditional quantiles, and consequently the whole conditional distribution.

This problem, of model selection to find a good regularization parameter, is often handled through *cross-validation*. In its simplest form, cross-validation entails having a second, independent set of data $\{\tilde{\mathbf{x}}_i, \tilde{y}_i\}_{i=1}^N$ (often referred to as a *validation set*), which is used to evaluate the performance of the models and select a good regularization parameter. For a fixed τ, we can write our model selection problem as a *Bi-level programming* extension of problems (1, 3), where $f^*(\tau) = \hat{f}(\tau, \lambda^*)$ and λ^* solves:

$$\begin{aligned} \min_{\lambda} \quad & \sum_{i=1}^{N} L_\tau(\tilde{y}_i, \hat{f}(\tau, \lambda)^\mathsf{T}\tilde{\mathbf{x}}_i) \\ & \text{s.t.} \quad \hat{f}(\tau, \lambda) \text{ solves problem (3)} \end{aligned} \quad (4)$$

The objective of this minimization problem is not convex as a function of λ. A similar non-convex optimization problem has been tackled by Kunapuli et al. (2007). The fundamental difference between their setting and ours is that they had a single bi-level optimization problem, while we have a family of such problems, parameterized by τ. This allows us to take advantage of internal structure to solve the bi-level

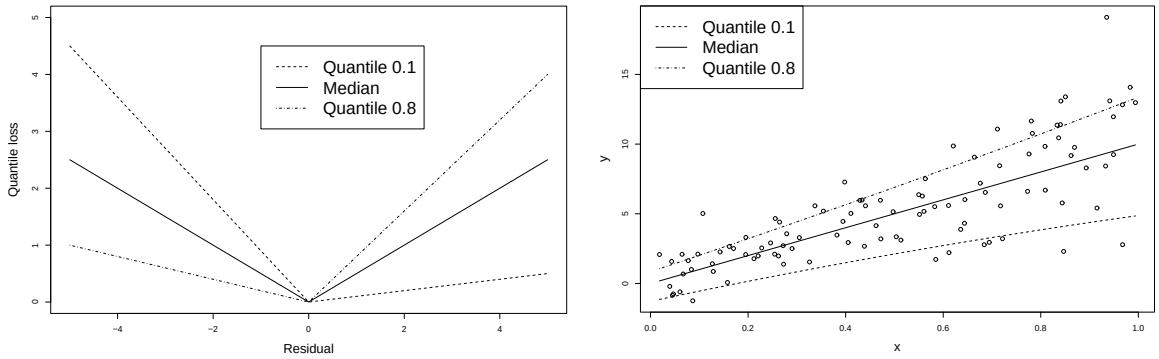

Figure 1. Quantile loss function for some values of τ (left) and an example where the median of Y is linear in X but the quantiles of $P(Y|X)$ are not because the noise is not identically distributed (right).

problem for all values of τ *simultaneously* (or more accurately, in one run of our algorithm).

The concept of a parameterized family of bi-level regularized quantile regression problems is demonstrated in Figure 2, where we see the cross-validation curves of the objective of (4) as a function of λ for several values of τ on the same dataset. As we can see, the optimal level of regularization varies with the quantile, and correct choice of the regularization parameter can have a significant effect on the success of our quantile prediction model.

The main goal of this paper is to devise algorithms for following the bi-level optimal solution path $f^*(\tau)$ as a function of τ, and demonstrate their practicality. We show that this non-convex family of bi-level programs can be solved exactly, as the optimum among the solutions of $O(n+N)$ standard (convex) path-following problems, with some additional twists. This result is based on a characterization of the evolution of the solution path $\hat{f}(\tau,\cdot)$ as τ varies, and on an understanding of the properties of optimal solutions of the bi-level problem, which can only occur at a limited set of points. We combine these insights to formulate an actual algorithm for solving this family of bi-level programs via path-following.

The rest of this paper is organized as follows. In Section 2 we discuss the properties of the quantile regression solution paths $\hat{f}(\tau,\lambda)$ and their evolution as τ changes. We then discuss in Section 3 the properties of the bi-level optimization problem (4) and demonstrate that the solutions change predictably with τ. Bringing together all our insights leads us to formulate an algorithm in Section 4, which allows us to follow the path of solutions $\{f^*(\tau)\ ,\ 0<\tau<1\}$ and only requires following a large but manageable number of solution paths of problem (3) simultaneously. We demonstrate our methods with a simulated data study in Section 5, where we demonstrate the computational efficiency of our approach and the ability of KQR to capture non-standard conditional distributions $P(Y|X)$.

This paper is a short version of Rosset (2008), and we defer the proofs, some of the technical details and much of the discussion to that version.

2. Quantile Regression Solution Paths

We concentrate our discussion on the kernel quantile regression (KQR) formulation in (3), with the understanding that it subsumes the linear formulation (1) with ℓ_2 regularization by using the *linear* kernel $K(\mathbf{x},\tilde{\mathbf{x}})=\mathbf{x}^\mathsf{T}\tilde{\mathbf{x}}$.

We briefly survey the results of Li et al. (2007) regarding the properties of $\hat{f}(\tau,\cdot)$, the optimal solution path of (3), with τ fixed. The representer theorem (Kimeldorf & Wahba, 1971) implies that the solution can be written as:

$$\hat{f}(\tau,\lambda)(\mathbf{x})=\frac{1}{\lambda}\left[\hat{\beta}_0+\sum_{i=1}^{n}\hat{\theta}_i K(\mathbf{x},\mathbf{x}_i)\right] \qquad (5)$$

For a proposed solution $f(\mathbf{x})$ define:

- $\mathcal{E}=\{i: y_i-f(\mathbf{x}_i)=0\}$ (points on *elbow* of L_τ)
- $\mathcal{L}=\{i: y_i-f(\mathbf{x}_i)<0\}$ (left of elbow)
- $\mathcal{R}=\{i: y_i-f(\mathbf{x}_i)>0\}$ (right of elbow)

Then Li et al. (2007) show that the Karush-Kuhn-Tucker (KKT) conditions for optimality of a solution $\hat{f}(\tau,\lambda)$ of problem (3) can be phrased as:

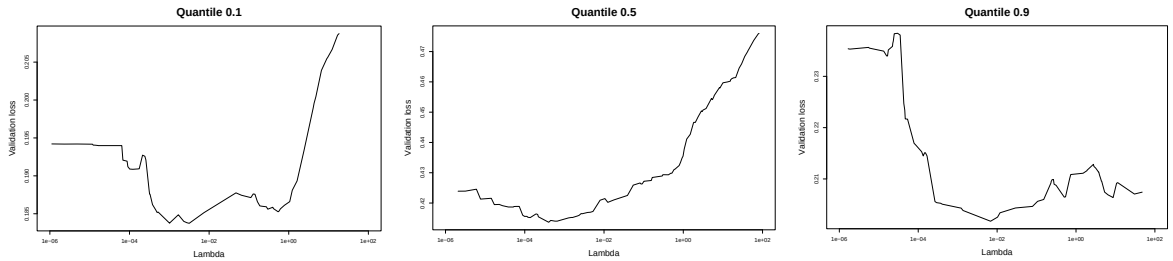

Figure 2. Estimated prediction error curves of Kernel Quantile Regression for some quantiles on one dataset. The errors are shown as a function of the regularization parameter λ

- $i \in \mathcal{E} \;\Rightarrow\; -(1-\tau) \le \hat{\theta}_i \le \tau$
- $i \in \mathcal{L} \;\Rightarrow\; \hat{\theta}_i = -(1-\tau)$
- $i \in \mathcal{R} \;\Rightarrow\; \hat{\theta}_i = \tau$
- $\sum_i \hat{\theta}_i = 0$

with some additional algebra they show that for a fixed τ, there is a series of *knots*, $0 = \lambda_0 < \lambda_1 < ... < \lambda_m < \infty$ such that for $\lambda \ge \lambda_m$ we have $\hat{f}(\tau, \lambda) =$ constant and for $\lambda_{k-1} < \lambda \le \lambda_k$ we have:

$$\hat{f}(\tau,\lambda)(\mathbf{x}) = \frac{1}{\lambda}\left(\lambda_k \hat{f}(\tau,\lambda_k)(\mathbf{x}) + (\lambda-\lambda_k)h_k(\mathbf{x})\right) \quad (6)$$

where $h_k(\mathbf{x}) = b_0^k + \sum_{i\in\mathcal{E}_k} b_i^k K(\mathbf{x},\mathbf{x}_i)$ can be thought of as the *direction* in which the solution is moving for the region $\lambda_{k-1} < \lambda \le \lambda_k$. The knots λ_k are points on the path where an observation passes between $\mathcal{E}$ and either $\mathcal{L}$ or $\mathcal{R}$, that is $\exists i \in \mathcal{E}$ such that exactly $\theta_i = \tau$ or $\theta_i = -(1-\tau)$. These insights lead Li et al. (2007) to an algorithm for incrementally generating $\hat{f}(\tau,\lambda)$ as a function of λ for fixed τ, starting from $\lambda = \infty$ (where the solution only contains the intercept β_0).

Although Li et al. (2007) suggest it is a topic for further study, it is in fact a reasonably straight forward extension of their results to show that a similar scenario holds when we fix λ and allow τ only to change, and also when both τ, λ are changing together *along a straight line*, i.e., a 1-dimensional subspace of the (τ,λ) space (this has been observed by Wang et al. (2006) for SVR, which is very similar from an optimization perspective). The explicit result is given in (Rosset, 2008), but we omit it here for brevity, given its marginal novelty.

Armed with this result, we next show the main result of this section: that the knots themselves move in a (piecewise) straight line as τ changes, and can therefore be *tracked* as τ and the regularization path change. Fix a quantile τ_0 and assume that λ_k is a knot in the λ-solution path for quantile τ_0. Further, let i_k be the observation that is passing in or out of the elbow at knot λ_k. Assume WLOG that $\hat{\theta}_{i_k}(\tau_0,\lambda_k) = \tau_0$, i.e. it is on the boundary between $\mathcal{R}_k$ and $\mathcal{E}_k$. Let $\tilde{\mathbf{K}}_{\mathcal{E}_k}$ be the matrix $\mathbf{K}_{\mathcal{E}_k}$ with the i_k column removed, and $\tilde{\mathbf{b}}^k = \mathbf{b}^k$ with index i_k removed. Let $s_i = \sum_{j\in\mathcal{R}\cup\mathcal{L}\cup\{i_k\}} K(\mathbf{x}_i,\mathbf{x}_j)$ for $i \in \mathcal{E}_k$. Let $\mathbf{s}_{\mathcal{E}_k}$ be the vector of all these values.

Theorem 1 *Any knot λ_k moves linearly as τ changes. That is, there exists a constant c_k such that for quantile $\tau_0 + \delta$ there is a knot in the λ-solution path at $\lambda_k + c_k\delta$, for $\delta \in [-\epsilon_k, \nu_k]$, a non-empty neighborhood of 0. c_k is determined through the solution of another set of $|\mathcal{E}_k|+1$ linear equations with $|\mathcal{E}_k|+1$ unknowns:*

$$\mathbf{B}^k \begin{pmatrix} \tilde{\mathbf{b}}^k \\ c_k \end{pmatrix} = \begin{pmatrix} -(|\mathcal{R}|+|\mathcal{L}|+1) \\ -\mathbf{s}_{\mathcal{E}_k} \end{pmatrix}$$

with

$$\mathbf{B}^k = \begin{pmatrix} 0 & \mathbf{1}^\mathsf{T} & 0 \\ \mathbf{1} & \tilde{\mathbf{K}}_{\mathcal{E}_k} & -\mathbf{y}_{\mathcal{E}_k} \end{pmatrix}$$

And the fit at this knot progresses as:

$$\hat{f}(\tau_0+\delta, \lambda_k + c_k\delta) = \quad (7)$$
$$= \frac{1}{\lambda_k + c_k\delta}\left(\lambda_k \hat{f}(\lambda_k,\tau_0)(\mathbf{x}) + \delta h_k(\mathbf{x})\right)$$
$$h_k(\mathbf{x}) = \tilde{b}_0^k + \sum_{i\in\mathcal{E}_k - i_k} \tilde{b}_i^k K(\mathbf{x},\mathbf{x}_i) + \quad (8)$$
$$+ \sum_{i\in\mathcal{L}\cup\mathcal{R}\cup\{i_k\}} K(\mathbf{x},\mathbf{x}_i)$$

This theorem tells us that we can in fact track the knots in the solution efficiently as τ changes. We still have to account for various types of *events* that can change the direction the knot is moving in. The value θ_i for a point in $\mathcal{E}_k - \{i_k\}$ can reach τ or $-(1-\tau)$, or a point in $\mathcal{L}\cup\mathcal{R}$ may reach the elbow $\mathcal{E}$. These events correspond to *knots crossings*, i.e., the knot λ_k is encountering another knot (which is tracking the other event). There are also *knot birth* events, and *knots*

merge events, which are possible but rare, and somewhat counter-intuitive. The details of how these are identified and handled can be found in the detailed algorithm description (Rosset, 2008). When any of these events occurs, the set of knots has to be updated and their directions have to be re-calculated using Theorem 1 and the new identity of the sets $\mathcal{E}, \mathcal{L}, \mathcal{R}$ and the observation i_k. This in essence allows us to map the whole 2-dimensional solution surface $\hat{f}(\tau, \lambda)$.

3. The Bi-Level Optimization Problem

Our next task is to show how our ability to track the knots as τ changes allows us to track the solution of the bi-level optimization problem (4), as τ changes. The key to this step is the following result.

Theorem 2 *Any minimizer*[1] *of (4) is always either at a knot in the λ-path for this τ or a point where a validation observation crosses the elbow. In other words, one of the two following statements must hold:*

- *λ^* is a knot: $\exists i \in \{1...n\}$ s.t. $\hat{f}(\tau, \lambda^*(\tau))(\mathbf{x}_i) = y_i$ and $\theta_i \in \{\tau, -(1-\tau)\}$, or*
- *λ^* is a* validation crossing*: $\exists i \in \{1...N\}$ s.t. $\hat{f}(\tau, \lambda^*(\tau))(\tilde{\mathbf{x}}_i) = \tilde{y}_i$*

Corollary 1 *Given the complete solution path for $\tau = \tau_0$, the solutions of the bi-level problem (4) for a range of quantiles around τ_0 can be obtained by following the paths of the knots and the validation crossings only, as τ changes.*

To implement this corollary in practice, we have two main issues to resolve: 1. How do we follow the paths of the validation crossings? 2. How do we determine which one of the knots and validation crossings is going to be optimal for every value of τ?

The first question is easy to answer when we consider the similarity between the knot following problem we solve in Theorem 1 and the validation crossing following problem. In each case we have a set of *elbow* observations whose fit must remain fixed as τ changes, but whose $\hat{\theta}$ values may vary; sets $\mathcal{L}, \mathcal{R}$ whose $\hat{\theta}$ are changing in a pre-determined manner with τ, but whose fit may vary freely; and one special observation which *characterizes* the knot or validation crossing. The only difference is that in a knot this is a *border* observation from the training set, so both its fit and its $\hat{\theta}$ are predetermined, while in the case of validation crossing it is a *validation* observation, whose fit must remain fixed (at the *elbow*), but which does not even have a $\hat{\theta}$ value. Taking all of this into account, it is easy to show a result similar to Theorem 1 for the validation crossings. We refer the reader to Rosset (2008) for the details.

The second question we have posed requires us to explicitly express the validation loss (i.e., L_τ on the validation set) at every knot and validation crossing in terms of δ, so we can compare them and identify the optimum at every value of δ. Using the representation in (7) we can write the *validation loss* for a knot k :

$$\sum_{i=1}^{N} \quad L_\tau(\tilde{y}_i, \hat{f}(\tau_0 + \delta, \lambda_k + c_k\delta)(\tilde{\mathbf{x}}_i)) = \ldots = \\ = \frac{\text{quadratic in } \delta}{\lambda_k + c_k\delta} \tag{9}$$

see Rosset (2008) for details, and note that similar expressions can naturally be derived for validation crossings. These are rational functions of δ with quadratic expressions in the numerator and linear expressions in the denominator. Our cross-validation task can be re-formulated as the identification of the minimum of these rational functions among all knots and validation crossings, for every value of τ in the current *segment*, where the directions h_k, h_v of all knots and validation crossings are fixed (and therefore so are the coefficients in the rational functions). This is a *lower-envelope* tracking problem, which has been extensively studied in the literature (Sharir and Agarwal (1995) and references therein).

To calculate the meeting point of two elements with neighboring scores we find the zeros of the cubic equation obtained by requiring equality for the two rational functions of the form (9) corresponding to the two elements. The smallest non-negative solution for δ is the one we are interested in.

4. Algorithm Overview

Bringing together all the elements from the previous sections, we now give (Algorithm 1) a succinct overview of the resulting algorithm. Since there is a multitude of details, we defer a detailed pseudo-code description of our algorithm to Rosset (2008).

The algorithm follows the knots of the λ-solution path as τ changes using the results of Section 2, and keeps track of the cross-validated solution using the results of Section 3. Every time an *event* happens (like a knot crossing), the direction in which two of the knots are moving has to be changed, or knots have to be added or deleted. Between these events, the evolution of the cross-validation objective at all knots and validation crossings has to be sorted and followed. Their order

[1] In pathological cases there may be a "segment" of minimizers. In this case it can be shown that such a segment will always be flanked by points described in the theorem.

is maintained, and updated whenever crossings occur between them.

4.1. Approximate Computational Complexity

Looking at Algorithm 1, we should consider the number of steps of the two loops and the complexity of the operations inside the loops. Even for a "standard" λ-path following problem for fixed τ, it is in fact impossible to rigorously bound the number of steps in the general case, but it has been argued and empirically demonstrated by several authors that the number of knots in the path behaves as $O(n)$, the number of samples (Rosset & Zhu, 2007; Hastie et al., 2004; Li et al., 2007). In our case the outer loop of Algorithm 1 implements a 2-dimensional path following problem, that can be thought of as following $O(n)$ 1-dimensional paths traversed by the knots of the path. It therefore stands to reason (and we confirm it empirically below) that the outer loop typically has $O(n^2)$ steps where *events* happen. The events in the inner loop, in turn, have to do with N validation observations meeting the $O(n)$ knots. So a similar logic would lead us to assume that the number of meeting events (counted by the inner loop) should be at most $O(nN)$ total for the whole running of the algorithm (i.e., many iterations of the outer loop may have no events happening in the inner loop). Each iteration of either loop requires a re-calculation of up to three directions (of knots or validation crossings), using Theorem 1. These calculations involve updating and inversion of matrices that are roughly $|\mathcal{E}| \times |\mathcal{E}|$ in size (where $|\mathcal{E}|$ is the number of observations in the elbow). However note that only one row and column are involved in the updating, leading to a complexity of $O(n + |\mathcal{E}|^2)$ for the whole direction calculation operation, using the Sherman-Morrison formula for updating the inverse. In principle, $|\mathcal{E}|$ can be equal to n, although it is typically much smaller for most of the steps of the algorithm, on the order of $\sqrt{n}$ or less. So we assume here that the loop cost is between $O(n)$ and $O(n^2)$.

Putting all of these facts and assumptions together, we can estimate the algorithm's complexity's *typical* dependence on the number of observations in the training and validation set as ranging between $O(n^2 \cdot \max(n, N))$ and $O(n^3 \cdot \max(n, N))$. Clearly, this estimation procedure falls well short of a formal "worst case" complexity calculation, but we offer it as an intuitive guide to support our experiments below and get an idea of the dependence of running time on the amount of data used.

We have not considered the complexity of the lower envelope tracking problem in our analysis, because it is expected to have a much lower complexity (number of order changes $O(\max(n, N) \log(\max(n, N)))$ and each order change involves $O(1)$ work).

5. Experiments

We demonstrate two main aspects of our methodology: The computational behavior as a function of the amount of training data used; and the ability of KQR to capture the form of the conditional distribution $P(Y|X)$, both in standard (i.i.d error) situations and when the error is not homoscedastic and asymmetric. We limit the experiments to simple simulated data, where we know the truth and can understand the behavior of KQR. This is due to shortage of space, and since our main contribution is not a new method that should be compared to competitors on real data, but rather a new algorithmic approach for an existing method.

Our simulation setup starts from univariate data $x \in [0, 1]$ and a "generating" function $f(x) = 2 \cdot \left(\exp(-30 \cdot (x - 0.25)^2) + \sin(\pi \cdot x^2)\right)$ (see Figure 3). We then let $Y = f(x) + \epsilon$, where the errors ϵ are independent, with a distribution that can be either:

1. $\epsilon \sim N(0, 1)$, i.e., i.i.d standard normal errors
2. $\epsilon + (x+1)^2 \sim \exp(1/(x+1)^2)$, which gives us errors that are still independent and have mean 0, but are asymmetric and have non-constant variance, with small signal-to-noise ratio on the higher values of x (see Figure 4).

Figure 3 demonstrates the results of the algorithm with i.i.d normal errors, 200 training samples and 200 validation samples and Gaussian kernel with parameter $\sigma = 0.2$. We see that the quantile estimates all capture the general shape of the true curve, with some "smoothing" due to regularization.

Next we consider the computational complexity of the algorithm, and its dependence on the number of training samples (with 200 validation samples). We compare it to the 1-dimensional KQR algorithm of Li et al. (2007), who have already demonstrated that their algorithm is significantly more efficient than grid-based approaches for generating 1-dimensional paths for fixed τ. Table 1 shows the number of steps of the main (outer) loop of Algorithm 1 and the total run time of our algorithm for generating the complete set of cross-validated solutions for $\tau \in [0.1, 0.9]$ as a function of the number of training samples (with validation sample fixed at 200). Also shown is the run time for the algorithm of Li et al. (2007), when we use it on a

Algorithm 1 Main steps of our bi-level path following algorithm

Input: The entire λ-solution path for quantile τ_0; the bi-level optimizer $\lambda^*(\tau_0)$
Output: Cross-validated solutions $f^*(\tau)$ for $\tau \in [\tau_0, \tau_{\text{end}}]$
Initialization: identify all knots and validation crossings in the solution path for τ_0;
Find direction of each knot according to Theorem 1
Find direction of each validation crossing
Create a list M of knots and validation crossings sorted by their validation loss
Let $\lambda^*(\tau_0)$ be the one at the bottom of the list M, and $f^*(\tau_0)$ accordingly
Calculate future meeting of each pair of neighbors in M by solving the cubic equation implied by (9)
Set $\tau_{\text{now}} = \tau_0$
while $\tau_{\text{now}} < \tau_{\text{end}}$ **do**
  Find value $\tau_1 > \tau_{\text{now}}$ where first knot crossing occurs
  Find value $\tau_2 > \tau_{\text{now}}$ where first knot merge occurs
  Find value $\tau_3 > \tau_{\text{now}}$ where first knot birth occurs
  Set $\tau_{\text{new}} = \min(\tau_1, \tau_2, \tau_3)$
  while $\tau_{\text{now}} < \tau_{\text{new}}$ **do**
    Find value $\tau_4 > \tau_{\text{now}}$ where first future meeting (order change) in M occurs
    Find value $\tau_5 > \tau_{\text{now}}$ where first validation crossing birth occurs
    Find value $\tau_6 > \tau_{\text{now}}$ where first validation crossing cancelation occurs
    Set $\tau_{\text{next}} = \min(\tau_4, \tau_5, \tau_6)$
    Update $\lambda^*(\tau), f^*(\tau)$ for $\tau \in (\tau_{\text{now}}, \tau_{\text{next}})$ as the evolution of the knot or validation crossing attaining the minimal L_τ in M (i.e., the one at $\lambda^*(\tau_{\text{now}})$)
    Update M according to the first event (order change, birth, cancelation)
    Update the future meetings of the affected elements using (9)
    Set $\tau_{\text{now}} = \tau_{\text{next}}$
  end while
  Update the list of knots according to the first event (knot crossing, birth, merge)
  Update the directions of affected knots using Theorem 1
end while

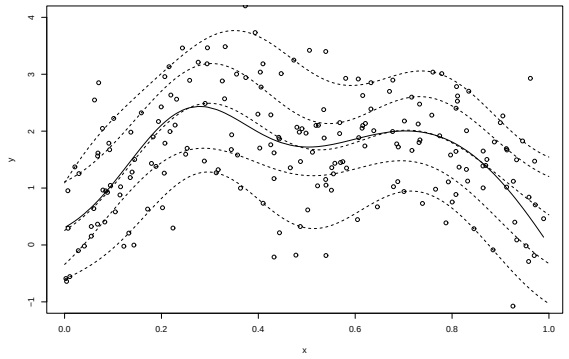

Figure 3. The function $f(x)$ (solid), data points drawn from it with i.i.d normal error, and our cross-validated estimates of quantiles $0.1, 0.25, 0.5, 0.75, 0.9$ (dahsed lines, from bottom to top).

grid of 8000 evenly spaced τ values in $[0.1, 0.9]$ and find the best cross validated solution by enumerating the candidates as identified in Section 3. Our conjecture that the number of knots in the 2-dimensional path behaves like $O(n^2)$ seems to be consistent with these results, as is the hypothesized overall time complexity dependence of $O(n^3)$.

Finally, we demonstrate the ability of KQR to capture the quantiles with "strange" errors from model 2. Figure 4 shows a data sample generated from this model and the $(0.25, 0.5, 0.75)$ quantiles of the conditional distribution $P(Y|X)$ (solid), compared to their cross-validated KQR estimates (dashed), using 500 samples for learning and 200 for validation (more data is needed for learning because of the very large variance at values of x close to 1). As expected, we can see that estimation is easier of the lower quantiles and at smaller values of x, because the distribution $P(Y|X = x)$ has long right tails everywhere and has much larger variance when x is big.

Table 1. Number of steps and run times of our algorithm and of Li et al. (2007), for the whole path from $\tau = 0.1$ to $\tau = 0.9$.

100	12269	99 SEC.	900 SEC.
50	2249	23 SEC.	480 SEC.

6. Conclusions and Extensions

In this paper we have demonstrated that the family of bi-level optimization problems (4) defined by the

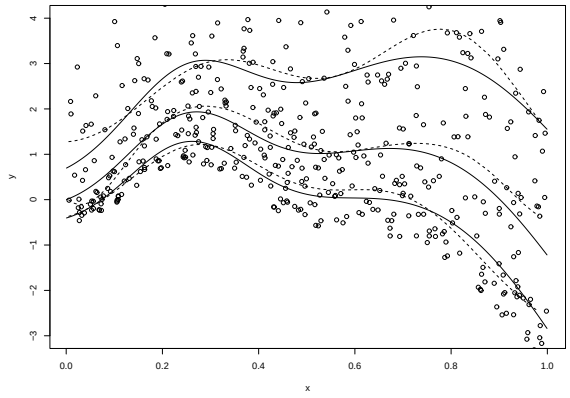

Figure 4. Quantiles of $P(Y|X)$ (solid), and their estimates (dashed) for quantiles $(0.25, 0.5, 0.75)$ with the exponential error model.

family of loss functions L_τ can be solved via a *path following* approach which essentially maps the whole surface of solutions $\hat{f}(\tau, \lambda)$ as a function of both τ and λ and uses insights about the possible locations of the bi-level optima to efficiently find them. This leads to a closed-form algorithm for finding $f^*(\tau)$ for all quantiles. We see two main contributions in this work: a. Identification and solution of a family of non-convex optimization problem of great practical interest which can be solved using solely convex optimization techniques; and b. Formulation of a practical algorithm for generating the full set of cross-validated solutions for the family of kernel quantile regression problems.

Our algorithm as presented here can easily be adapted to bi-level path following of cross validated solutions of SVR, as the size ϵ of the *don't-care* region changes (see Rosset (2008) for details). However, it should be noted that the statistical motivation for solving quantile regression for multiple quantiles does not really carry through to ϵ-SVR, as the parameter ϵ and the loss function it parameterizes do not have a natural interpretation in the spirit of τ.

There are many other interesting aspects of our work, which we have not touched on here, including: development of further optimization shortcuts to improve algorithmic efficiency; investigation of the range of applicability of our algorithmic approach beyond KQR and SVR; analysis of the use of various kernels for KQR and how the kernel parameters and kernel properties interact with the solutions; implementation of in-sample model selection approaches such as SIC (Koenker, 2005; Li et al., 2007) instead of cross validation in our framework (which should require minimal changes).

Abstract

The Group-Lasso method for finding important explanatory factors suffers from the potential non-uniqueness of solutions and also from high computational costs. We formulate conditions for the uniqueness of Group-Lasso solutions which lead to an easily implementable test procedure that allows us to identify all potentially active groups. These results are used to derive an efficient algorithm that can deal with input dimensions in the millions and can approximate the solution path efficiently. The derived methods are applied to large-scale learning problems where they exhibit excellent performance and where the testing procedure helps to avoid misinterpretations of the solutions.

1. Introduction

In many practical learning problems we are not only interested in low prediction errors but also in identifying important explanatory factors. These explanatory factors can often be represented as groups of input variables. Common examples are k-th order polynomial expansions of the inputs where the groups consist of products over combinations of variables up to degree k. Such expansions compute explicit mappings into feature spaces induced by polynomial kernel functions of the form $k(\boldsymbol{x}, \boldsymbol{y}) = (1 + \boldsymbol{x} \cdot \boldsymbol{y})^k$. Another popular example are categorical variables that are represented as groups of dummy variables.

A method for variable selection which has gained particular attention is the Lasso (Tibshirani, 1996) which exploits the idea of using ℓ_1-constraints in fitting problems. The Group-Lasso (Yuan & Lin, 2006) extends the former in the sense that it finds solutions that are sparse on the level of *groups* of variables, which makes this method a good candidate for situations described above. The Group-Lasso estimator, however, has several drawbacks: (i) in high-dimensional spaces, the solutions may not be unique. The potential existence of several solutions that involve different variables seriously hampers the interpretability of "identified" explanatory factors; (ii) existing algorithms can handle input dimensions up to thousands (Kim et al., 2006) or even several thousands (Meier et al., 2008), but in practical applications with high-order interactions or polynomial expansions these limits are easily exceeded; (iii) contrary to the standard Lasso, the solution path (i.e. the evolution of the individual group norms as a function of the constraint) is not piecewise linear, which precludes the application of efficient optimization methods like *least angle regression* (LARS) (Efron et al., 2004).

In this paper we address all these issues: (i) we derive conditions for the *completeness* and *uniqueness* of Group-Lasso estimates, where we call a solution *complete*, if it includes all groups that might be relevant in other solutions (meaning that we cannot have "overlooked" relevant groups). Based on these conditions we develop an easily implementable *test procedure*. If a solution is not complete, this procedure *identifies all other groups* that may be included in alternative solutions with identical costs. (ii) These results allow us to formulate a *highly efficient active-set algorithm* that can deal with input dimensions in the millions. (iii) The *solution path* can be approximated on a fixed grid of constraint values with almost no additional computational costs. Large-scale applications using both synthetic and real data illustrate the excellent performance of the developed concepts and algorithms. In particular, we demonstrate that the proposed completeness test successfully detects ambiguous solutions and thus avoids the misinterpretation of "identified" explanatory factors.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

2. Characterization of Group-Lasso Solutions for Generalized Linear Models

This section largely follows (Osborne et al., 2000), with the exception that here we address the *Group*-Lasso problem and a more general class of likelihood functions.

According to (McCullaghand & Nelder, 1983), a generalized linear model (GLM) consists of three elements:
(i) a random component $f(y;\mu)$ specifying the stochastic behavior of a response variable Y;
(ii) a systematic component $\eta = \boldsymbol{x}^\top\boldsymbol{\beta}$ specifying the variation in the response variable accounted for by known covariates $\boldsymbol{x}$; and
(iii) a link function $g(\mu) = \eta$ specifying the relationship between the random and systematic components.
The random component $f(y;\mu)$ is typically an exponential family distribution

$$f(y;\theta,\phi) = \exp(\phi^{-1}(y\theta - b(\theta)) + c(y,\phi)), \qquad (1)$$

with natural parameter θ, sufficient statistics y/ϕ, log partition function $b(\theta)/\phi$ and a scale parameter $\phi > 0$.

Note that in the model (1) the mean of the responses $\mu = E_\theta[y]$ is related to the natural parameter θ by $\mu = b'(\theta)$. The link function g can be any strictly monotone differentiable function. In the following, however, we will consider only *canonical* link functions for which $g(\mu) = \eta = \theta$. We will thus use the parametrization $f(y;\eta,\phi)$.

From a technical perspective, an important property of this framework is that $\log f(y;\eta,\phi)$ is strictly concave in η. This follows from the fact that the one-dimensional sufficient statistics y/ϕ is necessarily *minimal*, which implies that the log partition function $b(\eta)/\phi$ is strictly convex, see (Brown, 1986; Wainwright et al., 2005).

The standard linear regression model is a special case derived from the normal distribution with $\phi = \sigma^2$, the identity link $\eta = \mu$ and $b(\eta) = (1/2)\eta^2$. Other popular models include logistic regression (binomial distribution), Poisson regression for count data and gamma- (or exponential-, Weibull-) models for cost- or survival analysis.

Given an i.i.d. data sample $\{\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n\}$, $\boldsymbol{x}_i \in \mathbb{R}^d$, arranged as rows of the data matrix X, and a corresponding vector of responses $\boldsymbol{y} = (y_1,\ldots,y_n)^\top$, we will consider the problem of minimizing the negative log-likelihood

$$\begin{aligned} l(\boldsymbol{y},\boldsymbol{\eta},\boldsymbol{\phi}) &= -\sum_i \log f(y_i;\eta_i,\phi) \\ &= -\sum_i \phi^{-1}(y_i\eta_i - b(\eta_i)) + c(y_i,\phi). \end{aligned} \qquad (2)$$

We assume that the scale parameter is known, and for the sake of simplicity we assume $\phi = 1$. Since $\eta = x^T\beta$, the gradient of l can be viewed as a function in either $\boldsymbol{\eta}$ or $\boldsymbol{\beta}$:

$$\begin{aligned} \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta}) &= -(\boldsymbol{y} - g^{-1}(\boldsymbol{\eta})), \\ \nabla_{\boldsymbol{\beta}} l(\boldsymbol{\beta}) &= -X^\top \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta}) = -X^\top(\boldsymbol{y} - g^{-1}(X\boldsymbol{\beta})), \end{aligned} \qquad (3)$$

where $g^{-1}(\boldsymbol{\eta}) := (g^{-1}(\eta_1),\ldots,g^{-1}(\eta_n))^\top$. The corresponding Hessians are

$$H_{\boldsymbol{\eta}} = W, \quad H_{\boldsymbol{\beta}} = X^\top W X, \qquad (4)$$

where W is diagonal with elements $W_{ii} = (g^{-1})'(\eta_i) = 1/(g'(\mu_i)) = \mu'(\eta_i) = b''(\eta_i)$.

For the following derivation, it is convenient to partition X, $\boldsymbol{\beta}$ and $\boldsymbol{h} := \nabla_{\boldsymbol{\beta}} l$ into J subgroups: $X = (X_1,\ldots,X_j)$,

$$\boldsymbol{\beta} = \begin{pmatrix} \boldsymbol{\beta}_1 \\ \vdots \\ \boldsymbol{\beta}_J \end{pmatrix}, \quad \boldsymbol{h} = \begin{pmatrix} \boldsymbol{h}_1 \\ \vdots \\ \boldsymbol{h}_J \end{pmatrix} = \begin{pmatrix} X_1^\top \nabla_{\boldsymbol{\eta}} l \\ \vdots \\ X_J^\top \nabla_{\boldsymbol{\eta}} l \end{pmatrix}. \qquad (5)$$

As stated above, b is strictly convex in $\theta = \eta$, thus $b''(\eta_i) > 0$ which in turn implies that $H_{\boldsymbol{\eta}} \succ 0$ and $H_{\boldsymbol{\beta}} \succeq 0$. This means that l is a strictly convex function in $\boldsymbol{\eta}$. For general matrices X it is convex in $\boldsymbol{\beta}$, and it is strictly convex in $\boldsymbol{\beta}$ if X has full rank and $d \leq n$.

Given X and $\boldsymbol{y}$, the Group-Lasso minimizes the negative log-likelihood viewed as a function in $\boldsymbol{\beta}$ under a constraint on the sum of the ℓ_2-norms of the subvectors $\boldsymbol{\beta}_j$:

$$\text{minimize } l(\boldsymbol{\beta}) \quad \text{s.t.} \quad g(\boldsymbol{\beta}) \geq 0, \qquad (6)$$

$$\text{where} \quad g(\boldsymbol{\beta}) = \kappa - \textstyle\sum_{i=1}^J \|\boldsymbol{\beta}_j\|. \qquad (7)$$

Here $g(\boldsymbol{\beta})$ is implicitly a function of the fixed parameter κ.

Considering the *unconstrained* problem, the solution is not unique if the dimensionality exceeds n: every $\boldsymbol{\beta}^* = \boldsymbol{\beta}^0 + \boldsymbol{\xi}$ with $\boldsymbol{\xi}$ being an element of the null space $\boldsymbol{N}(X)$ is also a solution. By defining the unique value

$$\kappa_0 := \min_{\boldsymbol{\xi}\in\boldsymbol{N}(X)} \textstyle\sum_{i=1}^J \|\boldsymbol{\beta}_j^0 + \boldsymbol{\xi}_j\|, \qquad (8)$$

we will require that the constraint is active i.e. $\kappa < \kappa_0$. Note that the minimum κ_0 is unique, even though there might exist several vectors $\boldsymbol{\xi} \in \boldsymbol{N}(X)$ which attain this minimum. Enforcing the constraint to be active is essential for the following characterization of solutions. Although it might be infeasible to ensure this activeness by computing κ_0 and selecting κ accordingly, practical algorithms will not suffer from this problem: given a solution, we can always check if the constraint was active. If this was not the case, then the uniqueness question reduces to checking if $d \leq n$ (if X has full rank). In this case the solutions are usually not sparse, because the feature selection mechanism has been switched off. To produce a sparse solution,

one can then try smaller κ-values until the constraint is active. In section 3 we propose a more elegant solution to this problem in the form of an algorithm that approximates the solution path, i.e. the evolution of the group norms when relaxing the constraint. This algorithm can be initialized with an arbitrarily small constraint value κ^0 which typically ensures that the constraint is active in the first optimization step. Activeness of the constraint in the following steps can then be monitored by observing the decay of the Lagrange parameter when increasing κ, cf. Eq. (14) below.

Under the assumption $l > -\infty$ a minimum of (6) is guaranteed to exist, since l is continuous and the region of feasible vectors β is compact. The assumption $l > -\infty$ simply means that the likelihood is finite ($f < +\infty$) for all parameter values θ which is usually satisfied for models of practical importance (see (Wedderburn, 1973) for a detailed discussion), and we will restrict our further analysis to models of this kind[1]. Since we assume that the constraint is active, any solution $\widehat{\boldsymbol{\beta}}$ will lie on the boundary of the constraint region. It is easily seen that $\sum_{j=1}^{J} \|\boldsymbol{\beta}_j\|$ is convex which implies that $g(\boldsymbol{\beta})$ is concave. Thus, the region of feasible values defined by $g(\boldsymbol{\beta}) \geq 0$ is convex. If $d \leq n$, the objective function l will be strictly convex if X has full rank, which additionally implies that the minimum is unique. In summary, we can state the following theorem:

Theorem 1. *If $\kappa < \kappa_0$ and X has maximum rank, then the following holds: (i) A solution $\widehat{\boldsymbol{\beta}}$ exists and $\sum_{i=1}^{J} \|\widehat{\boldsymbol{\beta}}_j\| = \kappa$ for any such solution. (ii) If $d \leq n$, the solution is unique.*

The Lagrangian for problem (6) reads

$$\mathcal{L}(\boldsymbol{\beta}, \lambda) = l(\boldsymbol{\beta}) - \lambda g(\boldsymbol{\beta}). \tag{9}$$

For a given $\lambda > 0$, $\mathcal{L}(\boldsymbol{\beta}, \lambda)$ is a convex function in $\boldsymbol{\beta}$. Under the assumption $l > -\infty$ a minimum is guaranteed to exist, since g goes to infinity if $\|\boldsymbol{\beta}\| \to \infty$.

The vector $\widehat{\boldsymbol{\beta}}$ minimizes $\mathcal{L}(\boldsymbol{\beta}, \lambda)$ iff the d-dimensional null-vector $\mathbf{0}_d$ is an element of the subdifferential $\partial_{\boldsymbol{\beta}} \mathcal{L}(\boldsymbol{\beta}, \lambda)$. Let d_j denote the dimension of the j-th subvector $\boldsymbol{\beta}_j$ (i.e. the size of the j-th subgroup). The subdifferential is

$$\partial_{\boldsymbol{\beta}} \mathcal{L}(\boldsymbol{\beta}, \lambda) = \nabla_{\boldsymbol{\beta}} l(\boldsymbol{\beta}) + \lambda \boldsymbol{v} = X^\top \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta}) + \lambda \boldsymbol{v}, \tag{10}$$

with $\boldsymbol{v} = (\boldsymbol{v}_1, \dots \boldsymbol{v}_J)^\top$ defined by

$$\begin{aligned} \boldsymbol{v}_j &= \frac{\boldsymbol{\beta}_j}{\|\boldsymbol{\beta}_j\|}, \text{ if } \boldsymbol{\beta}_j \neq \mathbf{0}_{d_j} \text{ and} \\ \boldsymbol{v}_j &\in \{\boldsymbol{a} \in \mathbb{R}^{d_j} : \|\boldsymbol{a}\| \leq 1\}, \text{ else.} \end{aligned} \tag{11}$$

Thus, $\widehat{\boldsymbol{\beta}}$ is a minimizer for λ fixed iff

$$\mathbf{0}_d = X^\top \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\widehat{\boldsymbol{\eta}}} + \lambda \boldsymbol{v} \qquad (\text{with } \widehat{\boldsymbol{\eta}} = X\widehat{\boldsymbol{\beta}}), \tag{12}$$

[1]Technically we require that the domain of l is $\mathbb{R}^d$, which implies that Slater's condition holds.

for some $\boldsymbol{v}$ of the form described above. Hence, for all j with $\widehat{\boldsymbol{\beta}}_j \neq \mathbf{0}_{d_j}$ it holds that

$$\|X_j^\top \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\widehat{\boldsymbol{\eta}}}\| = \lambda. \tag{13}$$

For all other j with $\widehat{\boldsymbol{\beta}}_j = \mathbf{0}_{d_j}$ it holds that $\|X_j^\top \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\widehat{\boldsymbol{\eta}}}\| \leq \lambda$ which implies

$$\lambda = \max_j \|X_j^\top \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\widehat{\boldsymbol{\eta}}}\|. \tag{14}$$

Lemma 1. *Let $\widehat{\boldsymbol{\beta}}$ be a solution of (6). Let $\lambda = \lambda(\widehat{\boldsymbol{\beta}})$ be the associated Lagrangian multiplier. Then λ and $\widehat{\boldsymbol{h}} = \nabla_{\boldsymbol{\beta}} l(\boldsymbol{\beta})|_{\boldsymbol{\beta}=\widehat{\boldsymbol{\beta}}}$ are constant across all solutions $\widehat{\boldsymbol{\beta}}_{(i)}$ of (6).*

Proof. Since the value of the objective function $l(\boldsymbol{\eta}_{(i)}) = l_*$ is constant across all solutions and l is strictly convex in $\boldsymbol{\eta} = X\boldsymbol{\beta}$ and convex in $\boldsymbol{\beta}$, it follows that $\widehat{\boldsymbol{\eta}}$ must be constant across all solutions $\widehat{\boldsymbol{\beta}}_{(i)}$, which implies that $\nabla_{\boldsymbol{\beta}} l(\boldsymbol{\beta})|_{\boldsymbol{\beta}=\widehat{\boldsymbol{\beta}}} = X^\top \nabla_{\boldsymbol{\eta}} l(\boldsymbol{\eta})|_{\boldsymbol{\eta}=\widehat{\boldsymbol{\eta}}}$ is constant across all solutions. Uniqueness of λ follows now from (14). □

Theorem 2. *Let λ be the Lagrangian parameter associated with some (any) solution $\widehat{\boldsymbol{\beta}}$ of (6) and let $\widehat{\boldsymbol{h}}$ be the unique gradient vector at the optimum. Let $\mathcal{B} = \{j_1, \dots, j_p\}$ be the unique set of indices for which $\|\widehat{\boldsymbol{h}}_j\| = \lambda$. Then $\widehat{\boldsymbol{\beta}}_j = \mathbf{0}_{d_j}$ $\forall j \notin \mathcal{B}$ across all solutions $\widehat{\boldsymbol{\beta}}_{(i)}$ of (6).*

Proof. A solution with $\widehat{\boldsymbol{\beta}}_j \neq \mathbf{0}_{d_j}$ for at least one $j \notin \mathcal{B}$ would contradict (13). □

Assume that an algorithm has found a solution $\widehat{\boldsymbol{\beta}}$ of (6) with the set of "active" groups $\mathcal{A} := \{j : \widehat{\boldsymbol{\beta}}_j \neq \mathbf{0}\}$. If $\mathcal{A} = \mathcal{B} = \{j : \|\widehat{\boldsymbol{h}}_j\| = \lambda\}$, then there cannot exist any other solution with an active set $\mathcal{A}'$ with $|\mathcal{A}'| > |\mathcal{A}|$. Thus, $\mathcal{A} = \mathcal{B}$ implies that all relevant groups are contained in the solution $\widehat{\boldsymbol{\beta}}$. Otherwise, the additional elements in $\mathcal{B}$ which are not contained in $\mathcal{A}$ define all possible groups that potentially become active in alternative solutions.

Note that $\mathcal{A} = \mathcal{B}$ guarantees that we cannot have "overlooked" relevant groups, which is typically sufficient in practical applications. We will call such a solution *complete*. However, $\mathcal{A}$ might still contain redundant groups, and we might be additionally interested if we have found a *unique* (an thus minimal) set $\mathcal{A}$. The following theorem characterizes a simple test for uniqueness under a further rank assumption of the data matrix X.

Theorem 3. *Assume that every $n \times n$ submatrix of X has full rank. Let $\mathcal{A}$ be the active set corresponding to some solution $\widehat{\boldsymbol{\beta}}$ of (6) and let $X_{\mathcal{A}}$ be the $n \times s$ submatrix of X composed of all active groups. Assume further that $\mathcal{A}$ is complete, i.e. $\mathcal{A} = \mathcal{B}$. Then, if $s \leq n$, $\widehat{\boldsymbol{\beta}}$ is the unique solution of (6).*

Proof. Since the set $\mathcal{B}$ is unique, the assumption $\mathcal{A} = \mathcal{B}$ implies that the search for the optimal solution can be restricted to the space $\mathbb{S} = \mathbb{R}^s$. If $s \leq n$, $X_\mathcal{A}$ must have full rank by assumption. Thus, $l(\beta_\mathbb{S})$ is a strictly convex function on $\mathbb{S}$ which is minimized over the convex constraint set. Thus, $\widehat{\boldsymbol{\beta}}_\mathbb{S}$ is the unique minimizer on $\mathbb{S}$. Since all other $\widehat{\boldsymbol{\beta}}_{j:j\notin\mathcal{A}}$ must be zero, $\widehat{\boldsymbol{\beta}}$ is unique on the whole space. □

In practice, it might be difficult to guarantee the rank condition in the above theorem. Note, however, that for a given set $\mathcal{A}$ and associated matrix $X_\mathcal{A}$ it is sufficient to check if *rank*$(X_\mathcal{A}) = s$ via SVD or QR-decomposition.

3. An Efficient Active-Set Algorithm

The characterization of optimal solutions presented above is now used to build a highly efficient algorithm, which is a straight-forward generalization of the subset algorithm for the standard Lasso problem presented in (Osborne et al., 2000). Similar ideas for the standard Lasso have also been introduced in (Shevade & Keerthi, 2003). The algorithm starts with only one active group. The selection of further active groups (or their removal) is guided by observing Lagrangian violations. Testing for completeness of the active set will then identify all groups that could have nonzero coefficients in alternative solutions.

A: Initialize set $\mathcal{A} = \{j_0\}$, $\boldsymbol{\beta}_{j_0}$ arbitrary with $\|\boldsymbol{\beta}_{j_0}\| = \kappa$.
B: Optimize over the current active set $\mathcal{A}$. Define set $\mathcal{A}^+ = \{j \in \mathcal{A} : \|\boldsymbol{\beta}_j\| > 0\}$ (some $\boldsymbol{\beta}_j$ could have vanished during optimization). Define $\lambda = \max_{j\in\mathcal{A}^+} \|\boldsymbol{h}_j\|$. Adjust the active set $\mathcal{A} = \mathcal{A}^+$.
C: Lagrangian violation. $\forall j \notin \mathcal{A}$, check if $\|\boldsymbol{h}_j\| \leq \lambda$. If this is the case, we have found a global solution. Otherwise, include the group with the largest violation to $\mathcal{A}$ and go to **B**.
D: Completeness and uniqueness. $\forall j \notin \mathcal{A}$, check if $\|\boldsymbol{h}_j\| = \lambda$. If so, there might exist other solutions with identical costs that include these groups in the active set. Otherwise, the active set is *complete* in the sense that it contains all relevant groups. If X_a has full rank $s \leq n$, *uniqueness* can be checked additionally via theorem 3. Note that step **D** requires (almost) no additional computations, since it is a by-product of step **C**.

The above algorithm is easily extended to practical optimization routines in which we stop the fitting process at a predefined tolerance level: testing for "completeness within a ϵ-range" ($|\|\boldsymbol{h}_j\| - \lambda| < \epsilon$ in **D** with ϵ being the maximum deviation of gradient norms from λ in the active set) will then identify all potentially active groups in alternative solutions with costs close to the actual costs.

The minimization in step **B** can be performed efficiently by the projected gradient method introduced in (Kim et al., 2006), which is applicable for all continuous convex cost functions. Finding the projection is typically the computational bottleneck in methods of this kind. For our special case, however, the projection can be found very efficiently. We refer the reader to (Kim et al., 2006) for details.
Iterate:
B1: Gradient. At time $t-1$, set $\boldsymbol{b} = \boldsymbol{\beta}^{t-1} - s\nabla_{\boldsymbol{\beta}} l(\boldsymbol{\beta}^{t-1})$ and $\mathcal{A}^+ = \mathcal{A}$, where s is a step-size parameter.
B2: Projection. For all $j \in \mathcal{A}^+$ define $M_j := \|\boldsymbol{b}_j\| + (\kappa - \sum_j \|\boldsymbol{b}_j\|)/|\mathcal{A}^+|$. If $M_j \geq 0\, \forall j \in \mathcal{A}^+$, go to **B3**. Else update the active set $\mathcal{A}^+ = \{j : M_j > 0\}$ and repeat **B2**.
B3: New solution. For all $j \in \mathcal{A}^+$ set $\boldsymbol{\beta}_j^t = \boldsymbol{b}_j M_j / \|\boldsymbol{b}_j\|$. For all other $j \in \mathcal{A}, j \notin \mathcal{A}^+$ set $\boldsymbol{\beta}_j^t = 0$.

Note that during the whole algorithm, access to the full set of variables is only necessary in steps **C** and **D**, which are outside the core optimization routine. Thus, in large-scale applications where not all groups can be hold in the main memory, we still have a rather efficient method, even if we have to access external storage in steps **C/D**.

Computing the Solution Path. Contrary to the standard Lasso, the Group-Lasso does not exhibit a piecewise linear solution path. Algorithms like LARS (Efron et al., 2004) are therefore not applicable. Despite this problem, we can still approximate the solution path on a grid of constraint values with almost no additional costs: starting with a very small $\kappa^{(0)}$ (which will result in a small active set), we iteratively relax the constraint, resulting in a series of increasing values $\kappa^{(i)}$. Note that at the i-th step, the previous solution $\boldsymbol{\beta}(\kappa^{(i-1)})$ is a feasible initial estimate since $\kappa^{(i)} > \kappa^{(i-1)}$. Typically only few further iterations are needed to find $\boldsymbol{\beta}(\kappa^{(i)})$. Completeness/uniqueness can be tested efficiently at every step i. In practical applications we observed that the stepwise approximation of the solution path up to some final $\kappa^{(f)}$ is usually *faster* than directly computing the solution for $\kappa^{(f)}$, probably because the stepwise procedure allows the use of larger stepsizes.

4. Applications

As a first application example we use synthetic data generated by a script that has been used in the context of the NIPS'03 feature selection workshop (follow the link "dataset description" on the workshop webpage www.clopinet.com/isabelle/Projects/NIPS2003/#challenge). We reproduced the XOR example explained in the above cited document: there are two classes, each of which is composed of two Gaussian clusters. Two "useful" features are drawn from $N(0,1)$ for each cluster. Some covariance is added by multiplying by a random matrix. The clusters are placed in an XOR configuration and 3200 "useless" features are added, drawn from $N(0,1)$. All the features are shifted and rescaled randomly. Random noise is then added according to $N(0, 0.1)$. Finally, 1% of the labels are ran-

domly flipped. We construct a training set of size 2000 and a test set of size 6000.

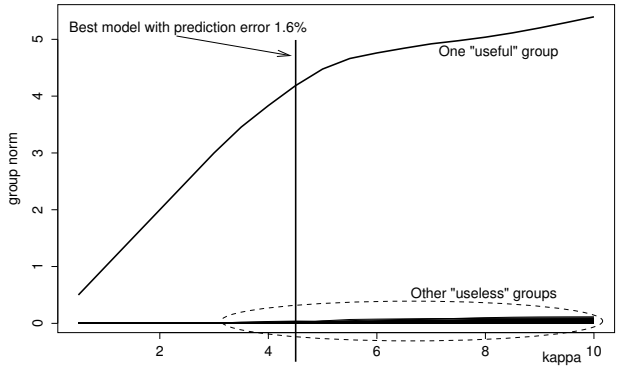

Figure 1. Solution path for the XOR problem with 3200 noise dimensions. The norm of the one "useful" group grows steeply when the constraint is relaxed. What appears as a horizontal "thickening" line is an overlay of 275 "useless" groups.

Without feature selection, prediction becomes very difficult: a SVM with RBF kernel achieves 42% test error (on the subset of the two "useful" features the error decreases to 1.5%). Moreover, simple feature selection methods like correlation-based scoring fail badly on these data.

We expand the dataset in a polynomial basis of degree 2, i.e. each pair of features (a, b) is mapped to a 5-dimensional vector $(a, b, a \cdot b, a^2, b^2)$. Given the 3202 features (2 + 3200 "useless"), this expansion yields $\approx 5 \cdot 10^6$ groups of size 5, each of which contains 5 quadratic interactions. We are, thus, working in a $\approx 2.5 \cdot 10^7$-dimensional space. Since the expanded feature set cannot be hold in the main memory, we only store the original dataset and recompute the expansions on demand. Despite this computational overhead, our active set algorithm allows us to optimize the Group-Lasso functional very efficiently, see also Figure 2. Since we are dealing with a classification problem, we choose the logistic model from the GLM family. Figure 1 shows the solution path for the logistic Group-Lasso when relaxing κ in 20 steps. Note that in the first iterations the algorithm was able to determine the one "useful" group of variables. The norm of the corresponding weight vector increases almost linearly until $\kappa \approx 4.5$, where the minimum error rate of 1.6% on the test set is obtained.

Testing both the completeness and the uniqueness of the active set gives a positive result, which guarantees that at this constraint value there are no alternative solutions. Further increasing κ leads to the selection of additional groups with spurious weights. The model obtained for $\kappa = 10$ uses 275 groups which include "useless" features and have norms < 0.2. Solutions for $\kappa > 5$ appear to be lacking completeness: our test identified a steeply increasing number of other groups that may also become active. Given that the "useless" variables are randomly drawn from a normal distribution, the observed lack of completeness might be caused by the limited numerical precision in the optimization routine: for models with $\kappa < 7$ we could indeed show by increasing the numerical precision that the solutions are complete, however at the price of drastically increasing computational costs. For larger models, however, we were not able to find complete solutions within any reasonable time limits. This result nicely shows that lacking completeness of Group-Lasso solutions is indeed a relevant issue in real-world applications which are necessarily computed with limited numerical precision. Besides the theoretical properties of our completeness test, this test might thus be also a valuable *practical* tool to detect possible ambiguities that are caused by numerical problems.

To compare the efficiency of our active set algorithm with related approaches, we measured the time needed to compute ten steps of the solution path ($\kappa = 1, 2, \ldots, 10$) for different numbers of "useless" groups. Figure 2 shows the observed computation times of three different methods: (1): the *blockwise sparse* method (Kim et al., 2006), (2): the *block coordinate* method by (Meier et al., 2008), (3): our algorithm. The comparison with method 1 was straight forward, since the same implementation was used (note that by dropping the active set selection mechanism, our method simply reduces to method (1)). In order to guarantee a fair comparison with method (2) for which we used the R-package `grplasso`, a few modifications were necessary: we first trained our method on the data and recorded the sequence of Lagrange parameters $\lambda_1, \ldots, \lambda_{10}$ corresponding to the sequence of constraints $\kappa = 1, 2, \ldots, 10$, since the `grplasso` package needs the Lagrange parameters on input. We also recorded the achieved log-likelihood at each step. We then trained method (2) on the dataset and adjusted its tolerance parameters as to (roughly) reproduce the recorded sequence of log-likelihoods. The double logarithmic scale in Figure 2 should make the interpretation of the plot rather insensitive against performance differences caused by using different implementations, since such differences are expected to produce additive shifts without changing the slopes.

For input instances that could be hold in the main memory, the log-log plot shows a relatively steep increase for the models (1) and (2), whereas method (3) increases linearly with a moderate slope. For the "out-of-core" models, we recomputed the groups whenever necessary (step **C/D** in our algorithm). We again see an almost linear increase of costs up to models including $\approx 10^6$ groups. Three observations seem to be important: (i) the slope of the curve for method (3) in the "out-of-core" regime does not even exceed the slope of the corresponding curve for method (2) at the end of the "cached" region; (ii) when fixing the costs at the level of method (2) at the end of the "cached" region, method (3) was able to solve instances which are larger by

at least $1 - 1.5$ orders of magnitude; (iii) comparison with method (1) shows that the active set formalism leads to a speed-up of several orders of magnitudes.

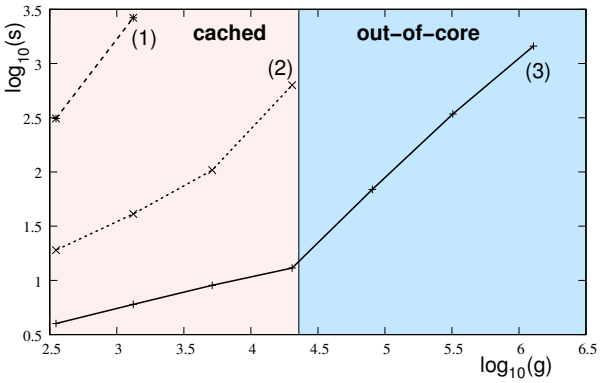

Figure 2. Log-log plot of computation time (y-axis, in seconds) for the XOR problem with logistic loss as a function of the number g of groups (x-axis). The three different methods are: 1:(Kim et al., 2006), 2:(Meier et al., 2008), 3: our algorithm.

Splice Site Detection. The prediction of splice sites has an important role in gene finding algorithms. Splice sites are the regions between coding (exons) and non-coding (introns) DNA segments. The $5'$ end of an intron is called a donor splice site and the $3'$ end an acceptor splice site. The *MEMset Donor* dataset (http://genes.mit.edu/burgelab/maxent/ssdata/) consists of a training set of 8415 true and 179438 false human donor sites. An additional test set contains 4208 true and 89717 "false" (or *decoy*) donor sites. A sequence of a real splice site is modeled within a window that consists of the last 3 bases of the exon and the first 6 bases of the intron. Decoy splice sites also match the consensus sequence at position zero and one. Removing this consensus "GT" results in sequences of length 7, i.e. sequences of 7 factors with 4 levels $\{A, C, G, T\}$, see (Yeo & Burge, 2004) for details. The goal of this experiment is to overcome the restriction to marginal probabilities (main effects) in the widely used *Sequence-Logo* approach (see Figure 4) by exploring all possible interactions up to order 4.

Following (Meier et al., 2008), the original training dataset is used to build a balanced training dataset and an unbalanced validation set which exhibits the same true/false ratio as the test set. The data are represented as a collection all factor interactions up to degree 4. Every interaction is encoded using dummy variables and treated as a group, leading to 120 groups of sizes varying between 4 (main effects) and 4^5 (4th order interactions). In total, we are working in a 33068-dimensional feature space. This dataset has also been analyzed in (Meier et al., 2008) with the Group-Lasso, but only up to 2nd order interactions.

To correct for the unbalancedness of the classes, the validation set is used to choose the best threshold τ on the classifier output. It is further used to select κ. The performance is measured in terms of the maximum correlation coefficient $\rho_{\max}$ between predicted and true labels.

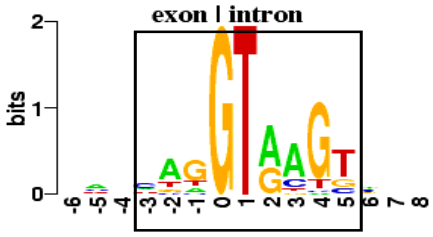

Figure 3. Sequence Logo representation of the human $5'$ splice site. The consensus "GT" appears at positions $0, 1$. The overall height of the stack of symbols at a certain position indicates the sequence conservation at that position, while the height of symbols within the stack indicates the relative frequency of each nucleic acid, see (Crooks et al., 2004). We model the splice sites in a window over positions $[-3, 5]$.

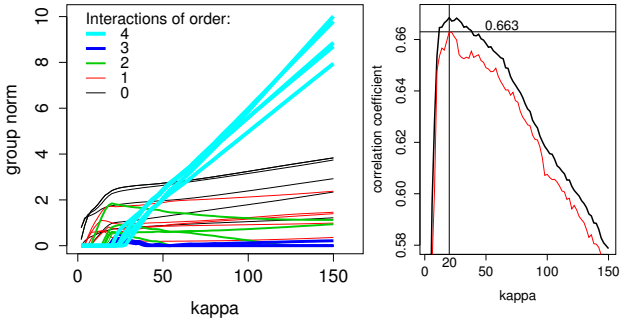

Figure 4. Left: solution path for donor splice site prediction. Color and thickness of curves indicate different orders of interactions. Right: Correlation coefficient as a function of κ. Bold curve: correlation on the validation set that is used for model selection (the thin vertical line indicates the chosen model). Thin curve: correlation on the separate test set.

From the correlation curve in Figure 4 we conclude that the inclusion of interactions of order three and greater does not improve the predictive performance and produces some pronounced overfitting effects. The model with the highest correlation coefficient ($\kappa = 20$) contains 36 groups: all 7 main effects, 21 1st-order interactions and 8 2nd-order interactions. Among the top-scoring groups we find the main effects at positions -1, 2 and 4, the interactions at positions $(4 : 5)$, $(-2 : -1)$ and $(2 : 3)$ and the triplet $(-3 : -2 : -1)$, which all share the property that they exclusively contain exon positions (or intron positions, respectively). One might conclude that long-range interactions between the preceding exon and the starting intron are of minor importance for splice site recognition. The completeness test reveals, however, that the solution with

36 groups is not complete, and that a complete model for $\kappa = 20$ additionally contains the four interactions $(-1:4)$, $(-2:5)$, $(-1:3:4)$ and $(-3:-1:2:5)$, all of which combine exon and intron positions. This is a nice example where the completeness test gives rise to query an initial hypothesis (about the weak exon-intron dependencies) which seems to be plausible from observing the Group-Lasso solution. It should be noticed that the obtained correlation coefficient of $\rho_{\max} = 0.663$ compares favorably with the result in the original paper (Yeo & Burge, 2004) ($\rho_{\max} = 0.659$), which has been viewed as among the best methods for short motive modeling.

The next experiment shows a situation where the completeness test indicates that the interpretability of the Group-Lasso might be generally complicated if relatively complex models are required. The problem is again the discrimination between true and "false" splice sites, this time, however, at the $3'$ end. Compared to the $5'$ situation, $3'$ (acceptor) splice site motives are less concentrated around the consensus nucleotide pair ("AG" at positions -2,-1 in Figure 5), which requires the use of larger windows. We trained the logistic Group-Lasso model on all interactions up to order 4 using windows of length 21. In total, we have 27896 groups which span a $22,458,100$-dimensional feature space. Despite this huge dimensionality, our active set algorithm was able to compute the solution path up to $\kappa = 150$ within roughly 20 hours. From the correlation curve in Figure 6 we conclude that in this example, the inclusion of 3rd- and 4th-order interactions does indeed increase the predictive performance. The optimal model at $\kappa = 66$ contains 386 groups. Among the 10 highest-scoring groups are the main effects at positions -3, -5 and 0, the 1st-order interactions $(-9:-8)$, $(-11:-10)$, $(-11:-9)$ and $(-12:-11)$, the triplet $(-6:-5:-3)$, the 3rd-order interaction $(-14:-9:0:1)$ and the 4th-order interaction $(-10:-8:-6:-3:2)$. The latter might be of particular interest, since it couples the position 2 which appears to be non-informative in the Sequence-Logo representation (Fig. 5) with positions at the end of the intron. This observation nicely emphasizes the strength of a model that is capable of exploring high-order dependencies among the positions.

A closer look at the results of the completeness tests in Figure 7 shows, however, that probably all solutions with $\kappa > 40$ are rather difficult to interpret, since a steeply increasing number of groups must be added to obtain complete models. This means that care should be taken when it comes to interpreting specific groups occurring in particular solutions (as we have done above). Since most of the models are not complete, it might well be that other groups not contained in a particular solution might be of high importance or even "substitute" identified groups. For the 4th-order interaction $(-10:-8:-6:-3:2)$ in the optimal solution with $\kappa = 66$ it might well be that there exist other groups that can take over the role of this interaction. Even though the high score of this group might indicate that a complete substitution is not very likely, the "discovery" of the coupling between position 2 and intron positions should not be accepted unquestioningly.

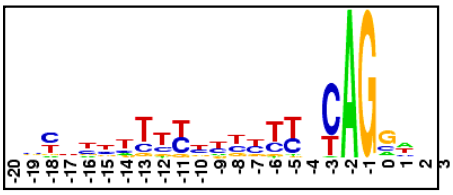

Figure 5. Sequence Logo representation of the human $3'$ splice site. The consensus "AG" appears at positions $-2, -1$. We use a window over positions $[-20, 2]$.

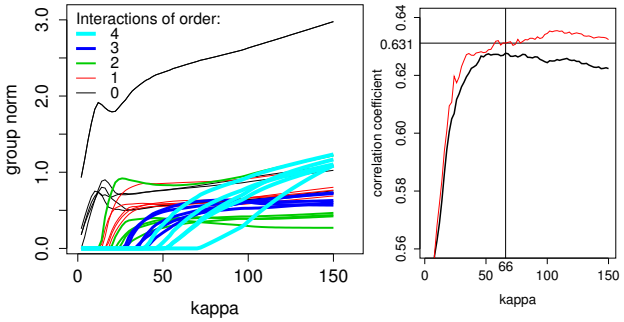

Figure 6. Left: solution path for $3'$ splice site prediction. The upper most curve represents the most important position -3 (last position of the intron). Right: Correlation coefficient as a function of κ. Bold curve: correlation on the validation set that is used for model selection. Thin curve: correlation on the separate test set.

5. Conclusion

The completeness- and uniqueness test presented here overcomes a severe problem of the Group-Lasso estimator for generalized linear models (GLM). Since in many practical applications the dimensionality exceeds the sample size, we cannot *a priori* assume that the active set of groups is unique, which somehow contradicts our goal of identifying important factors. Our testing procedure has the advantage that it identifies all groups that are potential candidates for the active set. Even if a solution is not complete, this latter property still allows us to explicitly list (and potentially investigate) the set of all *candidate* groups.

We have presented a highly efficient active-set algorithm that can handle extremely high-dimensional input spaces which typically arise when investigating high-order factor interactions or when using polynomial basis expansions. Our theoretical characterization of solutions is used to check both optimality and completeness/uniqueness.

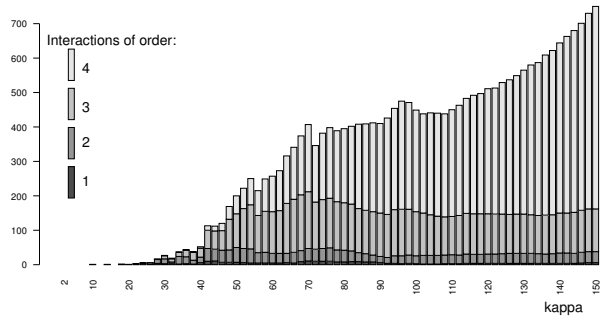

Figure 7. Acceptor splice site prediction: groups that must be included in the logistic Group-Lasso estimates to obtain complete models (gray values represent different orders of interactions).

The experiment on synthetic data in XOR configuration with additional noise features showed that the methods and concepts presented here can be successfully applied to problems with millions of groups. We demonstrated that non-completeness of solutions is indeed an important issue in real-world applications where round-off errors are unavoidable. Without any additional computational costs, the proposed completeness/uniqueness test easily detects such situations and additionally identifies all groups that must be included to achieve a complete model.

The splice-site prediction example confirmed these observations in a real-world context, where the inclusion of high-order factor interactions helps to increases the predictive performance but also leads to incomplete and, thus, potentially ambiguous solutions. The active set algorithm was able to approximate the solution path of the logistic Group-Lasso for feature-space dimensions up to $\approx 2 \cdot 10^7$ within a reasonable time, and the completeness test helped to avoid mis- or over-interpretations of identified interactions between the nucleotide positions. In particular for the $5'$ (donor-) splicing sites, we could show that the completeness test avoids a potentially severe misinterpretation regarding the independence of exon and intron positions.

While in the application examples we have focused on logistic classification problems, both the characterization of solutions and the algorithms proposed are valid for the much richer class of GLMs. Notable extensions include models for counting processes (e.g. Poisson or log-linear models). Details of such models for the analysis of sparse contingency tables in the spirit of the work in (Dahinden et al., 2007) will appear elsewhere. A C++ implementation of the active set algorithm with completeness test is available from the authors on request.

In the broad perspective – and in the light of recent theoretical results on the algorithmic complexity of feature selection (Nilsson et al., 2007) – one might conclude that feature selection can be simpler than previously thought.

Abstract

The success of kernel methods including support vector machines (SVMs) strongly depends on the design of appropriate kernels. While initially kernels were designed in order to handle fixed-length data, their extension to unordered, variable-length data became more than necessary for real pattern recognition problems such as object recognition and bioinformatics.

We focus in this paper on object recognition using a new type of kernel referred to as "context-dependent". Objects, seen as constellations of local features (interest points, regions, etc.), are matched by minimizing an energy function mixing (1) a fidelity term which measures the quality of feature matching, (2) a neighborhood criterion which captures the object geometry and (3) a regularization term. We will show that the fixed-point of this energy is a "context-dependent" kernel ("CDK") which also satisfies the Mercer condition. Experiments conducted on object recognition show that when plugging our kernel in SVMs, we clearly outperform SVMs with "context-free" kernels.

1. Introduction

Object recognition is one of the biggest challenges in vision and its interest is still growing (Everingham et al., 2007). Among existing methods, those based on machine learning (ML), show a particular interest as they are performant and theoretically well grounded (Bishop, 2007). ML approaches, such as the popular support vector networks (Boser et al., 1992), basically require the design of similarity measures, also referred to as *kernels*, which should provide high values when two objects share similar structures/appearances and should be invariant, as much as possible, to the linear and non-linear transformations. Kernel-based object recognition methods were initially *holistic*, i.e., each object is mapped into one or multiple fixed-length vectors and a similarity, based on color, texture or shape (Swain & Ballard, 1991; Chapelle et al., 1999), is then defined. *Local* kernels, i.e., those based on bags or local sets were introduced in order to represent data which cannot be represented by ordered and fixed-length feature vectors, such as graphs, trees, interest points, etc (Gartner, 2003). It is well known that both holistic and local kernels should satisfy certain properties among them the positive definiteness, low complexity for evaluation, flexibility in order to handle variable-length data and also invariance. Holistic kernels have the advantage of being simple to evaluate, discriminating but less flexible than local kernels in order to handle invariance[1]. While the design of kernels gathering flexibility, invariance and low complexity is a challenging task; the proof of their positive definiteness is sometimes harder (Cuturi, 2005). This property also known as the Mercer condition ensures, according to Vapnik's SVM theory (Vapnik, 1998), optimal generalization performance and also the uniqueness of the SVM solution.

Consider a database of objects (images), each one seen as a constellation of local features, for instance interest points (Schmid & Mohr, 1997; Lowe, 2004; Lazebnik et al., 2004), extracted using any suitable filter (Harris & Stephens, 1988). Again, original

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] In case of object recognition, invariance means robustness to occlusion, geometric transformations and illumination.

holistic kernels explicitly (or implicitly) map objects into fixed-length feature vectors and take the similarity as a decreasing function of any well-defined distance (Barla et al., 2002). In contrast to holistic kernels, local ones are designed in order to handle variable-length and unordered data. Two families of local kernels can be found in the literature; those based on statistical "length-insensitive" measures such as the Kullback Leibler divergence, and those which require a preliminary step of alignment. In the first family, the authors in (Kondor & Jebara, 2003; Moreno et al., 2003) estimate for each object (constellation of local features) a probability distribution and compute the similarity between two objects (two distributions) using the "Kullback Leibler divergence" in (Moreno et al., 2003) and the "Bhattacharyya affinity" in (Kondor & Jebara, 2003). Only the function in (Kondor & Jebara, 2003) satisfies the Mercer condition and both kernels were applied for image recognition tasks. In (Wolf & Shashua, 2003), the authors discuss a new type of kernel referred to as "principal angles" which is positive definite. Its definition is based on the computation of the principal angles between two linear subspaces under an orthogonality constraint. The authors demonstrate the validity of their method on visual recognition tasks including classification of motion trajectory and face recognition. An extension to subsets of varying cardinality is proposed in (Shashua & Hazan, 2004). In this first family of kernels, the main drawback, in some methods, resides is the strong assumption about the used probabilistic models in order to approximate the set of local features which may not hold true in practice.

In the second family, the "max" kernel (Wallraven et al., 2003) considers the similarity function, between two feature sets, as the sum of their matching scores and unlike discussed in (Wallraven et al., 2003) this kernel is actually not Mercer (Bahlmann et al., 2002). In (Lyu, 2005), the authors introduced the "circular-shift" kernel defined as a weighted combination of Mercer kernels using an exponent. The latter is chosen in order to give more prominence to the largest terms so the resulting similarity function approximates the "max" and also satisfies the Mercer condition. The authors combined local features and their relative angles in order to make their kernel rotation invariant and they show its performance for the particular task of object recognition. In (Boughorbel, 2005), the authors introduced the "intermediate" matching kernel, for object recognition, which uses virtual local features in order to approximate the "max" while satisfying the Mercer condition. Recently, (Grauman & Darrell, 2007) introduced the "pyramid-match" kernel, for object recognition and document analysis, which maps feature sets using a multi-resolution histogram representation and computes the similarity using a weighted histogram intersection. The authors showed that their function is positive definite and can be computed linearly with respect to the number of local features. Other matching kernels include the "dynamic programming" function which provides, in (Bahlmann et al., 2002), an effective matching strategy for handwritten character recognition, nevertheless the Mercer condition is not guaranteed.

Naive matching	**'H'**	**'i'**		**'S'**	**'i'**	**'r'**

'r'	0	0	-	0	0	.38

Table 1. This table shows a simple comparison between similarity measures when using naive matching (upper table) and context-dependent matching (lower table).

1.1. Motivation and Contribution

The success of the second family of local kernels strongly depends on the quality of alignments which are difficult to obtain mainly when images contain redundant and repeatable structures. Regardless the Mercer condition, a naive matching kernel (such as the "max"), which looks for all the possible alignments and sums the best ones, will certainly fail and results into many false matches (see Figure 1, left). The same argument is supported in (Schmid & Mohr, 1997), for the general problem of visual features matching, about the strong spatial correlation between interest points and the corresponding close local features in the image space. This limitation also appears in closely related areas such as text analysis, and particularly string alignment. A simple example, of aligning two strings ("Sir" and "Hi Sir") using a simple similarity measure $\mathbb{1}_{\{c_1=c_2\}}$ between any two characters c_1 and c_2, shows that without any extra information about the *context* (i.e., the sub-string) surrounding each character in ("Sir" and "Hi Sir"), the alignment process results into false matches (See Table 1). *Hence, it is necessary to consider the context as a part of the alignment process when designing kernels.*

In this paper, we introduce a new kernel, called "context-dependent" (or "CDK") and defined as the

fixed-point of an energy function which balances an "alignment quality" term and a "neighborhood" criterion. The alignment quality is inversely proportional to the expectation of the Euclidean distance between the most likely aligned features (see Section 2) while the neighborhood criterion measures the spatial coherence of the alignments; given a pair of features (f_p, f_q) with a high alignment quality, the neighborhood criterion is proportional to the alignment quality of all the pairs close to (f_p, f_q). *The general form of "CDK" captures the similarity between any two features by incorporating also their context, i.e., the similarity of the surrounding features.* Our proposed kernel can be viewed as a variant of "dynamic programming" kernel (Bahlmann et al., 2002) where instead of using the ordering assumption we consider a neighborhood assumption which states that two points match if they have similar features and if they satisfies a neighborhood criterion i.e., their neighbors match too. This also appears in other well studied kernels such as Fisher (Jaakkola et al., 1999), which implements the conditional dependency between data using the Markov assumption. "CDK" also implements such dependency with an extra advantage of being the fixed-point and the (sub)optimal solution of an energy function closely related to the goal of our application. This goal is to gather the properties of flexibility, invariance and mainly discrimination by allowing each local feature to consider its context in the matching process. Notice that the goal of this paper is not to extend local features to be global and doing so (as in (Mortensen et al., 2005; Amores et al., 2005)) makes local features less invariant, but rather to design a similarity kernel ("CDK") which captures the context while being invariant. Even though we investigate "CDK" in the particular task of object recognition, we can easily extend it to handle closely related areas in machine learning such as text alignment for document retrieval (Nie et al., 1999), machine translation (Sim et al., 2007) and bioinformatics (Scholkopf et al., 2004).

In the remainder of this paper we consider the following terminology and notation. A feature refers to a local interest point $x_i^p = (\ _g(x_i^p),\ _f(x_i^p), y_p)$, here i stands for the i^{th} sample of the subset $\mathcal{S}_p = \{x_1^p, \ldots, x_n^p\}$ and $y_p \in \mathbb{N}^+$ is a unique indicator which provides the class or the subset including x_i^p. $_g(x_i^p) \in \mathbb{R}^2$ stands for the $2D$ coordinates of the interest-point x_i^p while $_f(x_i^p) \in \mathbb{R}^s$ corresponds to the descriptor of x_i^p (for instance the 128 coefficients of the SIFT(Lowe, 2004)). We define $\mathcal{X}$ as the set of all possible features taken from all the possible images in the world and X is a random variable standing for a sample in $\mathcal{X}$. We also consider $k_t : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ as a symmetric function which, given two samples (x_i^p, x_j^q), provides a similarity measure. Other notations will be introduced as we go along through different sections of this paper which is organized as follows. We first introduce in Section 2, our energy function which makes it possible to design our context-dependent kernel and we show that this kernel satisfies the Mercer condition so we can use it for support vector machine training and other kernel methods. In Section 3 we show the application of this kernel in object recognition. We discuss in Section 4 the advantages and weaknesses of this kernel and the possible extensions in order to handle other tasks such as string matching and machine translation. We conclude in Section 5 and we provide some future research directions.

2. Kernel Design

Define $\mathcal{X} = \cup_{p \in \mathbb{N}^+} \mathcal{S}_p$ as the set of all possible interest points taken from all the possible objects in the world. We assume that all the objects are sampled with a given cardinality i.e., $|\mathcal{S}_p| = n$, $|\mathcal{S}_q| = m$, $\forall\ p, q \in \mathbb{N}^+$ (n and m might be different). Our goal is to design a kernel K which provides the similarity between any two objects (subsets) $\mathcal{S}_p$, $\mathcal{S}_q$ in $\mathcal{X}$.

Definition 1 (Subset Kernels) *let $\mathcal{X}$ be an input space, and consider $\mathcal{S}_p, \mathcal{S}_q \subseteq \mathcal{X}$ as two finite subsets of $\mathcal{X}$. We define the similarity function or kernel K between $\mathcal{S}_p = \{x_i^p\}$ and $\mathcal{S}_q = \{x_j^q\}$ as $K(\mathcal{S}_p, \mathcal{S}_q) = \sum_i^n \sum_j^m k\left(x_i^p, x_j^q\right)$.*

here k is symmetric and continuous on $\mathcal{X} \times \mathcal{X}$, so K will also be continuous and symmetric. Since K is defined as the cross-similarity k between all the possible sample pairs taken from $\mathcal{S}_p \times \mathcal{S}_q$, it is obvious that K has the big advantage of not requiring any (hard) alignment between the samples of $\mathcal{S}_p$ and $\mathcal{S}_q$. Nevertheless, for a given $\mathcal{S}_p$, $\mathcal{S}_q$, the value of $K(\mathcal{S}_p, \mathcal{S}_q)$ should be dominated by $\sum_i \max_j k\left(x_i^p, x_j^q\right)$, so k should be appropriately designed (see Section 2.1).

Let X be a random variable standing for samples taken from $\mathcal{S}_p$ and X' is defined in a similar way for the subset $\mathcal{S}_q$. We design our kernel $k(x_i^p, x_j^q) = \mathbb{P}(X' = x_j^q, X = x_i^p)$ as the *joint probability* that x_j^q matches x_i^p. Again, it is clear enough (see Figure 1 and Table 1) that when this joint probability is estimated using only the sample coordinates (without their contexts), this may result in many false matches and wrong estimate of $\left\{\mathbb{P}(X' = x_j^q, X = x_i^p)\right\}_{i,j}$.

Before describing the whole design of k, we start with our definition of context-dependent kernels.

Definition 2 (Context-Dependent Kernels) *we define a context-dependent kernel k as any symmetric, continuous and recursive function $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ such that $k(x_i^p, x_j^q)$ is equal to*

$$c(x_i^p, x_j^q) \times h\left(\sum_{k,\ell} k(x_k^p, x_\ell^q) \ \mathbb{V}\left(x_i^p, x_k^p, x_j^q, x_\ell^q\right)\right),$$

here c is a positive (semi) definite and context-free (non-recursive) kernel, $\mathbb{V}(x, x', y, y')$ is a monotonic decreasing function of any (pseudo) distance involving (x, x', y, y') and $h(x)$ is monotonically increasing.

2.1. Approach

We consider the issue of designing k using a variational framework. Let $\mathcal{I}_p = \{1, \ldots, n\}$, $\mathcal{I}_q = \{1, \ldots, m\}$, $\mu = \{k(x_i^p, x_j^q)\}$, $d(x_i^p, x_j^q) = \| \ {}_f(x_i^p) - \ {}_f(x_j^q)\|_2$ and $\mathcal{N}_p(x_i^p) = \{x_k^p \in \mathcal{S}_p : k \neq i, \ \| \ {}_g(x_i^p) - \ {}_g(x_k^p)\|_2 \leq \epsilon_p\}$ (ϵ_p defines a neighborhood and $\mathcal{N}_q$ is defined in the same way for $\mathcal{S}_q$). Consider $\alpha, \beta \geq 0$, $(i, j) \in \mathcal{I}_p \times \mathcal{I}_q$, $\mu = \{k(x_i^p, x_j^q)\}$ is found by solving

$$\begin{aligned}
\min_{\mu} \quad & \sum_{i \in \mathcal{I}_p, j \in \mathcal{I}_q} k(x_i^p, x_j^q) \ d(x_i^p, x_j^q) + \\
& \beta \sum_{i \in \mathcal{I}_p, j \in \mathcal{I}_q} k(x_i^p, x_j^q) \ \log(k(x_i^p, x_j^q)) + \\
\alpha \quad & \sum_{i \in \mathcal{I}_p, j \in \mathcal{I}_q} k(x_i^p, x_j^q) \left(- \sum_{\substack{x_k^p \in \mathcal{N}_p(x_i^p), \\ x_\ell^q \in \mathcal{N}_q(x_j^q)}} k(x_k^p, x_\ell^q) \right) \\
\text{s.t.} \quad & k(x_i^p, x_j^q) \in [0, 1], \quad \sum_{i,j} k(x_i^p, x_j^q) = 1
\end{aligned} \tag{1}$$

The first term measures the quality of matching two descriptors ${}_f(x_i^p)$, ${}_f(x_j^q)$. In the case of SIFT, this is considered as the distance, $d(x_i^p, x_j^q)$, between the 128 SIFT coefficients of x_i^p and x_j^q. A high value of $d(x_i^p, x_j^q)$ should result into a small value of $k(x_i^p, x_j^q)$ and vice-versa.

The second term is a regularization criterion which considers that without any a priori knowledge about the aligned samples, the probability distribution $\{k(x_i^p, x_j^q)\}$ should be flat so the negative of the entropy is minimized. This term also helps defining a simple solution and solving the constrained minimization problem easily. The third term is a neighborhood criterion which considers that a high value of $k(x_i^p, x_j^q)$ should imply high kernel values in the neighborhoods $\mathcal{N}_p(x_i^p)$ and $\mathcal{N}_q(x_j^q)$. This criterion makes it possible to consider the context (spatial configuration) of each sample in the matching process.

We formulate the minimization problem by adding an equality constraint and bounds which ensure that $\{k(x_i^p, x_j^q)\}$ is a probability distribution.

Proposition 1 *(1) admits a solution in the form of a context-dependent kernel $k_t(x_i^p, x_j^q) = v_t(x_i^p, x_j^q)/Z_t$, with $t \in \mathbb{N}^+$, $Z_t = \sum_{i,j} v_t(x_i^p, x_j^q)$ and $v_t(x_i^p, x_j^q)$ defined as*

$$\exp\left(-\frac{d(x_i^p, x_j^q)}{\beta} - 1\right) \times \exp\left(\frac{2\alpha}{\beta} \sum_{k,\ell} \mathbb{V}(x_i^p, x_k^p, x_j^q, x_\ell^q) \ \ k_{t-1}(x_k^p, x_\ell^q)\right) \tag{2}$$

which is also a Gibbs distribution.

Proof. the proof, lengthy, is omitted and it is available in a research report (Sahbi et al., 2007).□

In (2), we set v_0 to any positive definite kernel (see proposition 3) and we define $\mathbb{V}(x_i^p, x_k^r, x_j^q, x_\ell^s)$ as $g(x_i^p, x_k^r) \times g(x_j^q, x_\ell^s)$ where g is a decreasing function of any (pseudo) distance involving (x_i^p, x_k^r), *not necessarily symmetric*. In practice, we consider $g(x_i^p, x_k^r) = \mathbb{1}_{\{r=p\}} \times \mathbb{1}_{\{x_k^r \in \mathcal{N}_p(x_i^p)\}}$.

It is easy to see that k_t is a P-kernel on any $\mathcal{S}_p \times \mathcal{S}_q$ (Haussler, 1999) (as the joint probability over sample pairs taken from any $\mathcal{S}_p$ and $\mathcal{S}_q$ sums to one), so the value of the subset kernel $K(\mathcal{S}_p, \mathcal{S}_q)$ defined in (1) is constant and *useless*. To make k_t (up to a factor) a P-kernel on $\mathcal{X} \times \mathcal{X}$ (and not on $\mathcal{S}_p \times \mathcal{S}_q$), we cancel the equality constraint in (1) and we can prove in a similar way that $k_t(x_i^p, x_j^q)$ is equal to $v_t(x_i^p, x_j^q)$ which is still a context-dependent kernel.

2.2. Mercer Condition

Let $\mathcal{X}$ be an input space and let $k_t : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ be symmetric and continuous. k_t is Mercer, i.e., positive (semi) definite, if and only if any Gram (kernel scalar product) matrix built by restricting k_t to any finite subset of $\mathcal{X}$ is positive (semi) definite. A Mercer kernel k_t guarantees the existence of a reproducing kernel Hilbert space $\mathcal{H}$ where k_t can be written as a dot product i.e., $\exists \Phi_t : \mathcal{X} \rightarrow \mathcal{H}$ such that $\forall \ x, x' \in \mathcal{X}$, $k_t(x, x') = \langle \Phi_t(x), \Phi_t(x') \rangle$.

Proposition 2 *ex. (S-Taylor & Cristianini, 2000) the sum and the product of any two Mercer kernels is a*

Mercer kernel. The exponential of any Mercer kernel is also a Mercer kernel.

Proof. see, for instance, (S-Taylor & Cristianini, 2000). □

Now, let us state *our result* about the positive definiteness of the "CDK" kernel.

Proposition 3 *consider* $g : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$, *let* $\mathbb{V}(x_i^p, x_k^p, x_j^q, x_\ell^q) = g(x_i^p, x_k^p) g(x_j^q, x_\ell^q)$, *and* k_0 *positive definite. The kernel* k_t *is then positive definite.*

Proof. Initially ($t = 0$), k_0 is per definition a positive definite kernel. By induction, let us assume k_{t-1} a Mercer kernel i.e., $\exists \Phi_{t-1} : k_{t-1}(x, x') = \langle \Phi_{t-1}(x), \Phi_{t-1}(x') \rangle$, $\forall x, x' \in \mathcal{X}$. Now, the sufficient condition will be to show that $\left(\sum_{y,y'} \mathbb{V}(x, y, x', y')\ k_{t-1}(y, y') \right)$ is also a Mercer kernel. Then, by the closure of the exponential and the product (see proposition 2), k_t will then be Mercer. We need to show

$$\forall x_1, \ldots, x_d \in \mathcal{X}, \quad \forall c_1, \ldots, c_d \in \mathbb{R},$$
$$(*) = \sum_{i,j} c_i\ c_j \left(\sum_{y,y'} \mathbb{V}(x_i, y, x_j, y')\ k_{t-1}(y, y') \right) \geq 0$$

We have

$$\begin{aligned}
(*) &= \sum_{i,j} c_i\ c_j \sum_{y,y'} g(x_i, y)\ g(x_j, y')\ k_{t-1}(y, y') \\
&= \sum_{y,y'} \left(\sum_i c_i\ g(x_i, y) \right) \times \\
&\qquad \left(\sum_j c_j\ g(x_j, y') \right)\ k_{t-1}(y, y') \\
&= \sum_{y,y'} \gamma_y\ \gamma_{y'}\ k_{t-1}(y, y') \\
&= \left\| \sum_y \gamma_y \Phi_{t-1}(y) \right\|_{\mathcal{H}} \geq 0. \quad \square
\end{aligned}$$

Corollary 1 *K defined in (1) is also a Mercer kernel.*

Proof. the proof is straightforward for the particular case $n = m$. As $k_t(x_i^p, x_j^q) = \langle \Phi_t(x_i^p), \Phi_t(x_j^q) \rangle$, we can write $K(\mathcal{S}_p, \mathcal{S}_q) = \sum_{i,j} \langle \Phi_t(x_i^p), \Phi_t(x_j^q) \rangle = \langle \sum_i \Phi_t(x_i^p), \sum_j \Phi_t(x_j^q) \rangle$ and this corresponds to a dot product in some Hilbert space. The proof can be found in (S-Taylor & Cristianini, 2000) for the general case of finite subsets of any length. □

2.3. Algorithm and Setting

The factor β, in k_t, acts as a scale parameter and it is selected using

$$\beta \leftarrow \mathbb{E}_r \left[\mathbb{E}_{\{X_1^r, X_2^r : d(X_1^r, X_2^r) \leq \epsilon\}} \left[d(X_1^r, X_2^r) \right] \right] \quad (3)$$

here $\mathbb{E}$ denotes the expectation and X_1^r (also X_2^r) denotes a random variable standing for samples in $\mathcal{S}_r$. The coefficient α controls the tradeoff between the alignment quality and the neighborhood criteria. It is selected by cross-validation and it should guarantee $k_t(x_i^p, x_j^q) \in [0, 1]$. If $A = \sup_{i,j} \sum_{k,\ell} g(x_i^p, x_k^p) \times g(x_j^q, x_\ell^q)$, α should then be selected in $[0, \frac{\beta}{2\ A}]$.

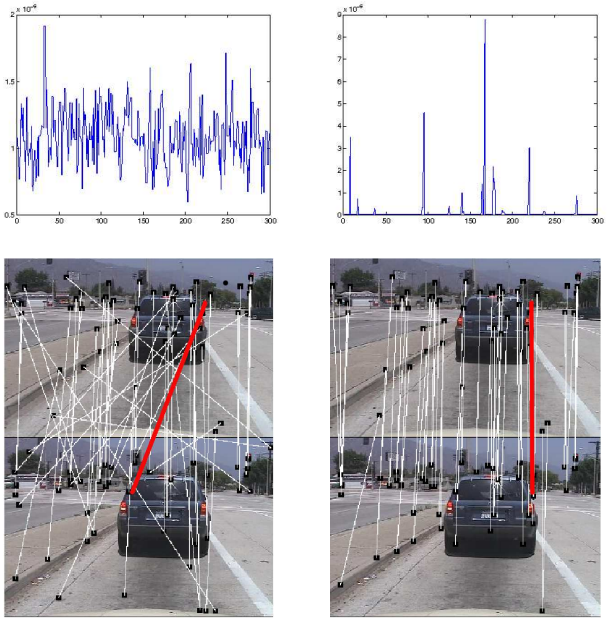

Figure 1. This figure shows a comparison of the matching results when using a naive matching strategy without geometry and our "context-dependent" kernel matching. (Top figures) show the distribution of the kernel values $k(x_i, x_j), j \in \mathcal{I}_q$ using a context-free kernel (left) and our "CDK" kernel (right). We can clearly see that the highest value changes its location so the matching results are now corrected (as shown for one particular and multiple matches in bottom figures).

Consider P, Q as the intrinsic adjacency matrices of $\mathcal{S}_p$ and $\mathcal{S}_q$ respectively defined as $P_{i,k} = g(x_i^p, x_k^p)$, $Q_{j,\ell} = g(x_j^q, x_\ell^q)$. Let U denote the unit matrix and consider $D_{i,j} = d(x_i^p, x_j^q)$, $\mu_{i,j}^{(t)} = k_t(x_i^p, x_j^q)$. Now, $\mu_{i,j}^{(t)}$ is iteratively found using Algorithm ("CDK") (see table 2) and converges to a fixed point (see. Section 2.4).

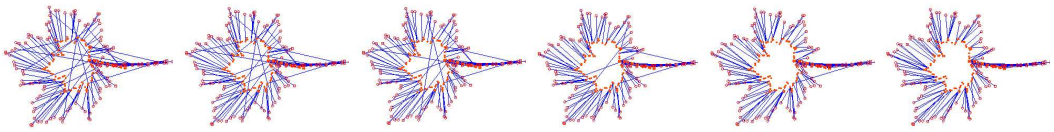

Figure 2. This figure shows the evolution of context-dependent silhouette matching on the Swedish set, for different and increasing values of α. We clearly see that when α increases the matching results are better. We set $\beta = 0.1$ and $t = 1$.

Algorithm (CDK)

Initialization:

Set β using (3) and $\alpha \in [0, \frac{\beta}{2\,A}]$
Set $\mu^{(0)} \leftarrow k_0$, $t \leftarrow 0$

Repeat until $t \to T_{max}$ or $\|\mu^{(t)} - \mu^{(t-1)}\|_2 \to 0$

$$\mu^{(t)} \leftarrow \exp\left(-D/\beta \;+\frac{2\alpha}{\beta} P\,\mu^{(t-1)}\,Q \;-\; U\right)$$

Table 2. The "CDK" kernel evaluation.

2.4. Convergence

Let us assume $0 \leq g \leq 1$, and remind $\mu^{(t)} \in \mathbb{R}^{n\times m}$ be the vector of components $\mu^{(t)}_{i,j} = k_t(x^p_i, x^q_j)$. Introduce the mapping $f : \mathbb{R}^{n\times m} \to \mathbb{R}^{n\times m}$ defined by its component $f_{i,j}(v)$ as

$$\exp\left(-1 - \frac{d(x^p_i, x^q_j)}{\beta} + \frac{2\alpha}{\beta}\sum_{k,\ell} g(x^p_i, x^p_k) g(x^q_j, x^q_\ell) v_{k,\ell}\right)$$

By construction of the kernel k_t, we have $\mu^{(t)} = f\big(\mu^{(t-1)}\big)$. Let A and B satisfy

$$\sup_{1\leq i\leq n,\ 1\leq j\leq m} \sum_{k,\ell} g(x^p_i, x^p_k) g(x^q_j, x^q_\ell) \leq A \qquad (4)$$

$$\sum_{i,j} \exp\left(-1 - \frac{d(x^p_i, x^q_j)}{\beta}\right) \leq B \qquad (5)$$

Consider $L = \frac{2B\alpha}{\beta}\exp\big(\frac{2\alpha A}{\beta}\big)$, and let $\mathcal{B} = \big\{v \in \mathbb{R}^{n\times m} : \forall\ 1 \leq i \leq n,\ 1 \leq j \leq m,\ |v_{i,j}| \leq 1\big\}$ be the $\|\cdot\|_\infty$-ball of radius 1. Finally, let $\|\cdot\|_1$ denote the 1-norm on $\mathbb{R}^{n\times m}$: $\|u\|_1 = \sum_{1\leq i\leq n,\ 1\leq j\leq n} |u_{i,j}|$.

Proposition 4 *If $\|\mu^{(0)}\|_\infty \leq 1$ and $2\alpha A \leq \beta$, then we have $f(\mathcal{B}) \subset \mathcal{B}$, and on $\mathcal{B}$, f is L-Lipschitz for the norm $\|\cdot\|_1$.*

In particular, if $L < 1$, then there exists a unique $\tilde{v} \in \mathcal{B}$ such that $f(\tilde{v}) = \tilde{v}$, and the sequence $(\mu^{(t)})$ satisfies

$$\|\mu^{(t)} - \tilde{v}\|_1 \leq L^t \|\mu^{(0)} - \tilde{v}\|_1 \underset{t\to+\infty}{\longrightarrow} 0. \qquad (6)$$

Proof. The first assertion is proved by induction by checking that for $\|v\|_\infty \leq 1$, we have

$$\begin{aligned} f_{i,j}(v) &\leq \exp\left(-1 + \tfrac{2\alpha}{\beta}\textstyle\sum_{k,\ell} g(x^p_i, x^p_k) g(x^q_j, x^q_\ell) v_{k,\ell}\right) \\ &\leq \exp\left(-1 + \tfrac{2\alpha}{\beta} A\right) \leq 1. \end{aligned}$$

For the second assertion, note that for any v in $\mathcal{B}$, we have $|\frac{\partial f_{i,j}}{\partial v_{k,\ell}}(v)| \leq \exp\big(-1 - \frac{d(x^p_i, x^q_j)}{\beta}\big)$. Let $C = \exp\big(\frac{2\alpha}{\beta}A\big)$, for any v, v' in $\mathcal{B}$, we have

$$\|f(v) - f(v')\|_1 \;=\; \sum_{i,j} |f_{i,j}(v) - f_{i,j}(v')| = (*)$$

$$\begin{aligned} (*) &\leq \sum_{i,j} \exp\big(-1 - \frac{d(x^p_i, x^q_j)}{\beta}\big)\frac{2\alpha}{\beta}\exp\big(\frac{2\alpha}{\beta}A\big) \\ &\quad \times \sum_{k,\ell} \big| g(x^p_i, x^p_k) g(x^q_j, x^q_\ell) v_{k,\ell} \\ &\qquad - g(x^p_i, x^p_k) g(x^q_j, x^q_\ell) v'_{k,\ell}\big| \\ &\leq \sum_{i,j} \exp\big(-1 - \frac{d(x^p_i, x^q_j)}{\beta}\big)\frac{2\alpha}{\beta} C\ \|v - v'\|_1 \\ &\leq L\|v - v'\|_1 \end{aligned}$$

which proves the second assertion. The last assertion directly comes from the fixed-point theorem. □

3. Performance

Experiments were conducted on the Swedish set (15 classes, 75 images per category) and a random subset of MNIST digit database (10 classes, 200 images per category). Each class in Swedish (resp. MNIST) is split into 50+25 (resp. 100+100) contours for training and testing. Interest points were sampled from each contour in MNIST (resp. Swedish) and encoded using the 60 (resp. 16) coefficients of the shape-context descriptor (Belongie et al., 2000).

3.1. Generalization and Comparison

We evaluate k_t, $t \in \mathbb{N}^+$ using two initializations: (i) linear $k_0(x, x') = k_l(x, x') = \langle x, x'\rangle$ (ii) and

polynomial $k_0(x,x') = k_p(x,x') = (\langle x,x'\rangle + 1)^2$. Our goal is to show the improvement brought when using $k_t,\ t \in \mathbb{N}^+$, so we compared it against the standard context-free kernels k_l and k_p (i.e., $k_t,\ t=0$). For this purpose, we trained a "one-versus-all" SVM classifier for each class in both MNIST and Swedish using the subset kernel $K(\mathcal{S}_p,\mathcal{S}_q) = \sum_{x\in\mathcal{S}_p, x'\in\mathcal{S}_q} k_t(x,x')$. The performance are measured, on different test sets, using n-fold cross-validation error ($n=5$).

We remind that β is set using (3) as the left-hand side of k_t corresponds to the Gaussian kernel with scale β. In practice, $\beta = 0.1$. The influence (and the performance) of the right-hand side of k_t increases as α increases (see. Figure 2), nevertheless the convergence of k_t to a fixed point is guaranteed only if $\alpha \in [0, \frac{\beta}{2\ A}]$. Therefore, it becomes obvious that α should be set to $\frac{\beta}{2\ A}$ where $A = \sup_{i,j} \sum_{k,\ell} g(x_i^p, x_k^p) \times g(x_j^q, x_\ell^q)$ (in practice, $0 \leq g \leq 1$ and $A = 1$).

Table 3 shows the 5-fold cross validation errors on MNIST and Swedish for different iterations; we clearly see the out-performance and the improvement of the "CDK" kernel ($k_t, t \in \mathbb{N}^+$) with respect to the context-free kernels used for initialization ($k_0 = k_l$ or k_p.)

Initialization	Linear	Polynomial
Iterations (MNIST)		
k_0	11.4± 4.42	9.15 ± 4.63
k_1	8.80± 4.77	5.6 ± 2.72
k_2	6.90± 3.55	5.8 ± 2.36
k_3	6.90± 3.41	5.2 ± 2.07
k_4	**6.90± 3.41**	**5.2 ± 2.07**
Iterations (Swedish)		
k_0	11.7± 2.88	6.53± 6.34
k_1	6.00± 2.30	3.33± 2.73
k_2	**3.06± 1.88**	**3.33± 2.73**

Table 3. This table shows the mean and the standard deviation of the 5-fold error on the MNIST (top) and Swedish (bottom) databases. We can see a clear and a consistent gain through different iterations and also the convergence of the errors.

4. Remarks and Discussion

The adjacency matrix P, in k_t, provides the intrinsic properties and also characterizes the geometry of an object $\mathcal{S}_p$. Let us remind $\mathcal{N}_p(x_i^p) = \{x_k^p \in \mathcal{S}_p : k \neq i,\ \| \ _g(x_i^p) - \ _g(x_k^p)\|_2 \leq \epsilon_p\}$ and $P_{i,j} = \mathbb{1}_{\{x_j^q \in \mathcal{N}_p(x_i^p)\}}$. It is easy to see that P is translation and rotation invariant and can also be made scale invariant when ϵ_p is adapted to the scale of $_g(x_i^p)$. It follows that the right-hand side of our kernel is invariant to any $2D$ similarity transformation. Notice, also, that the left-hand side of k_t involves similarity invariant descriptors $\ _f(x_i^p)$, $\ _f(x_j^q)$ so k_t (and K) is similarity invariant.

One current limitation of our kernel k_t resides in its evaluation complexity. Assuming k_{t-1} known, for a given pair x_i^p, x_j^q, this complexity is $O\left(\max(N^2, s)\right)$, where s is the dimension of $\ _f(x_i^p)$ and $N = \max_{i,p} \#\{\mathcal{N}_p(x_i^p)\}$. It is clear enough that when $N < \sqrt{s}$, the complexity of evaluating our kernel is strictly equivalent to that of usual kernels such as the linear. Nevertheless, the worst case ($N \gg \sqrt{s}$) makes our kernel evaluation prohibitive and this is mainly due to the right-hand side of $k_t(x_i^p, x_j^q)$ which requires the evaluation of kernel sums in a hypercube of dimension 4. A simple and straightforward generalization of the integral image (see for instance (Viola & Jones, 2001)) will reduce this complexity to $O(s)$.

Finally, the out-performance of our kernel comes essentially from the inclusion of the context. This strongly improves the precision and helps including the intrinsic properties (geometry) of objects. Even though tested only on visual object recognition, our kernel can be extended to many other pattern analysis problems such as bioinformatics, speech and text. For instance, in text analysis and particularity machine translation (Sim et al., 2007), the design of a similarity kernel between words in two different languages, can be achieved using any standard dictionary. Of course, the latter defines similarity between any two words (w_e, w_f) independently from their bilingual training text (or bitext), i.e., the phrases where (w_e, w_f) might appear and this results into bad translation performances. A better estimate of similarity between two words (w_e, w_f), can be achieved using their context i.e., the set of words which cooccur frequently with (w_e, w_f) (Koehn et al., 2003).

5. Conclusion

We introduced in this paper a new type of kernels referred to as context-dependent. Its strength resides in the improvement of the alignments between interest points and this is considered as a preliminary step in order to increase the robustness and the precision of object recognition.

We have also shown that our kernel is Mercer and applicable to SVM learning. The latter, achieved for shape recognition problems, has better performance than SVMs with context-free kernels. Future work in-

cludes the comparison of our kernel with other context-free kernels and its application in scene and object understanding using other standard databases.

Abstract

We consider the problem of distributed reinforcement learning (DRL) from private perceptions. In our setting, agents' perceptions, such as states, rewards, and actions, are not only distributed but also should be kept private. Conventional DRL algorithms can handle multiple agents, but do not necessarily guarantee privacy preservation and may not guarantee optimality. In this work, we design cryptographic solutions that achieve optimal policies without requiring the agents to share their private information.

1. Introduction

With the rapid growth of computer networks and networked computing, a large amount of information is being sensed and gathered by distributed agents physically or virtually. Distributed reinforcement learning (DRL) has been studied as an approach to learn a control policy thorough interactions between distributed agents and environments—for example, sensor networks and mobile robots. DRL algorithms, such as the distributed value function approach (Schneider et al., 1999) and the policy gradient approach (Moallemi & Roy, 2004), typically seek to satisfy two types of physical constraints. One is constraints on communication, such as an unstable network environment or limited communication channels. The other is memory constraints to manage the huge state/action space. Therefore, the main emphasis of DRL has been to learn good, but sub-optimal, policies with minimal or limited sharing of agents' perceptions.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

In this paper, we consider the privacy of agents' perceptions in DRL. Specifically, we provide solutions for privacy-preserving reinforcement learning (PPRL), in which agents' perceptions, such as states, rewards, and actions, are not only distributed but are desired to be kept private. Consider two example scenarios:

Optimized Marketing (Abe et al., 2004): Consider the modeling of the customer's purchase behavior as a Markov Decision Process (MDP). The goal is to obtain the optimal catalog mailing strategy which maximizes the long-term profit. Timestamped histories of customer status and mailing records are used as state variables. Their purchase patterns are used as actions. Value functions are learned from these records to learn the optimal policy. If these histories are managed separately by two or more enterprises, they may not want to share their histories for privacy reasons (for example, in keeping with privacy promises made to their customers), but might still like to learn a value function from their joint data in order that they can all maximize their profits.

Load Balancing (Cogill et al., 2006): Consider a load balancing among competing factories. Each factory wants to accept customer jobs, but in order to maximize its own profit, may need to redirect jobs when heavily loaded. Each factory can observe its own backlog, but factories do not want to share their backlog information with each other for business reasons, but they would still like to make optimal decisions.

Privacy constraints prevent the data from being combined in a single location where centralized reinforcement algorithms (CRL) could be applied. Although DRL algorithms work in a distributed setting, they are designed to limit the total amount of data sent between agents, but do not necessarily do so in a way that guarantees privacy preservation. Additionally, DRL often sacrifices optimality in order to learn with low communication. In contrast, we propose solutions

that employ cryptographic techniques to achieve optimal policies (as would be learned if all the information were combined into a centralized reinforcement learning (CRL) problem) while also explicitly protecting the agents' private information. We describe solutions both for data that is "partitioned-by-time" (as in the optimized marketing example) and "partitioned-by-observation" (as in the load balancing example).

Related Work. Private distributed protocols have been considered extensively for data mining, pioneered by Lindell and Pinkas (Lindell & Pinkas, 2002), who presented a privacy-preserving data-mining algorithm for ID3 decision-tree learning. Private distributed protocols have also been proposed for other data mining and machine learning problems, including k-means clustering (Jagannathan & Wright, 2005; Sakuma & Kobayashi, 2008), support vector machines (Yu et al., 2006), boosting (Gambs et al., 2007), and belief propagation (Kearns et al., 2007).

Agent privacy in reinforcement learning has been previously considered by Zhang and Makedon (Zhang & Makedon, 2005). Their solution uses a form of average reward reinforcement learning that does not necessarily guarantee an optimal solution; further, their solution only applies partitioning by time. In contrast, our solutions guarantee optimality under appropriate conditions and we provide solutions both when the data is partitioned by time and by observation.

In principle, private distributed computations such as these can be carried out using secure function evaluation (SFE) (Yao, 1986; Goldreich, 2004), which is a general and well studied methodology for evaluating any function privately. However, although asymptotically polynomially bounded, these computations can be too inefficient for practical use, particular when the input size is large. For the reinforcement learning algorithms we address, we make use of existing SFE solutions for small portions of our computation in order as part of a more efficient overall solution.

Our Contribution. We introduce the concepts of partitioning by time and partitioning by observation in distributed reinforcement learning (Section 2). We show privacy-preserving solutions for SARSA learning algorithms with random action selection for both kinds of partitioning (Section 4). Additionally, these algorithms are expanded to Q-learning with greedy or ϵ-greedy action selection (Section 5). We provide experimental results in Section 6.

Table 1 provides a qualitative comparison of variants of reinforcement learning in terms of efficiency, learning accuracy, and privacy loss. We compare five approaches: CRL, DRL, independent distributed reinforcement learning (IDRL, explained below), SFE, and our privacy-preserving reinforcement learning solutions (PPRL). In CRL, all the agents send their perceptions to a designated agent, and then a centralized reinforcement is applied. In this case, the optimal convergence of value functions is theoretically guaranteed when the dynamics of environments follow a discrete MDP; however, privacy is not provided, as all the data must be shared.

	comp.	comm.	accuracy	privacy
CRL	good	good	good	none
DRL	good	good	medium	imperfect
IDRL	good	good	bad	perfect
PPRL	**medium**	**medium**	**good**	**perfect**
SFE	bad	bad	good	perfect

Table 1. Comparison of different approaches

On the opposite end of the spectrum, in IDRL (independent DRL), each agent independently applies CRL only using its own local information; no information is shared. In this case, privacy is completely preserved, but the learning results will be different and independent. In particular, accuracy will be unacceptable if the agents have incomplete but important perceptions about the environment. DRL can be viewed as an intermediate approach between CRL and IDRL, in that the parties share only some information and accordingly reap only some gains in accuracy.

The table also includes the direct use of general SFE and our approach of PPRL. Both PPRL and SFE obtain good privacy and good accuracy. Although our solution incurs a significant cost (as compared to CRL, IDRL, and DRL) in computation and communication to obtain this, it does so with significantly improved computational efficiency over SFE. We provide a more detailed comparison of the privacy, accuracy, and efficiency of our approach and other possible approaches along with our experimental results in Section 6.

2. Preliminaries

2.1. Reinforcement Learning and MDP

Let S be a finite *state set* and A be a finite *action set.* A *policy* π is a mapping from state/action pair (s, a) to the probability $\pi(s, a)$ with which action a is taken at state s. At time step t, we denote by s_t, a_t, and r_t, the state, action, and *reward* at time t, respectively.

A *Q-function* is the expected return $Q^\pi(s, a) = E_\pi \left\{ \sum_{k=0}^{\infty} \gamma^k r_{t+k+1} \mid s_t = s, a_t = a \right\}$, where γ is a discount factor ($0 \leq \gamma < 1$). The goal is to learn the optimal policy π maximizing the Q-function: $Q^*(s, a) =$

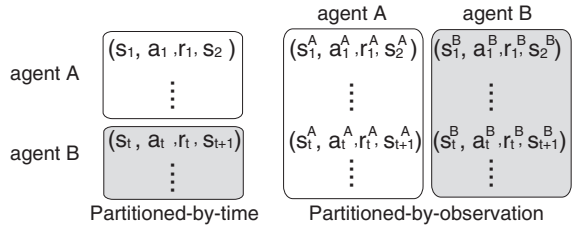

Figure 1. Partitioning model in the two-agent case

$\max_\pi Q(s,a)$ for all (s,a). In SARSA learning, Q-values are updated at each step as:

$$\begin{aligned} \Delta Q(s_t,a_t) &\leftarrow \alpha(r_t+\gamma Q(s_{t+1},a_{t+1})-Q(s_t,a_t)), \\ Q(s_t,a_t) &\leftarrow \Delta Q(s_t,a_t)+Q(s_t,a_t), \end{aligned} \quad (1)$$

where α is the learning rate. Q-learning is obtained by replacing the update of ΔQ by:

$$\Delta Q(s_t,a_t) \leftarrow \alpha(r_t+\gamma \max_a Q(s_{t+1},a)-Q(s_t,a_t)).$$

Iterating these updates under appropriate conditions, optimal convergence of Q-values is guaranteed with probability 1 in discrete MDPs (Sutton & Barto, 1998; Watkins, 1989); the resulting optimal policy can be readily obtained.

2.2. Modeling Private Information in DRL

Let $h_t=(s_t,a_t,r_t,s_{t+1},a_{t+1})$, let $H=\{h_t\}$, and suppose there are m agents. We consider two kinds of partitioning of H (see Fig. 1).

Partitioned-by-Time. This model assumes that only one agents interacts with the environment at any time step t. Let T^i be the set of time steps at which only ith agent has interactions with the environment. Then $T^i \cap T^j = \emptyset, (i \neq j)$ and the set $H^i=\{h_t \mid t \in T^i\}$ is considered the private information of the ith agent.

Partitioned-by-Observation. This model assumes that states and actions are represented as a collection of state and action variables. The state space and the action space are $S=\prod_i S^i$ and $A=\prod_i A^i$ where S^i and A^i are the space of the ith agent's state and action variables, respectively. Without loss of generality (and for notational simplicity), we consider each agent's local state and action spaces to consist of a single variable. If $s_t \in S$ is the joint state of the agents at time t, we denote by s_t^i the state that ith agent perceives and by a_t^i the action of ith agent. Let r_t^i be the *local reward* of ith agent obtained at time t. We define the *global reward* (or *reward* for short) as $r_t=\sum_i r_t^i$ in this model. Our Q-functions are evaluated based on this global reword. The perception of the ith agent at time t is denoted as $h_t^i=\{s_t^i,a_t^i,r_t^i,s_{t+1}^i,a_{t+1}^i\}$. The private information of the ith agent is $H^i=\{h_t^i\}$.

We note that partitioning by observation is more general than partitioning by time, in that one can always represent a sequence that is partitioned by time by one that is partitioned by observation. However, we provide more efficient solutions in simpler case of partitioning by time.

Let π^c be a policy learned by CRL. Then, informally, the objective of PPRL is stated as follows:

Statement 1. *The ith agent takes H^i as inputs. After the execution of PPRL, all agents learn a policy π which is equivalent to π^c. Furthermore, no agent can learn anything that cannot be inferred from π and its own private input.*

This problem statement can be formalized as in SFE (Goldreich, 2004). This is a strong privacy requirement which precludes consideration of solutions that reveal intermediate Q-values, actions taken, or states visited. We assume our agents behave *semi-honestly*, a common assumption in SFE—this assumes agents follows their specified protocol properly, but might also use their records of intermediate computations in order to attempt to learn other parties' private information.

3. Cryptographic Building Blocks

Our solutions make use of several existing cryptographic tools. Specifically, in our protocol, Q-values are encrypted by an additive homomorphic cryptosystem, which allows the addition of encrypted values without requiring their decryption, as described in Section 3.1. Using the homomorphic properties, this allows encrypted Q-values are updated in the regular RL manner, while unencrypted Q-values are not known to agents. For computations which cannot be treated by the homomorphic property, we use SFE as a primitive, as we describe in Section 3.2.

3.1. Homomorphic Public Key Cryptosystems

In a public key cryptosystem, encryption uses a *public key* that can be known to everyone, while decryption requires knowledge of the corresponding *private key*. Given a corresponding pair of $(\mathsf{sk},\mathsf{pk})$ of private and public keys and a message m, then $c=e_{\mathsf{pk}}(m;\ell)$ denotes a (random) encryption of m, and $m=d_{\mathsf{sk}}(c)$ denotes decryption. The encrypted value c uniformly distributes over $\mathbb{Z}_N$ if ℓ is taken from $\mathbb{Z}_N$ randomly. An *additive homomorphic cryptosystem* allows addition computations on encrypted values without knowl-

edge of the secret key. Specifically, there is some operation $\cdot$ (not requiring knowledge of sk) such that for any plaintexts m_1 and m_2, $e_{\mathsf{pk}}(m_1 + m_2; \ell) = e_{\mathsf{pk}}(m_1; \ell_1) \cdot e_{\mathsf{pk}}(m_2; \ell_2)$, where ℓ is uniformly random provided that at least one of ℓ_1 and ℓ_2 is. Based on this property, it also follows that given a constant k and the encryption $e_{\mathsf{pk}}(m_1; \ell)$, we can compute multiplications by k via repeated application of $\cdot$. This also enables a re-randomization property, which allows the computation of a new random encryption $c' = e_{\mathsf{pk}}(m; \ell')$ of m from an existing encryption $c = e_{\mathsf{pk}}(m; \ell)$ of m, again without knowledge of the private key or of m, as follows: $e_{\mathsf{pk}}(m; \ell) = \mathrm{Enc}_{\mathsf{pk}}(m; \ell_1) \cdot \mathrm{Enc}_{\mathsf{pk}}(0; \ell_2)$. In the rest of the paper, we omit the random number ℓ from our encryptions for simplicity.

In an (m, t)-*threshold cryptosystem*, m agents share a common public key pk while the agents hold different private keys $\mathsf{sk}^1, ..., \mathsf{sk}^n$. Each agent can encrypt any message with the common public key. Decryption cannot be performed by fewer than t agents, and can be performed by any group of at least t agents using a recovery algorithm based on the public key and their *decryption shares* $d_{\mathsf{sk}^1}(c), ..., d_{\mathsf{sk}^n}(c)$. We require a cryptosystem that provides semantic security (under appropriate computational hardness assumptions), re-randomization, the additive homomorphic property, and threshold decryption, such as the generalized Paillier cryptosystem (Dåmgard & Jurik, 2001).

3.2. Private Comparison and Division

As mentioned, secure function evaluation (SFE) is a cryptographic primitive which allows two or more parties to evaluate a specified function of their inputs without revealing (anything else about) their inputs to each other (Goldreich, 2004; Yao, 1986). Although our overall solution is more efficient than using SFE, we do make use of SFE for two kinds of computations.

One is the problem of *private comparison of random shares*. Let $\boldsymbol{x} = (x_1, ..., x_d) \in \mathbb{Z}_N^d$. For our purposes, A and B have *random shares* of $\boldsymbol{x}$ if A has $\boldsymbol{x}^A = (x_1^A, ..., x_d^A)$ and B has $\boldsymbol{x}^B = (x_1^B, ..., x_d^B)$ such that x_i^A and x_i^B are uniformly distributed in $\mathbb{Z}_N$ such that $x_i = (x_i^A + x_i^B) \mod N$ for all i. If A holds $\boldsymbol{x}^A$ and B holds $\boldsymbol{x}^B$, where $\boldsymbol{x}^A$ and $\boldsymbol{x}^B$ are random shares of $\boldsymbol{x}$, then private comparison of random shares computes the index i^* such that $i^* = \arg\max_i (x_i^A + x_i^B)$ in such a way that A learns only i^* and B learns nothing.

The other is a problem of *private division of random shares*. The input of A and B are random shares of x, $x^A \in \mathbb{Z}_N$ and $x^B \in \mathbb{Z}_N$, respectively. Let K be an integer known to both parties. Then, private division of random shares computes random shares Q^A and Q^B of quotient $Q \in \mathbb{Z}_N$ such that $x = (QK + R) \mod N$, where $R \in \mathbb{Z}_N\, (0 \leq R < K), Q = (Q^A + Q^B) \mod N$. After the protocol, A and B learn Q^A and Q^B, respectively, and nothing else.

We use private division of random shares in several places in our protocols to achieve *private division of encrypted values*. Suppose agent A has a key pair $(\mathsf{pk}, \mathsf{sk})$ and agent B knows pk and $e_{\mathsf{pk}}(x)$. The following protocol allows B to learn the encrypted quotient $e_{\mathsf{pk}}(Q)$ from $e_{\mathsf{pk}}(x)$ and K:

1. B computes $c \leftarrow e_{\mathsf{pk}}(x) \cdot e_{\mathsf{pk}}(-x^B), x^B \in_r \mathbb{Z}_N$ and send c to A.
2. A computes the decryption $x^A \leftarrow d_{\mathsf{sk}}(c) (\equiv x - x^B \mod N)$.
3. Using SFE for private division on A and B's inputs x^A and x^B, respectively, A and B obtain outputs Q^A and Q^B, respectively.
4. A sends $e_{\mathsf{pk}}(Q^A)$ to B.
5. B computes $e_{\mathsf{pk}}(Q) \leftarrow e_{\mathsf{pk}}(Q^A) \cdot e_{\mathsf{pk}}(Q^B)$.

4. Private Q-Value Update

In this section, we describe privacy-preserving SARSA update of Q-values under random action selection is described for our two partitioning models. We extend this to (ϵ-)greedy action selection in Section 5. We assume that reward r, learning rate α, and discount rate γ are non-negative rational numbers and that $\sum_{t=1}^{\infty}(\gamma^t L r_{\max}) < N$, where $r_{\max}$ is the largest reward that agents can obtain and $L \in \mathbb{Z}_N$ is a parameter defined in Section 4.1. In this paper, we describe protocols for two agents; these can be extended to m-agent case ($m \geq 3$) straightforwardly, as will be shown in an extended version of the paper.

4.1. Partitioned-by-Time Model

We first restrict our attention to the case where agent A has perceptions during $T^A = \{1, ..., t-1\}$ and B has perceptions during $T^B = \{t\}$. In this setting, A first computes can learn intermediate Q-values during the time period T^A, because they can be locally computed only from A's perception. At time t, the new Q-values must be computed based on the intermediate Q-values known to A and B's observation at time t. In brief, we do this by carrying out the update on encrypted Q-values using the homomorphic property to carry this out privately. However, the update includes the multiplication of rational numbers, such as α or γ, so the computation is not closed in $\mathbb{Z}_N$. Hence, we first scale these rational numbers by multiplying with large enough integers so that all computations are closed in $\mathbb{Z}_N$. We use private division of encrypted values to remove the scaling.

- Public input; L, K, learning rate α, discount rate γ
- A's input: $Q(s,a)$ (trained by A during T^A)
- B's input: (s_t, a_t)
- A's output: Nothing
- B's output: Encryption of updated Q-value $c(s_t, a_t)$

1. A: Compute $e^A(Q(s,a))$ for all (s,a) and send to B.
2. B: Take action a_t and get r_t, s_{t+1}.
3. B: Choose a_{t+1} randomly.
4. Update Q-value:
   (a) B: Compute $e^A(K\Delta Q(s_t,a_t))$ by eq. 3.
   (b) B: Do private division of $e^A(K\Delta Q(s_t,a_t))$ with A, then B learns $e^A(\Delta Q'(s_t,a_t))$.
   (c) B: Update $c(s_t,a_t)$ by eq. 4.

Figure 2. Private update of Q-values in partitioned-by-time model (SARSA/random action selection)

We now describe our protocol for private update, shown in Fig. 2, in more detail. Let pk_A be A's public key. At step 1, A computes $c(s,a) = e_{\mathsf{pk}_A}(Q(s,a))$ for all (s,a) and sends them to B. B takes action a_t, gets r_t, s_{t+1} (step 2), and chooses a_{t+1} randomly (step 3). A and B must now update the encrypted Q-value $c(s,a)$. By encrypting both sides of SARSA update (eq. 1), we obtain:

$$\begin{aligned} c(s_t,a_t) &\leftarrow e_{\mathsf{pk}_A}(\Delta Q(s_t,a_t) + Q(s_t,a_t)), \\ &= e_{\mathsf{pk}_A}(\Delta Q(s_t,a_t)) \cdot e_{\mathsf{pk}_A}(Q(s_t,a_t)) \\ &= \Delta c(s_t,a_t) \cdot c(s_t,a_t), \end{aligned} \quad (2)$$

where $\Delta c(s_t,a_t) = e_{\mathsf{pk}_A}(\Delta Q(s_t,a_t))$. If $\Delta c(s_t,a_t)$ is computed by B from what B observes, B can update $c(s_t,a_t)$ by eq. 2 locally. Therefore, step 4 is devoted to the computation of $\Delta c(s_t,a_t)$.

As mentioned, large integers K and L are used to treat the multiplication of rationals α and γ, where $\alpha\gamma K \in \mathbb{Z}_N$ and $Lr_t \in \mathbb{Z}_N$ for all r_t. Multiplying K to both sides of eq. 1 and multiplying L to r_t, we obtain

$$K\Delta Q(s_t,a_t) \leftarrow K\alpha(Lr_t + \gamma Q(s_{t+1},a_{t+1}) - Q(s_t,a_t)),$$

in which the computation is closed in $\mathbb{Z}_N$. Encrypting both sides by A's public key, we obtain

$$\begin{aligned} &e_{\mathsf{pk}_A}(K\Delta Q(s_t,a_t)) \\ &\quad = e_{\mathsf{pk}_A}(Lr_t)^{\alpha K} \cdot c(s_{t+1},a_{t+1})^{\alpha\gamma K} \cdot c(s_t,a_t)^{-\alpha K} \end{aligned} \quad (3)$$

Since K, L, α, γ are public and B has r_t, $c(s,a)$, B can compute $e_{\mathsf{pk}_A}(K\Delta Q(s_t,a_t))$ by eq. 3 (step 4(a)). B needs to divide $e_{\mathsf{pk}_A}(K\Delta Q(s_t,a_t))$ by K, however, division is again not allowable. Instead, a quotient $\Delta Q'(s_t,a_t)$ satisfying $\Delta Q(s_t,a_t) = K\Delta Q'(s_t,a_T) + R (0 \le R < K)$ is computed by private encrypted division and B obtains $e_{\mathsf{pk}_A}(\Delta Q'(s_t,a_t))$ (step 4(b)). Then, B finally computes

$$c(s_t,a_t) \leftarrow e_{\mathsf{pk}_A}(\Delta Q'(s_t,a_t)) \cdot c(s_t,a_t). \quad (4)$$

It follows that eq. 4 is equivalent to eq. 2 except for the truncation error included by the private encrypted division step (step 4(c)). This truncation is negligibly small if L is sufficiently large.

Lemma 1. *If A and B behave semi-honestly, then after the private update of Q-values for SARSA and random action selection in partitioned-by-time model, B correctly updates encrypted Q-values but learn nothing else. A learns nothing.*

The proof of this lemma (omitted for space) follows the standardized proof methodology of secure multi-party computation (Goldreich, 2004), showing that one can create the required algorithms, called *simulators*, for A and B. Intuitively, Step 4(b) is secure because it is implemented by SFE. Everything else that B receives except for messages received at steps for step 4(b) are encrypted by A's public key, so do not reveal anything. A does not receive anything except messages that are part of the SFE in step 4(b), so does not learn anything. Thus, the protocol is secure overall.

For the general setting of T^A and T^B, after time t, if B interacts with the environment at time $t+1$ again, the protocol can be started from step 2. When interaction switches back to A, an SFE step is used to change the encryption of the Q-values from A's private key to B's private key via an SFE step, and then the roles of A and B are switched.

4.2. Partitioned-by-Observation Model

In this model, we use a $(2,2)$-threshold cryptosystem. Both parties share a common public key pk: encryption of m by pk is denoted by $e(m)$ in this section. A and B hold different secret keys sk^A and sk^B for decryption shares, respectively. A and B cannot decrypt without both cooperating.

In this partitioning model, we write $a_t = (a_t^A, a_t^B)$, $s_t = (s_t^A, s_t^B)$, and $r_t = r_t^A + r_t^B$. A receives only (s_t^A, a_t^A, r_t^A) and B receives only (s_t^B, a_t^B, r_t^B). Private update of Q-values in this model is shown in Fig. 3. In this model, eq. 3 is rewritten as

$$\begin{aligned} &e(K\Delta Q(s_t,a_t)) = X^A \cdot X^B \cdot X \\ &X^A = e(Lr_t^A)^{\alpha KL}, \quad X^B = e(Lr_t^B)^{\alpha KL}, \\ &X = c(s_{t+1},a_{t+1})^{\alpha\gamma K} \cdot c(s_t,a_t)^{-\alpha K}. \end{aligned} \quad (5)$$

X^A and X^B can be computed by A and B. To obtain $c(s_{t+1},a_{t+1})$ and $c(s_t,a_t)$, let h,i,j,k be indices of Q-tables where $h \in S^A, i \in S^B, j \in A^A, k \in A^B$. At

step 4(a), A sends X^A and tables $\{c_{ik}\}, \{c'_{ik}\}$ with re-randomization such that

$$c_{ik} = c(s_t^A, i, a_t^A, k) \cdot e(0)\ (i \in S^B, k \in A^B), \quad (6)$$
$$c'_{ik} = c(s_{t+1}^A, i, a_{t+1}^A, k) \cdot e(0)\ (i \in S^B, k \in A^B), \quad (7)$$

to B. B determines $c(s_t, a_t) = c_{s_t^B, a_t^B}$, $c(s_{t+1}, a_{t+1}) = c'_{s_{t+1}^B, a_{t+1}^B}$ and obtains $e(K\Delta Q(s_t, a_t))$ by eq. 5 (step 4(b)). Then computes $e(\Delta Q'(s_t, a_t))$ by private division (step 4(c)). For all $(hijk)$, B sets

$$\Delta c_{hijk} \leftarrow \begin{cases} e(\Delta Q'(s_t, a_t)) & (i = s_t^B, k = a_t^B) \\ e(0) & \text{(o.w.)} \end{cases} \quad (8)$$

and sends $\{\Delta c_{hijk}\}$ to A (step 4(d)). Finally, for all (ik), Q-values are updated as

$$c(s_t^A, i, a_t^A, k) \leftarrow c(s_t^A, i, a_t^A, k) \cdot \Delta c_{s_t^A i a_t^A k}. \quad (9)$$

by A. With this update, $e(\Delta Q'(s_t, a_t))$ is added only when $(h, i, j, k) = (s_t^A, s_t^B, a_t^A, a_t^B)$. Otherwise, $e(0)$ is added. Note that A cannot tell which element is $e(\Delta Q'(s_t, a_t))$ in $\{\Delta c_{hijk}\}$ because of the re-randomization. Thus, eq. 9 is the desired update.

Lemma 2. *If A and B behave semi-honestly, then after the private update of Q-values for SARSA and random action selection in partitioned-by-observation model, A updates encrypted Q-values correctly but learns nothing. B learns nothing.*

By iterating private updates, encrypted Q-values trained by SARSA learning are obtained.

5. Private Greedy Action Selection

Private distributed algorithms for greedy action selection to compute $a^* = \arg\max_a Q(s, a)$ from encrypted Q-values in both partitioning models are described. These are used for: (1) (ϵ-)greedy action selection, (2) max operation in updates of Q-learning, and (3) extracting learned policies from final Q-values. In the partitioned-by-time model, this is readily solved by using private comparison, so is omitted.

5.1. Private Greedy Action Selection in Partitioned-by-observation Model

When A and B observe s_t^A and s_t^B, respectively, private greedy action selection requires that (1) A obtains a^{A*} and nothing else, (2) B obtains a^{B*} and nothing else, where $(a^{A*}, a^{B*}) = \arg\max_{(a^A, a^B)}(Q(s_t^A, a^A, s_t^B, a^B))$.

The protocol is described in Fig. 4. Threshold decryption is used here, too. First, A sends encrypted Q-values $c(s_t^A, i, j, k)$ with re-randomization for all

- Public input; L, K, learning rate α, discount rate γ
- A's input: (s_t^A, a_t^A), B's input: (s_t^B, a_t^B)
- A's output: Encryption of updated Q-value $c(s_t, a_t)$
- B's output: Nothing

1. A: Initialize $Q(s, a)$ arbitrarily and compute $c(s, a)(= e(Q(s, a)))$ for all (s, a).
2. Interaction with the environment:
   - A: Take action a_t^A and get r_t^A, s_{t+1}^A.
   - B: Take action a_t^B and get r_t^B, s_{t+1}^B.
3. Action selection:
   - A: Choose a_{t+1}^A randomly.
   - B: Choose a_{t+1}^B randomly.
4. Update Q-value:
   (a) A: Send $X^A, \{c_{ik}\}, \{c'_{ik}\}$ to B by eq. 6, 7.
   (b) B: Compute $e(K\Delta Q(s_t, a_t))$ by eq. 5
   (c) B: Do private division of $e(K\Delta Q(s_t, a_t))$ with A, then B learns $e(\Delta Q'(s_t, a_t))$.
   (d) B: Generate $\{\Delta c_{hijk}\}$ by eq. 8 and send it to A.
   (e) A: Update $c(s, a)$ with $\{\Delta c_{hijk}\}$ by eq. 9.

Figure 3. Private update of Q-values in partitioned-by-observation model (SARSA/random action selection)

(i, j, k). For all (i, k), B generates and sends a table $\{c_{ik}\}$ and $\{\sigma_{ik}\}$ whose values are set to

$$c_{ik} = c(s_t^A, i, s_t^B, \pi(k)) \cdot e(-Q_{i\pi(k)}^B), \quad (10)$$
$$\sigma_{ik}^B = d^B(c_{ik}), \quad (11)$$

where $\pi : S^B \mapsto S^B$ is a random permutation and $Q_{i\pi(k)}^B \in_r \mathbb{Z}_N$. At the third step, A recovers $Q_{ik}^A (= Q(s_t^A, i, s_t^B, k) - Q_{ik}^B)$. With these random shares of $Q(s_t^A, i, s_t^B, \pi(k))$, the values $(i^*, k^*) = \arg\max_{(i,k)}(Q_{ik}^A + Q_{ik}^B)$ are obtained by A using private comparison. Finally, B learns $a^{B*} = \pi^{-1}(k^*)$, where π^{-1} is the inverse of π.

Lemma 3. *If A and B behaves semi-honestly, then, after the execution of private greedy action selection, A learns a^{A*} and nothing else. B learns a^{B*} and nothing else.*

Note that a^{B*} is not learned by A because index k is obscured by the random permutation generated by B.

5.2. Security of PPRL

Privacy-preserving SARSA learning is constructed by alternate iterations of private update and random action selection. The policy π can be extracted by computing $\arg\max_a Q(s, a)$ for all (s, a) using private greedy action selection. The security follows from the earlier lemmas:

- A's input: $c(s,a)$ for all (s,a), s_t^A, B's input: s_t^B
- A's output: a^{A*}, B's output: a^{B*}

1. A: For all $i \in S^B, j \in A^A, k \in A^B$, send $c(s_t^A, i, j, k)$ to B.
2. B: For all $j \in A^A, k \in A^B$, compute c_{ik}(eq. 10), σ_{ik}^B(eq. 11) and send $\{c_{ik}\}, \{\sigma_{ik}\}$to A.
3. A: For all $i \in A^A, k \in A^B$, compute $\sigma_{ik}^B = d^B(c_{ik})$. Then, compute Q_{ik}^A by applying the threshold decryption recovery algorithm with public key pk and shares $\sigma_{ik}^A, \sigma_{ik}^B$.
4. A and B: Compute $(i^*, k^*) = \arg\max_{(i,k)}(Q_{ik}^A + Q_{ik}^B)$ by private comparison. (A learns $(i^*.k^*)$.)
5. A: Send k^* to B. Then output $a^{A*} = i^*$.
6. B: Output $a^{B*} = \pi^{-1}(k^*)$.

Figure 4. Private greedy action selection in partitioned-by-observation model

Theorem 1. *SARSA learning with private update of Q-values and random action selection is secure in the sense of Statement 1.*

Privacy-preserving SARSA learning and Q-learning with (ϵ-)greedy action selection can be constructed by combining private update and private greedy random action selection. However, these PPRLs do not follow Statement 1 because it does not allow agents to know greedy actions obtained in the middle of the learning. Therefore, the problem definition is relaxed as follows:

Statement 2. *The ith agent takes H^i as inputs. After the execution of PPRL, all agents learn a series of greedy actions during learning steps and a policy π which is equivalent to π^c. Furthermore, no agent learns anything else.*

Theorem 2. *SARSA and Q-learning with private update of Q-values and private greedy/ϵ-greedy action selection is secure in the sense of Statement 2.*

6. Experimental Results

We performed experiments to examine the efficiency of PPRL. Programs were written in Java 1.5.0. As the cryptosystem, (Dåmgard & Jurik, 2001) with 1024-bit keys was used. For SFE, Fairplay (Malkhi et al., 2004) was used. Experiments were carried out under Linux with 1.2 GHz CPU and 2GB RAM.

6.1. Random Walk Task

This random walk task is partitioned by time. The state space is $S = \{s_1, ..., s_n\}(n = 40)$ and the action space is $A = \{a_1, a_2\}$. The initial and goal states are s_1 and s_n, respectively. When a_1 is taken at $s_p(p \neq n)$, the agent moves to s_{p+1}. When a_2 is taken at $s_p(p \neq 1)$, the agent moves to s_{p-1}, but the agent does not move when $p = 1$. A reward $r = 1$ is given only when the agent takes a_1 at s_{n-1}; else, $r = 0$. The episode is terminated at s_n or after $1,000$ steps.

A learns $15,000$ steps and then B learns $15,000$ steps. CRL, IDRL, PPRL, and SFE were compared. SARSA learning with random or ϵ-greedy action selection was used for all settings. Table 2 shows the comparison results of computational cost, learning accuracy (number of steps to reach the goal state, averaged over 30 trials, and number of trials that successfully reach the goal state), and privacy preservation.

Learning accuracy of PPRL and SFE are the same as CRL because the policy learned by PPRL and SFE are guaranteed to be equal to the one learned by CRL. In contrast, the optimal policy is not obtained successfully by IDRL because learning steps for IDRL agents correspond to the half of others. Because most of the computation time is spent for private division and comparison, computation time with random selection is much smaller than with ϵ-greedy selection. These experiments demonstrate that PPRL obtains good learning accuracy, while IDRL does not, though computation time is larger than DRL and IDRL.

6.2. Load Balancing Task

In these experiments, we consider a load balancing problem (Cogill et al., 2006) in the partitioned-by-observation model with two factories A and B. Each factory can observe its own backlog $s^A, s^B \in \{0, ..., 5\}$. At each time step, each factory decides whether or not to pass a job to other factories; the action variable is $a^A, a^B \in \{0, 1\}$. Jobs arrive and are processed independently at each time step with probability 0.4 and 0.48, respectively. Agent A receives reward $r^A = 50 - (s^A)^2$. If A passes the job to B, then A's reward is reduced by 2 as a cost for redirection. If an overflow happens, the job is lost and $r^A = 0$ is given. Similarly, r^B is computed as well. Perceptions (s^A, a^A, r^A) and (s^B, a^B, r^B) are to be kept private. (In this task, actions cannot be kept private because the parties learn them from whether the job was passed or not.)

Distributed reward DRL (RDRL) (Schneider et al., 1999) is tested in addition to the four RLs tested earlier. RDRL is a variant of DRL, which is the same with IDRL except that global rewards are shared among distributed agents (Schneider et al., 1999). SARSA/ϵ-greedy action selection was used in all settings. Fig 5 shows the changes of sum of global rewards per episode. For avoiding overflows, cooperation be-

tween agents is essential in this task. The performance of IDRL agents is inferior to others because selfish behavior is learned. In contrast, CRL, PPRL and SFE agents successfully obtain cooperative behavior. The performance of RDRL is intermediate because perceptions of RDRL agents are limited. Efficiency is shown in Table 3. Since ϵ-greedy action selection was used, the privacy of IDRL, PPRL and SFE follow Statement 2. The privacy preservation of RDRL is between CRL and PPRL. As discussed in Section 1, PPRL achieves both the guarantee of privacy preservation and the optimality which is equivalent to that of CRL; SFE does the same, but at a much higher computational time.

Abstract

Deep Belief Networks (DBN's) are generative models that contain many layers of hidden variables. Efficient greedy algorithms for learning and approximate inference have allowed these models to be applied successfully in many application domains. The main building block of a DBN is a bipartite undirected graphical model called a restricted Boltzmann machine (RBM). Due to the presence of the partition function, model selection, complexity control, and exact maximum likelihood learning in RBM's are intractable. We show that Annealed Importance Sampling (AIS) can be used to efficiently estimate the partition function of an RBM, and we present a novel AIS scheme for comparing RBM's with different architectures. We further show how an AIS estimator, along with approximate inference, can be used to estimate a lower bound on the log-probability that a DBN model with multiple hidden layers assigns to the *test data*. This is, to our knowledge, the first step towards obtaining quantitative results that would allow us to directly assess the performance of Deep Belief Networks as generative models of data.

1. Introduction

Deep Belief Networks (DBN's), recently introduced by Hinton et al. (2006) are probabilistic generative models that contain many layers of hidden variables, in which each layer captures strong high-order correlations between the activities of hidden features in the layer below. The main breakthrough introduced by Hinton et al. was a greedy, layer-by-layer unsupervised learning algorithm that allows efficient training of these deep, hierarchical models. The learning procedure also provides an efficient way of performing approximate inference, which makes the values of the latent variables in the deepest layer easy to infer. These deep generative models have been successfully applied in many application domains (Hinton & Salakhutdinov, 2006; Bengio & LeCun, 2007).

The main building block of a DBN is a bipartite undirected graphical model called the Restricted Boltzmann Machine (RBM). RBM's, and their generalizations to exponential family models, have been successfully applied in collaborative filtering (Salakhutdinov et al., 2007), information and image retrieval (Gehler et al., 2006), and time series modeling (Taylor et al., 2006). A key feature of RBM's is that inference in these models is easy. An unfortunate limitation is that the probability of data under the model is known only up to a computationally intractable normalizing constant, known as the partition function. A good estimate of the partition function would be extremely helpful for model selection and for controlling model complexity, which are important for making RBM's generalize well.

There has been extensive research on obtaining deterministic approximations (Yedidia et al., 2005) or deterministic upper bounds (Wainwright et al., 2005) on the log-partition function of arbitrary discrete Markov random fields (MRF's). These variational methods rely critically on an ability to approximate the entropy of the undirected graphical model. However, for densely connected MRF's, such as RBM's, these methods are unlikely to perform well. There have also been many developments in the use of Monte Carlo methods for estimating the partition function, including Annealed Importance Sampling (AIS) (Neal, 2001), Nested Sampling (Skilling, 2004), and many others (see e.g. Neal (1993)). In this paper we show how one such method, AIS, by taking advantage of the bipartite structure of an RBM, can be used to efficiently estimate its partition function. We further show that this estimator, along with approximate inference, can be used to estimate a lower bound on the log-probability that a DBN model with multiple hidden layers assigns to training or test data. This result allows us to assess the performance of DBN's as generative models and to compare them to other probabilistic models, such as plain mixture models.

2. Restricted Boltzmann Machines

A Restricted Boltzmann Machine is a particular type of MRF that has a two-layer architecture in which the visible, binary stochastic units $\mathbf{v} \in \{0,1\}^D$ are connected to hidden binary stochastic units $\mathbf{h} \in \{0,1\}^M$. The energy of the state $\{\mathbf{v}, \mathbf{h}\}$ is:

$$E(\mathbf{v}, \mathbf{h}; \theta) = -\sum_{i=1}^{D}\sum_{j=1}^{M} W_{ij} v_i h_j - \sum_{i=1}^{D} b_i v_i - \sum_{j=1}^{M} a_j h_j, \quad (1)$$

where $\theta = \{W, \mathbf{b}, \mathbf{a}\}$ are the model parameters: W_{ij} represents the symmetric interaction term between visible unit i and hidden unit j; b_i and a_j are bias terms. The probability that the model assigns to a visible vector $\mathbf{v}$ is:

$$p(\mathbf{v}; \theta) = \frac{p^*(\mathbf{v}; \theta)}{Z(\theta)} = \frac{1}{Z(\theta)} \sum_{h} \exp\left(-E(\mathbf{v}, \mathbf{h}; \theta)\right), \quad (2)$$

$$Z(\theta) = \sum_{\mathbf{v}} \sum_{\mathbf{h}} \exp\left(-E(\mathbf{v}, \mathbf{h}; \theta)\right), \quad (3)$$

where p^* denotes unnormalized probability, and $Z(\theta)$ is the partition function or normalizing constant. The conditional distributions over hidden units $\mathbf{h}$ and visible vector $\mathbf{v}$ are given by logistic functions:

$$p(\mathbf{h}|\mathbf{v}) = \prod_j p(h_j|\mathbf{v}), \quad p(\mathbf{v}|\mathbf{h}) = \prod_i p(v_i|\mathbf{h}) \quad (4)$$

$$p(h_j = 1|\mathbf{v}) = \sigma(\sum_i W_{ij} v_i + a_j) \quad (5)$$

$$p(v_i = 1|\mathbf{h}) = \sigma(\sum_j W_{ij} h_j + b_i), \quad (6)$$

where $\sigma(x) = 1/(1+\exp(-x))$. The derivative of the log-likelihood with respect to the model parameter W can be obtained from Eq. 2:

$$\frac{\partial \ln p(\mathbf{v})}{\partial W_{ij}} = \mathrm{E}_{P_0}[v_i h_j] - \mathrm{E}_{P_{\mathrm{Model}}}[v_i h_j],$$

where $\mathrm{E}_{P_0}[\cdot]$ denotes an expectation with respect to the data distribution and $\mathrm{E}_{P_{\mathrm{Model}}}[\cdot]$ is an expectation with respect to the distribution defined by the model. The expectation $\mathrm{E}_{P_{\mathrm{Model}}}[\cdot]$ cannot be computed analytically. In practice learning is done by following an approximation to the gradient of a different objective function, called the "Contrastive Divergence" (CD) (Hinton, 2002):

$$\Delta W_{ij} = \epsilon\big(\mathrm{E}_{P_0}[v_i h_j] - \mathrm{E}_{P_T}[v_i h_j]\big). \quad (7)$$

The expectation $\mathrm{E}_{P_T}[\cdot]$ represents a distribution of samples from running the Gibbs sampler (Eqs. 5, 6), initialized at the data, for T full steps. Setting $T = \infty$ recovers maximum likelihood learning, although T is typically set to one.

Even though CD learning may work well in practice, the problem of model selection and complexity control still remains. Suppose we have two RBM's with parameter values θ_A and θ_B. Suppose that each RBM has different number of hidden units and was trained using different learning rates and different numbers of CD steps. On the validation set, we are interested in calculating the ratio:

$$\frac{p(\mathbf{v}; \theta_A)}{p(\mathbf{v}; \theta_B)} = \frac{p^*(\mathbf{v}; \theta_A)}{p^*(\mathbf{v}; \theta_B)} \frac{Z(\theta_B)}{Z(\theta_A)},$$

which requires knowing the ratio of partition functions.

3. Estimating Ratios of Partition Functions

Suppose we have two distributions defined on some space $\mathcal{V}$ with probability density functions: $p_A(\mathbf{v}) = p_A^*(\mathbf{v})/Z_A$ and $p_B(\mathbf{v}) = p_B^*(\mathbf{v})/Z_B$. One way to estimate the ratio of normalizing constants is to use a simple importance sampling (IS) method. Suppose that $p_A(\mathbf{v}) \neq 0$ whenever $p_B(\mathbf{v}) \neq 0$:

$$\frac{Z_B}{Z_A} = \frac{\int p_B^*(\mathbf{v}) \mathrm{d}\mathbf{v}}{Z_A} = \int \frac{p_B^*(\mathbf{v})}{p_A^*(\mathbf{v})} p_A(\mathbf{v}) \mathrm{d}\mathbf{v} = \mathrm{E}_{p_A}\left[\frac{p_B^*(\mathbf{v})}{p_A^*(\mathbf{v})}\right].$$

Assuming we can draw independent samples from p_A, the unbiased estimate of the ratio of partition functions can be obtained by using a simple Monte Carlo approximation:

$$\frac{Z_B}{Z_A} \approx \frac{1}{M} \sum_{i=1}^{M} \frac{p_B^*(\mathbf{v}^{(i)})}{p_A^*(\mathbf{v}^{(i)})} \equiv \frac{1}{M} \sum_{i=1}^{M} w^{(i)} = \hat{r}_{\mathrm{IS}}, \quad (8)$$

where $\mathbf{v}^{(i)} \sim p_A$. If p_A and p_B are not close enough, the estimator $\hat{r}_{\mathrm{IS}}$ will be very poor. In high-dimensional spaces, the variance of $\hat{r}_{\mathrm{IS}}$ will be very large (or possibly infinite), unless p_A is a near-perfect approximation to p_B.

3.1. Annealed Importance Sampling (AIS)

Suppose that we can define a sequence of intermediate probability distributions: $p_0, ..., p_K$, with $p_0 = p_A$ and $p_K = p_B$, which satisfy the following conditions:

- C1 $p_k(\mathbf{v}) \neq 0$ whenever $p_{k+1}(\mathbf{v}) \neq 0$.
- C2 We must be able to easily evaluate the unnormalized probability $p_k^*(\mathbf{v})$, $\forall \mathbf{v} \in \mathcal{V}$, $k = 0, ..., K$.
- C3 For each $k = 0, ..., K-1$, we must be able to draw a sample $\mathbf{v}'$ given $\mathbf{v}$ using a Markov chain transition operator $T_k(\mathbf{v}'; \mathbf{v})$ that leaves $p_k(\mathbf{v})$ invariant:

$$\int T_k(\mathbf{v}'; \mathbf{v}) p_k(\mathbf{v}) \mathrm{d}\mathbf{v} = p_k(\mathbf{v}'). \quad (9)$$

- C4 We must be able to draw (preferably independent) samples from p_A.

The transition operators $T_k(\mathbf{v}'; \mathbf{v})$ represent the probability density of transitioning from state $\mathbf{v}$ to $\mathbf{v}'$. Constructing a suitable sequence of intermediate probability distributions

will depend on the problem. One general way to define this sequence is to set:

$$p_k(\mathbf{v}) \propto p_A^*(\mathbf{v})^{1-\beta_k} p_B^*(\mathbf{v})^{\beta_k}, \quad (10)$$

with $0 = \beta_0 < \beta_1 < ... < \beta_K = 1$ chosen by the user. Once the sequence of intermediate distributions has been defined we have:

Annealed Importance Sampling (AIS) run:

1. Generate $\mathbf{v}_1, \mathbf{v}_2, ..., \mathbf{v}_K$ as follows:
   - Sample $\mathbf{v}_1$ from $p_A = p_0$
   - Sample $\mathbf{v}_2$ given $\mathbf{v}_1$ using T_1
   - ...
   - Sample $\mathbf{v}_K$ given $\mathbf{v}_{K-1}$ using T_{K-1}
2. Set

$$w^{(i)} = \frac{p_1^*(\mathbf{v}_1)}{p_0^*(\mathbf{v}_1)} \frac{p_2^*(\mathbf{v}_2)}{p_1^*(\mathbf{v}_2)} ... \frac{p_{K-1}^*(\mathbf{v}_{K-1})}{p_{K-2}^*(\mathbf{v}_{K-1})} \frac{p_K^*(\mathbf{v}_K)}{p_{K-1}^*(\mathbf{v}_K)}$$

Note that there is no need to compute the normalizing constants of any intermediate distributions. After performing M runs of AIS, the importance weights $w^{(i)}$ can be substituted into Eq. 8 to obtain an estimate of the ratio of partition functions:

$$\frac{Z_B}{Z_A} \approx \frac{1}{M} \sum_{i=1}^{M} w^{(i)} = \hat{r}_{\text{AIS}}. \quad (11)$$

Neal (2005) shows that for sufficiently large number of intermediate distributions K, the variance of $\hat{r}_{\text{AIS}}$ will be proportional to $1/MK$. Provided K is kept large, the total amount of computation can be split in any way between the number of intermediate distributions K and the number of annealing runs M without adversely affecting the accuracy of the estimator. If samples drawn from p_A are independent, the number of AIS runs can be used to control the variance in the estimate of $\hat{r}_{\text{AIS}}$:

$$\text{Var}(\hat{r}_{\text{AIS}}) = \frac{1}{M} \text{Var}(w^{(i)}) \approx \frac{\hat{s}^2}{M} = \hat{\sigma}^2, \quad (12)$$

where $\hat{s}^2$ is estimated simply from the sample variance of the importance weights.

3.2. Ratios of Partition Functions of two RBM's

Suppose we have two RBM's with parameter values $\theta_A = \{W^A, \mathbf{b}^A, \mathbf{a}^A\}$ and $\theta_B = \{W^B, \mathbf{b}^B, \mathbf{a}^B\}$ that define probability distributions p_A and p_B over $\mathcal{V} \in \{0,1\}^D$. Each RBM can have a different number of hidden units $\mathbf{h}^A \in \{0,1\}^{M_A}$ and $\mathbf{h}^B \in \{0,1\}^{M_B}$. The generic AIS intermediate distributions (Eq. 10) would be harder to sample from than an RBM. Instead we introduce the following sequence of distributions for $k = 0, ..., K$:

$$p_k(\mathbf{v}) = \frac{p_k^*(\mathbf{v})}{Z_k} = \frac{1}{Z_k} \sum_{\mathbf{h}} \exp\left(-E_k(\mathbf{v}, \mathbf{h})\right), \quad (13)$$

where the energy function is given by:

$$E_k(\mathbf{v}, \mathbf{h}) = (1 - \beta_k) E(\mathbf{v}, \mathbf{h}^A; \theta_A) + \beta_k E(\mathbf{v}, \mathbf{h}^B; \theta_B), \quad (14)$$

with $0 = \beta_0 < \beta_1 < ... < \beta_K = 1$. For $i = 0$, we have $\beta_0 = 0$ and so $p_0 = p_A$. Similarly, for $i = K$, we have $p_K = p_B$. For the intermediate values of k, we will have some interpolation between p_A and p_B.

Let us now define a Markov chain transition operator $T_k(\mathbf{v}'; \mathbf{v})$ that leaves $p_k(\mathbf{v})$ invariant. Using Eqs. 13, 14, it is straightforward to derive a block Gibbs sampler. The conditional distributions are given by logistic functions:

$$p(h_j^A = 1|\mathbf{v}) = \sigma\left((1 - \beta_k)(\sum_i W_{ij}^A v_i + a_j^A)\right) \quad (15)$$

$$p(h_j^B = 1|\mathbf{v}) = \sigma\left(\beta_k(\sum_i W_{ij}^B v_i + a_j^B)\right) \quad (16)$$

$$p(v_i' = 1|\mathbf{h}) = \sigma\Big((1 - \beta_k)(\sum_j W_{ij}^A h_j^A + b_i^A) + \beta_k(\sum_j W_{ij}^B h_j^B + b_i^B)\Big). \quad (17)$$

Given $\mathbf{v}$, Eqs. 15, 16 are used to stochastically activate hidden units $\mathbf{h}^A$ and $\mathbf{h}^B$. Eq. 17 is then used to draw a new sample $\mathbf{v}'$ as shown in Fig. 1 (left panel). Due to the special structure of RBM's, the cost of summing out $\mathbf{h}$ is linear in the number of hidden units. We can therefore easily evaluate:

$$\begin{aligned} p_k^*(\mathbf{v}) &= \sum_{\mathbf{h}^A, \mathbf{h}^B} e^{(1-\beta_k)E(\mathbf{v}, \mathbf{h}^A; \theta_A) + \beta_k E(\mathbf{v}, \mathbf{h}^B; \theta_B)} \\ &= e^{(1-\beta_k)\sum_i b_i^A v_i} \prod_{j=1}^{M_A} (1 + e^{(1-\beta_k)(\sum_i W_{ij}^A v_i + a_j^A)}) \\ &\times e^{\beta_k \sum_i b_i^B v_i} \prod_{j=1}^{M_B} (1 + e^{\beta_k(\sum_i W_{ij}^B v_i + a_j^B)}). \end{aligned}$$

We will assume that the parameter values of each RBM satisfy $|\theta| < \infty$, in which case $p(\mathbf{v}) > 0$ for all $\mathbf{v} \in \mathcal{V}$. This will ensure that condition C1 of the AIS procedure is always satisfied. We have already shown that conditions C2 and C3 are satisfied. For condition C4, we can run a blocked Gibbs sampler (Eqs. 5, 6) to generate samples from p_A. These sample points will not be independent, but the AIS estimator will still converge to the correct value, provided our Markov chain is ergodic (Neal, 2001). However, assessing the accuracy of this estimator can be difficult, as it depends on both the variance of the importance weights and on autocorrelations in the Gibbs sampler.

3.3. Estimating Partition Functions of RBM's

The partition function of an RBM can be found by finding the ratio to the normalizer for $\theta_A = \{0, \mathbf{b}^A, \mathbf{a}^A\}$, an RBM

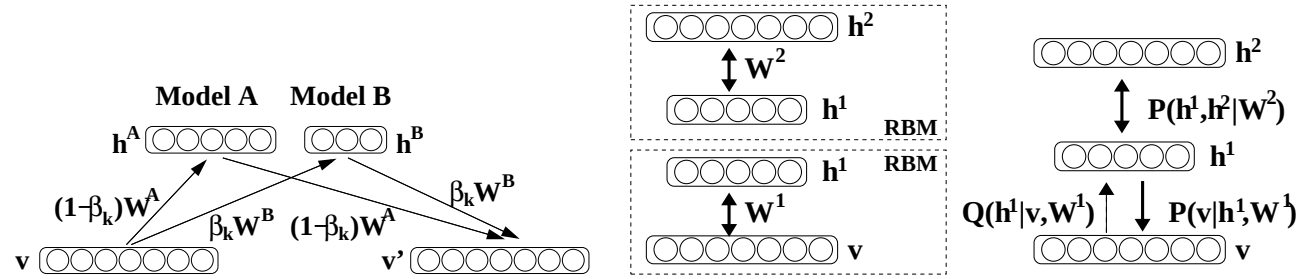

Figure 1. **Left:** The Gibbs transition operator $T_k(\mathbf{v}';\mathbf{v})$ leaves $p_k(\mathbf{v})$ invariant when estimating the ratio of partition functions Z_B/Z_A. **Middle:** Recursive greedy learning consists of learning a stack of RBMs. **Right:** Two-layer DBN as a generative model.

with a zero weight matrix. From Eq. 3, we know:

$$Z_A = 2^{M_A} \prod_i (1 + e^{b_i}). \tag{18}$$

Moreover,

$$p_A(\mathbf{v}) = \prod_i p_A(v_i) = \prod_i 1/(1 + e^{-b_i}),$$

so we can draw exact independent samples from this "base-rate" RBM. AIS in this case allows us to obtain an *unbiased* estimate of the partition function Z_B. This approach closely resembles simulated annealing, since the intermediate distributions of Eq. 13 take form:

$$p_k(\mathbf{v}) = \frac{\exp((1-\beta_k)\mathbf{v}^T\mathbf{b}^A)}{Z_k} \sum_{\mathbf{h}^B} \exp(-\beta_k E(\mathbf{v}, \mathbf{h}^B; \theta_B)).$$

We gradually change β_k (or inverse temperature) from 0 to 1, annealing from a simple "base-rate" model to the final complex model. The importance weights $w^{(i)}$ ensure that AIS produces correct estimates.

4. Deep Belief Networks (DBN's)

In this section we briefly review a greedy learning algorithm for training Deep Belief Networks. We then show how to obtain an estimate of the lower bound on the log-probability that the DBN assigns to the data.

4.1. Greedy Learning of DBN's

Consider learning a DBN with two layers of hidden features as shown in Fig. 1 (right panel). The greedy strategy developed by Hinton et al. (2006) uses a stack of RBM's (Fig. 1, middle panel). We first train the bottom RBM with parameters W^1, as described in section 2.

A key observation is that the RBM's joint distribution $p(\mathbf{v}, \mathbf{h}^1|W^1)$ is identical to that of a DBN with second-layer weights tied to $W^2 = W^{1\top}$. We now consider untying and refining W^2, improving the fit to the training data.

For any approximating distribution $Q(\mathbf{h}^1|\mathbf{v})$, the DBN's log-likelihood has the following variational lower bound:

$$\ln p(\mathbf{v}|W^1, W^2) \;\geq\; \sum_{\mathbf{h}^1} Q(\mathbf{h}^1|\mathbf{v}) \big[\ln p(\mathbf{h}^1|W^2) \;+\; \ln p(\mathbf{v}|\mathbf{h}^1, W^1) \big] + \mathcal{H}(Q(\mathbf{h}^1|\mathbf{v})), \tag{19}$$

where $\mathcal{H}(\cdot)$ is the entropy functional. We set $Q(\mathbf{h}^1|\mathbf{v}) = p(\mathbf{h}^1|\mathbf{v}, W^1)$ defined by the RBM (Eq. 5). Initially, when $W^2 = W^{1\top}$, Q is the DBN's true factorial posterior over $\mathbf{h}^1$, and the bound is tight. Therefore, any increase in the bound will lead to an increase in the true likelihood of the model. Maximizing the bound of Eq. 19 with frozen W^1 is equivalent to maximizing:

$$\sum_{\mathbf{h}^1} Q(\mathbf{h}^1|\mathbf{v}) \ln p(\mathbf{h}^1|W^2). \tag{20}$$

This is equivalent to training the second layer RBM with vectors drawn from $Q(\mathbf{h}^1|\mathbf{v})$ as data.

This scheme can be extended by training a third RBM on $\mathbf{h}^2$ vectors drawn from the second RBM. If we initialize $W^3 = W^{2\top}$, we are guaranteed to improve the lower bound on the log-likelihood, though the log-likelihood itself can fall (Hinton et al., 2006). Repeating this greedy, layer-by-layer training several times results in a deep, hierarchical model.

Recursive Greedy Learning Procedure for the DBN.

1. Fit parameters W^1 of a 1-layer RBM to data.
2. Freeze the parameter vector W^1 and use samples from $p(\mathbf{h}^1|\mathbf{v}, W^1)$ as the data for training the next layer of binary features with an RBM.
3. Proceed recursively for as many layers as desired.

In practice, when adding a new layer l, we typically do not initialize $W^l = W^{l-1\top}$, so the number of hidden units of the new RBM does not need to be the same as the number of the visible units of the lower-level RBM.

4.2. Estimating Lower Bounds for DBN's

Consider the same DBN model with two layers of hidden features shown in Fig. 1. The model's joint distribution is:

$$p(\mathbf{v}, \mathbf{h}^1, \mathbf{h}^2) = p(\mathbf{v}|\mathbf{h}^1)\, p(\mathbf{h}^2, \mathbf{h}^1), \tag{21}$$

where $p(\mathbf{v}|\mathbf{h}^1)$ is defined by Eq. 6), and $p(\mathbf{h}^1, \mathbf{h}^2)$ is the joint distribution defined by the second layer RBM. Note that $p(\mathbf{v}|\mathbf{h}^1)$ is normalized.

By explicitly summing out $\mathbf{h}^2$, we can easily evaluate an unnormalized probability $p^*(\mathbf{v},\mathbf{h}^1) = Zp(\mathbf{v},\mathbf{h}^1)$. Using the approximating factorial distribution Q, which we get as a byproduct of the greedy learning procedure, and the variational lower bound of Eq. 19, we obtain:

$$\ln \sum_{\mathbf{h}^1} p(\mathbf{v},\mathbf{h}^1) \geq \sum_{\mathbf{h}^1} Q(\mathbf{h}^1|\mathbf{v}) \ln p^*(\mathbf{v},\mathbf{h}^1) - \ln Z + \mathcal{H}(Q(\mathbf{h}^1|\mathbf{v})) = B(\mathbf{v}). \quad (22)$$

The entropy term $\mathcal{H}(\cdot)$ can be computed analytically, since Q is factorial. The partition function Z is estimated by running AIS on the top-level RBM. And the expectation term can be estimated by a simple Monte Carlo approximation:

$$\sum_{\mathbf{h}^1} Q(\mathbf{h}^1|\mathbf{v}) \ln p^*(\mathbf{v},\mathbf{h}^1) \approx \frac{1}{M} \sum_{i=1}^{M} \ln p^*(\mathbf{v},\mathbf{h}^{1(i)}), \quad (23)$$

where $\mathbf{h}^{1(i)} \sim Q(\mathbf{h}^1|\mathbf{v})$. The variance of this Monte Carlo estimator will be proportional to $1/M$ provided the variance of $\ln p^*(\mathbf{v},\mathbf{h}^{1(i)})$ is finite. In general, we will be interested in calculating the lower bound averaged over the test set containing N_t samples, so

$$\frac{1}{N_t} \sum_{n=1}^{N_t} B(\mathbf{v}^n) \approx \frac{1}{N_t} \sum_{n=1}^{N_t} \left[\frac{1}{M} \sum_{i=1}^{M} \ln p^*(\mathbf{v}^n,\mathbf{h}^{1(i)}) + \mathcal{H}(Q(\mathbf{h}^1|\mathbf{v}^n)) \right] - \ln \hat{Z} = \hat{r}_B - \ln \hat{Z} = \hat{r}_{\text{Bound}}. \quad (24)$$

In this case the variance of the estimator induced by the Monte Carlo approximation will asymptotically scale as $1/(N_t M)$. We will show in the experimental results section that the value of M can be small provided N_t is large.

The error of the overall estimator $\hat{r}_{\text{Bound}}$ in Eq. 24 will be mostly dominated by the error in the estimate of $\ln Z$. In our experiments, we obtained unbiased estimates of $\hat{Z}$ and its standard deviation $\hat{\sigma}$ using Eqs. 11, 12. We report $\ln \hat{Z}$ and $\ln(\hat{Z} \pm \hat{\sigma})$.

Estimating this lower bound for Deep Belief Networks with more layers is now straightforward. Consider a DBN with L hidden layers. The model's joint distribution and its approximate posterior distribution Q are given by:

$$p(\mathbf{v},\mathbf{h}^1,...,\mathbf{h}^L) = p(\mathbf{v}|\mathbf{h}^1)...p(\mathbf{h}^{L-2}|\mathbf{h}^{L-1})p(\mathbf{h}^{L-1},\mathbf{h}^L)$$
$$Q(\mathbf{h}^1,...,\mathbf{h}^L|\mathbf{v}) = Q(\mathbf{h}^1|\mathbf{v})Q(\mathbf{h}^2|\mathbf{h}^1)...Q(\mathbf{h}^L|\mathbf{h}^{L-1}).$$

The bound can now be obtained by using Eq. 22. Note that most of the computation resources will be spent on estimating the partition function Z of the top level RBM.

5. Experimental Results

In our experiments we used the MNIST digit dataset, which contains 60,000 training and 10,000 test images of ten handwritten digits (0 to 9), with 28×28 pixels. The dataset was binarized: each pixel value was stochastically set to 1 in proportion to its pixel intensity. Samples from the training set are shown in Fig. 2 (top left panel). Annealed importance sampling requires the β_k that define a sequence of intermediate distributions. In all of our experiments this sequence was chosen by quickly running a few preliminary experiments and picking the spacing of β_k so as to minimize the log variance of the final importance weights. The biases $\mathbf{b}^A$ of a base-rate model (see Eq. 18) were set by maximum likelihood, then smoothed to ensure that $p(\mathbf{v}) > 0, \forall\, \mathbf{v} \in \mathcal{V}$. Code that can be used to reproduce experimental results is available at www.cs.toronto.edu/∼rsalakhu.

5.1. Estimating partition functions of RBM's

In our first experiment we trained three RBM's on the MNIST digits. The first two RBM's had 25 hidden units and were learned using CD (section 2) with T=1 and T=3 respectively. We call these models CD1(25) and CD3(25). The third RBM had 20 hidden units and was learned using CD with T=1. For all three models we can calculate the exact value of the partition function simply by summing out the 784 visible units for each configuration of the hiddens. For all three models we used 500 β_k spaced uniformly from 0 to 0.5, 4,000 β_k spaced uniformly from 0.5 to 0.9, and 10,000 β_k spaced uniformly from 0.9 to 1.0, with a total of 14,500 intermediate distributions.

Table 1 shows that for all three models, using only 10 AIS runs, we were able to obtain good estimates of partition functions in just 20 seconds on a Pentium Xeon 3.00GHz machine. For model CD1(25), however, the variance of the estimator was high, even with 100 AIS runs. However, figure 3 (top row) reveals that as the number of annealing runs is increased, AIS can almost exactly recover the true value of the partition function across all three models.

We also estimated the ratio of normalizing constants of two RBM's that have different numbers of hidden units: CD1(20) and CD1(25). This estimator could be used to do complexity control. In detail, using 100 AIS runs with uniform spacing of 10,000 β_k, we obtained $\ln \hat{r}_{\text{AIS}} = \ln(Z_{\text{CD1(20)}}/Z_{\text{CD1(25)}}) = -24.49$ with an error estimate $\ln(\hat{r}_{\text{AIS}} \pm 3\hat{\sigma}) = (-24.19, -24.93)$. Each sample from CD1(25) was generated by starting a Markov chain at the previous sample and running it for 10,000 steps. Compared to the true value of -24.18, this result suggests that our estimates may have a small systematic error due to the Markov chain failing to visit some modes.

Our second experiment consisted of training two more realistic models: CD1(500) and CD3(500). We used exactly the same spacing of β_k as before and exactly the same base-rate model. Results are shown in table 1 (bottom row). For each model we were able to get what appears to be a rather

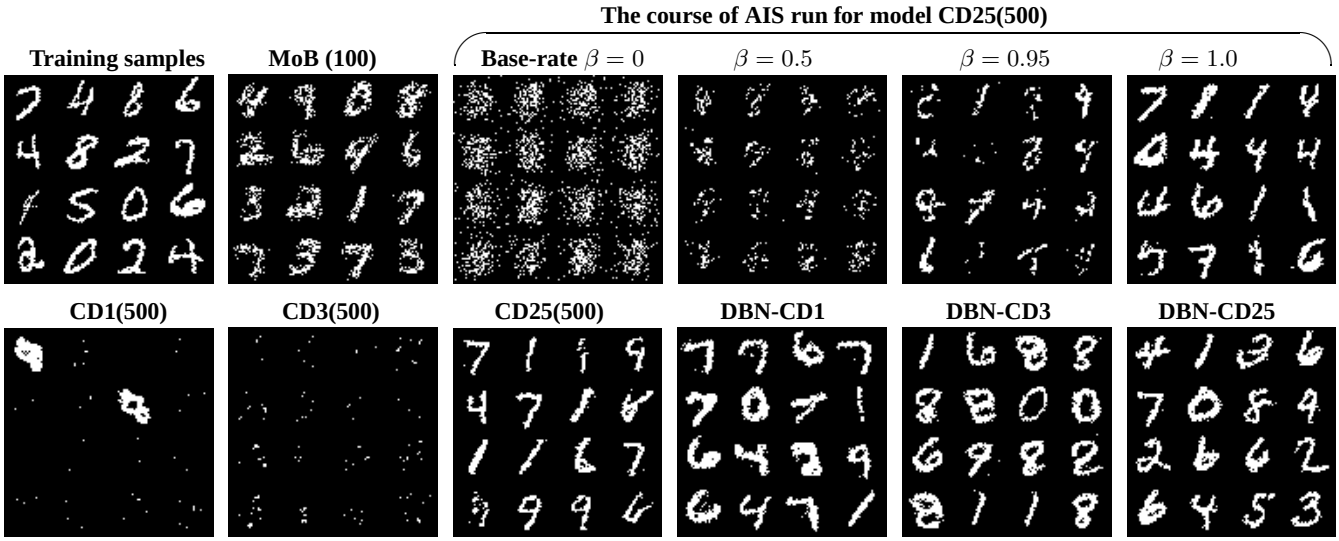

Figure 2. **Top row:** First two panels show random samples from the training set and a mixture of Bernoullis model with 100 components. The last 4 panels display the course of 16 AIS runs for CD25(500) model by starting from a simple base-rate model and annealing to the final complex model. **Bottom row:** Random samples generated from three RBM's and corresponding three DBN's models.

Table 1. Results of estimating partition functions of RBM's along with the estimates of the average training and test log-probabilities. For all models we used 14,500 intermediate distributions.

AIS Runs		True $\ln Z$	Estimates $\ln \hat{Z}$	Estimates $\ln(\hat{Z} \pm \hat{\sigma})$	Estimates $\ln(\hat{Z} \pm 3\hat{\sigma})$	Time (mins)	Avg. Test log-prob. true	Avg. Test log-prob. estimate	Avg. Train log-prob. true	Avg. Train log-prob. estimate
100	CD1(25)	255.41	256.52	255.00, 257.10	0.0000, 257.73	3.3	-151.57	-152.68	-152.35	-153.46
	CD3(25)	307.47	307.63	307.44, 307.79	306.91, 308.05	3.3	-143.03	-143.20	-143.94	-144.11
	CD1(20)	279.59	279.57	279.43, 279.68	279.12, 279.87	3.1	-164.52	-164.50	-164.89	-164.87
100	CD1(500)	—	350.15	350.04, 350.25	349.77, 350.42	10.4	—	-125.53	—	-122.86
	CD3(500)	—	280.09	279.99, 280.17	279.76, 280.33	10.4	—	-105.50	—	-102.81
	CD25(500)	—	451.28	451.19, 451.37	450.97, 451.52	10.4	—	-86.34	—	-83.10

accurate estimate of Z. Of course, we are relying on an empirical estimate of AIS's accuracy, which could potentially be misleading. Nonetheless, Fig. 3 (bottom row) shows that as we increase the number of annealing runs, the value of the estimator does not oscillate drastically.

While performing these tests, we observed that contrastive divergence learning with T=3 results in considerably better generative model than CD learning with T=1: the difference of 20 nats is striking! Clearly, the widely used practice of CD learning with T=1 is a rather poor "substitute" for maximum likelihood learning. Inspired by this result, we trained a model by starting with T=1, and gradually increasing T to 25 during the course of CD training, as suggested by (Carreira-Perpinan & Hinton, 2005). We call this model CD25(500). Training this model was computationally much more demanding. However, the estimate of the average test log-probability for this model was about -86, which is 39 and 19 nats better than the CD1(500) and CD3(500) models respectively. Fig. 2 (bottom row) shows samples generated from all three models by randomly initializing binary states of the visible units and running alternating Gibbs for 100,000 steps. Certainly, samples generated by CD25(500) look much more like the real handwritten digits, than either CD1(500) or CD3(500).

We also obtained an estimate of the log ratio of two partition functions $\hat{r}_{\text{AIS}} = \ln Z_{\text{CD25(500)}}/Z_{\text{CD3(500)}} = 169.96$, using 10,000 β_k and 100 annealing runs. The estimates of the individual log-partition functions were $\ln \hat{Z}_{\text{CD25(500)}} = 451.28$ and $\ln \hat{Z}_{\text{CD3(500)}} = 280.09$, in which case the log ratio is $451.28 - 280.09 = 171.19$. This is in agreement (to within three standard deviations) with the direct estimate of the ratio, $\hat{r}_{\text{AIS}} = 169.96$.

For a simple comparison we also trained several mixture of Bernoullis models (see Fig. 2, top left panel) with 10, 100, and 500 components. The corresponding average test log-probabilities were -168.95, -142.63, and -137.64. The data generated from the mixture model looks better than CD3(500), although our quantitive results reveal this is due to over-fitting. The RBM's make much better predictions.

5.2. Estimating lower bounds for DBN's

We greedily trained three DBN models with two hidden layers. The first model, called DBN-CD1, was greedily

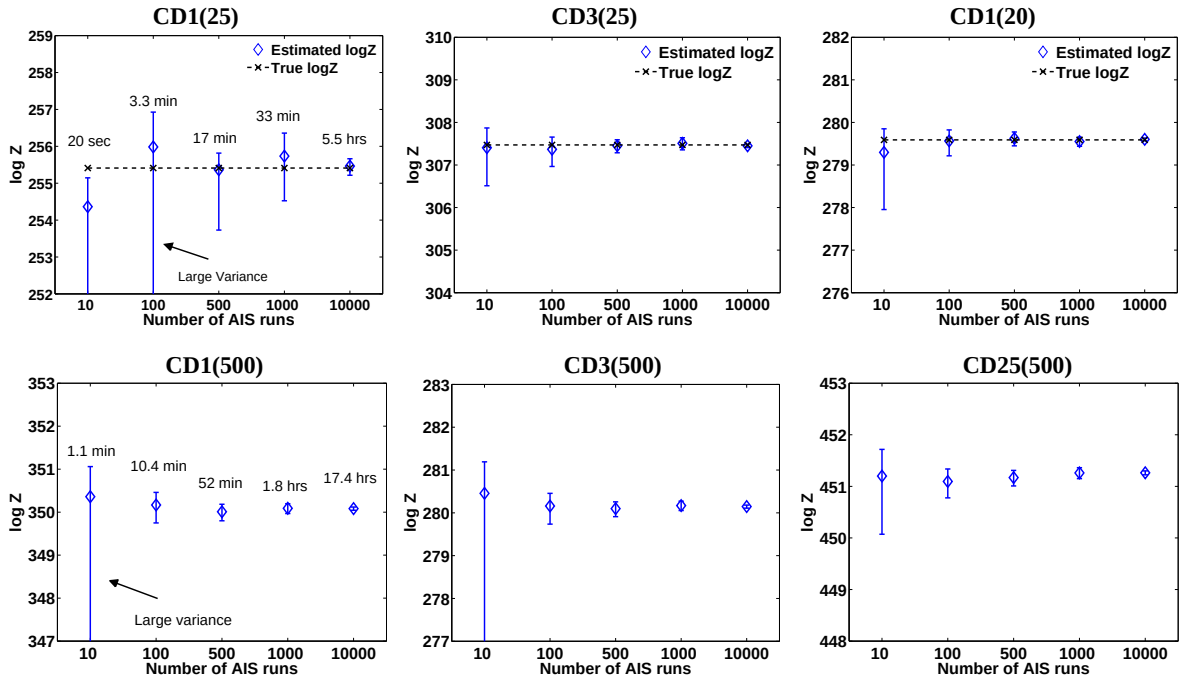

Figure 3. Estimates of the log-partition functions $\ln \hat{Z}$ as we increase the number of annealing runs. The error bars show $\ln(\hat{Z} \pm 3\hat{\sigma})$.

learned by freezing the parameter vector of the CD1(500) model and learning the 2^{nd} layer RBM with 2000 hidden units using CD with T=1. Similarly, the other two models, DBN-CD3 and DBN-CD25, added 2000 hidden units on top of CD3(500) and CD25(500), using CD with T=3 and T=25 respectively. Training the DBN's took roughly three times longer than the RBM's.

Table 2 shows the results. We used 15,000 intermediate distributions and 500 annealing runs to estimate the partition function of the 2^{nd} layer RBM. This took 2.3 hours. Further sampling was required for the simple Monte Carlo approximation of Eq. 23. We used M=5 samples from the approximating distribution $Q(\mathbf{h}|\mathbf{v})$ for each data vector $\mathbf{v}$. Setting M=100 did not make much difference. Table 2 also reports the empirical error in the estimate of the lower bound $\hat{r}_{\text{Bound}}$. From Eq. 24, we have $\text{Var}(\hat{r}_{\text{Bound}}) = \text{Var}(\hat{r}_B) + \text{Var}(\ln \hat{Z})$, both of which are shown in table 2. Note that models DBN-CD1 and DBN-CD3 significantly outperform their single layer counterparts: CD1(500) and CD3(500). Adding a second layer for those two models improves model performance by at least 25 and 7 nats. This corresponds to a dramatic improvement in the quality of samples generated from the models (Fig. 2, bottom row).

Observe that greedy learning of DBN's does not appear to suffer severely from overfitting. For single layer models, the difference between the estimates of training and test log-probabilities was about 3 nats. For DBN's, the corresponding difference in the estimates of the lower bounds was about 4 nats, even though adding a second layer introduced over twice as many (or one million) new parameters.

Table 2. Results of estimating lower bounds $\hat{r}_{\text{Bound}}$ (Eq. 24) on the average training and test log-probabilities for DBN's. On average, the total error of the estimator is about $\pm$ 2 nats.

	Model	Avg. bound log-prob	Error $\hat{r}_B$ ± 3 std	AIS error $\ln(\hat{Z} \pm 3\hat{\sigma}) - \ln \hat{Z}$
Test	DBN-CD1	-100.64	± 0.77	$-1.43, +0.57$
	DBN-CD3	-98.29	± 0.75	$-0.91, +0.31$
	DBN-CD25	-86.22	± 0.67	$-0.84, +0.65$
Train	DBN-CD1	-97.67	± 0.30	$-1.43, +0.57$
	DBN-CD3	-94.86	± 0.29	$-0.91, +0.31$
	DBN-CD25	-82.47	± 0.25	$-0.84, +0.65$

The result of our experiments for DBN-CD25, however, was very different. For this model, on the test data we obtained $\hat{r}_{\text{Bound}} = -86.22$. This is comparable to the estimate of -86.34 for the average test log-probability of the CD25(500) model. Clearly, we cannot confidently assert that DBN-CD25 is a better generative model compared to the carefully trained single layer RBM. This peculiar result also supports previous claims that if the first level RBM already models data well, adding extra layers will not help (LeRoux & Bengio, 2008; Hinton et al., 2006). As an additional test, instead of randomly initializing parameters of the 2^{nd} layer RBM, we initialized it by using the same parameters as the 1^{st} layer RBM but with hidden and visible units switched (see Fig. 1). This initialization ensures that the distribution over the visible units $\mathbf{v}$ defined by the two-layer DBN is *exactly the same* as the distribution over $\mathbf{v}$ defined by the 1^{st} layer RBM. Therefore, after learning parameters of the 2^{nd} layer RBM, the lower bound on the training data log-likelihood can only improve. After care-

fully training the second level RBM, our estimate of the lower bound on the test log-probability was only -85.97. Once again, we cannot confidently claim that adding an extra layer in this case yields better generalization.

6. Discussions

The original paper of Hinton et al. (2006) showed that for DBN's, each additional layer increases a lower bound (see Eq. 19) on the log-probability of the *training* data, provided the number of hidden units per layer does not decrease. However, assessing generalization performance of these generative models is quite difficult, since it requires enumeration over an exponential number of terms. In this paper we developed an annealed importance sampling procedure that takes advantage of the bipartite structure of the RBM. This can provide a good estimate of the partition function in a reasonable amount of computer time. Furthermore, we showed that this estimator, along with approximate inference, can be used to obtain an estimate of the lower bound on the log-probability of the *test* data, thus allowing us to obtain some quantitative evaluation of the generalization performance of these deep hierarchical models.

There are some disadvantages to using AIS. There is a need to specify the β_k that define a sequence of intermediate distributions. The number and the spacing of β_k will be problem dependent and will affect the variance of the estimator. We also have to rely on the empirical estimate of AIS accuracy, which could potentially be very misleading (Neal, 2001; Neal, 2005). Even though AIS provides an unbiased estimator of Z, it occasionally gives large overestimates and usually gives small underestimates, so in practice, it is more likely to underestimate of the true value of the partition function, which will result in an overestimate of the log-probability. But these drawbacks should not result in disfavoring the use of AIS for RBM's and DBN's: it is much better to have a slightly unreliable estimate than no estimate at all, or an extremely indirect estimate, such as discriminative performance (Hinton et al., 2006).

We find AIS and other stochastic methods attractive as they can just as easily be applied to undirected graphical models that generalize RBM's and DBN's to exponential family distributions. This will allow future application to models of real-valued data, such as image patches (Osindero & Hinton, 2008), or count data (Gehler et al., 2006).

Another alternative would be to employ deterministic approximations (Yedidia et al., 2005) or deterministic upper bounds (Wainwright et al., 2005) on the log-partition function. However, for densely connected MRF's, we would not expect these methods to work well. Indeed, preliminary results suggest that these methods provide quite inaccurate estimates of (or very loose upper bounds on) the partition function, even for small RBM's when *trained on real data*.

Bayesian Probabilistic Matrix Factorization using Markov Chain Monte Carlo

Ruslan Salakhutdinov RSALAKHU@CS.TORONTO.EDU
Andriy Mnih AMNIH@CS.TORONTO.EDU
Department of Computer Science, University of Toronto, Toronto, Ontario M5S 3G4, Canada

Abstract

Low-rank matrix approximation methods provide one of the simplest and most effective approaches to collaborative filtering. Such models are usually fitted to data by finding a MAP estimate of the model parameters, a procedure that can be performed efficiently even on very large datasets. However, unless the regularization parameters are tuned carefully, this approach is prone to overfitting because it finds a single point estimate of the parameters. In this paper we present a fully Bayesian treatment of the Probabilistic Matrix Factorization (PMF) model in which model capacity is controlled automatically by integrating over all model parameters and hyperparameters. We show that Bayesian PMF models can be efficiently trained using Markov chain Monte Carlo methods by applying them to the Netflix dataset, which consists of over 100 million movie ratings. The resulting models achieve significantly higher prediction accuracy than PMF models trained using MAP estimation.

1. Introduction

Factor-based models have been used extensively in the domain of collaborative filtering for modelling user preferences. The idea behind such models is that preferences of a user are determined by a small number of unobserved factors. In a linear factor model, a user's rating of an item is modelled by the inner product of an item factor vector and a user factor vector. This means that the $N \times M$ preference matrix of ratings that N users assign to M movies is modeled by the product of an $D \times N$ user coefficient matrix U and a $D \times M$ factor matrix V (Rennie & Srebro, 2005; Srebro & Jaakkola, 2003). Training such a model amounts to finding the best rank-D approximation to the observed $N \times M$ target matrix R under the given loss function.

A variety of probabilistic factor-based models have been proposed (Hofmann, 1999; Marlin, 2004; Marlin & Zemel, 2004; Salakhutdinov & Mnih, 2008). In these models factor variables are assumed to be marginally independent while rating variables are assumed to be conditionally independent given the factor variables. The main drawback of such models is that inferring the posterior distribution over the factors given the ratings is intractable. Many of the existing methods resort to performing MAP estimation of the model parameters. Training such models amounts to maximizing the log-posterior over model parameters and can be done very efficiently even on very large datasets.

In practice, we are usually interested in predicting ratings for new user/movie pairs rather than in estimating model parameters. This view suggests taking a Bayesian approach to the problem which involves integrating out the model parameters. In this paper, we describe a fully Bayesian treatment of the Probabilistic Matrix Factorization (PMF) model which has been recently applied to collaborative filtering (Salakhutdinov & Mnih, 2008). The distinguishing feature of our work is the use of Markov chain Monte Carlo (MCMC) methods for approximate inference in this model. In practice, MCMC methods are rarely used on large-scale problems because they are perceived to be very slow by practitioners. In this paper we show that MCMC can be successfully applied to the large, sparse, and very imbalanced Netflix dataset, containing over 100 million user/movie ratings. We also show that it significantly increases the model's predictive accuracy, especially for the infrequent users, compared to the standard PMF models trained using MAP with regularization parameters that have been carefully tuned on the validation set.

Previous applications of Bayesian matrix factorization methods to collaborative filtering (Lim & Teh, 2007; Raiko et al., 2007) have used variational approxima-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

tions for performing inference. These methods attempt to approximate the true posterior distribution by a simpler, factorized distribution under which the user factor vectors are independent of the movie factor vectors. The consequence of this assumption is that that the variational posterior distributions over the factor vectors is a product of two multivariate Gaussians: one for the viewer factor vectors and one for the movie factor vectors. This assumption of independence between the viewer and movie factors seems unreasonable, and, as our experiments demonstrate, the distributions over factors in such models turn out to be non-Gaussian. This conclusion is supported by the fact that the Bayesian PMF models outperform their MAP trained counterparts by a much larger margin than the variationally trained models do.

2. Probabilistic Matrix Factorization

Probabilistic Matrix Factorization (PMF) is a probabilistic linear model with Gaussian observation noise (see Fig. 1, left panel). Suppose we have N users and M movies. Let R_{ij} be the rating value of user i for movie j, U_i and V_j represent D-dimensional user-specific and movie-specific latent feature vectors respectively. The conditional distribution over the observed ratings $R \in \mathbb{R}^{N\times M}$ (the likelihood term) and the prior distributions over $U \in \mathbb{R}^{D\times N}$ and $V \in \mathbb{R}^{D\times M}$ are given by:

$$p(R|U,V,\alpha) = \prod_{i=1}^{N}\prod_{j=1}^{M}\left[\mathcal{N}(R_{ij}|U_i^T V_j, \alpha^{-1})\right]^{I_{ij}} \quad (1)$$

$$p(U|\alpha_U) = \prod_{i=1}^{N}\mathcal{N}(U_i|0,\alpha_U^{-1}I) \quad (2)$$

$$p(V|\alpha_V) = \prod_{j=1}^{M}\mathcal{N}(V_j|0,\alpha_V^{-1}I), \quad (3)$$

where $\mathcal{N}(x|\mu,\alpha^{-1})$ denotes the Gaussian distribution with mean μ and precision α, and I_{ij} is the indicator variable that is equal to 1 if user i rated movie j and equal to 0 otherwise.

Learning in this model is performed by maximizing the log-posterior over the movie and user features with fixed hyperparameters (i.e. the observation noise variance and prior variances):

$$\ln p(U,V|R,\alpha,\alpha_V,\alpha_U) = \ln p(R|U,V,\alpha) + \\ + \ln p(U|\alpha_U) + \ln p(V|\alpha_V) + C,$$

where C is a constant that does not depend on the parameters. Maximizing this posterior distribution with respect to U and V is equivalent to minimizing the sum-of-squares error function with quadratic regularization terms:

$$E = \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{M} I_{ij}\left(R_{ij} - U_i^T V_j\right)^2 \\ + \frac{\lambda_U}{2}\sum_{i=1}^{N} \| U_i \|_{\mathrm{Fro}}^2 + \frac{\lambda_V}{2}\sum_{j=1}^{M} \| V_j \|_{\mathrm{Fro}}^2, \quad (4)$$

where $\lambda_U = \alpha_U/\alpha$, $\lambda_V = \alpha_V/\alpha$, and $\| \cdot \|_{\mathrm{Fro}}^2$ denotes the Frobenius norm. A local minimum of the objective function given by Eq. 4 can be found by performing gradient descent in U and V.

The main drawback of this training procedure is the need for manual complexity control that is essential to making the model generalize well, particularly on sparse and imbalanced datasets. One way to control the model complexity is to search for appropriate values of regularization parameters λ_U and λ_V defined above. We could, for example, consider a set of reasonable parameter values, train a model for each setting of the parameters, and choose the model that performs best on the validation set. This approach however is computationally very expensive, since it requires training a multitude of models instead of training a single one.

Alternatively, we could introduce priors for the hyperparameters and maximize the log-posterior of the model over *both parameters and hyperparameters*, which allows model complexity to be controlled automatically based on the training data (Nowlan & Hinton, 1992; Salakhutdinov & Mnih, 2008). Though this approach has been shown to work in practice it is not well-grounded theoretically, and it is not difficult to construct a simple example for which such joint optimization would not produce the desired results.

In the next section we describe a fully Bayesian treatment of the PMF model with model parameters and hyperparameters integrated out using MCMC methods, which provides fully automatic complexity control.

3. Bayesian Probabilistic Matrix Factorization

3.1. The Model

The graphical model representing Bayesian PMF is shown in Fig. 1 (right panel). As in PMF, the likelihood of the observed ratings is given by Eq. 1. The prior distributions over the user and movie feature vec-

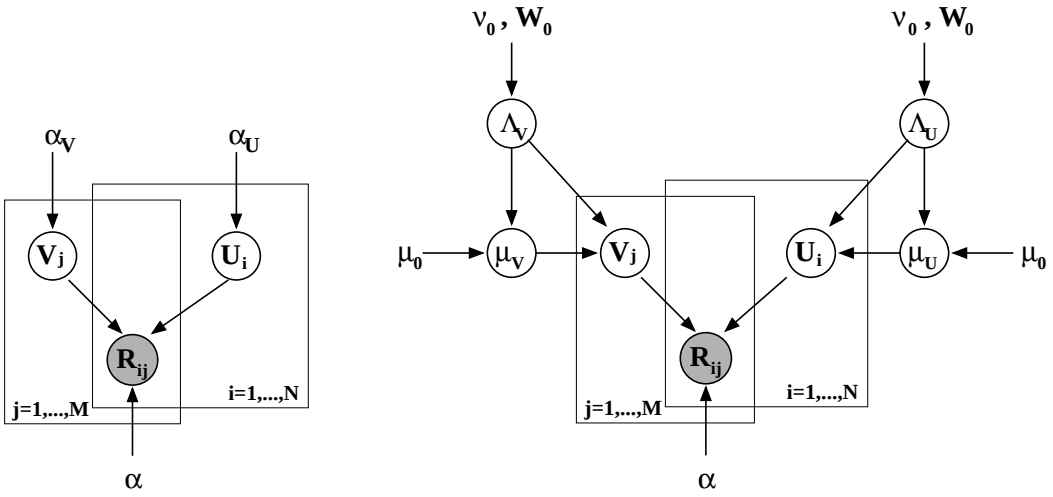

Figure 1. The left panel shows the graphical model for Probabilistic Matrix Factorization (PMF). The right panel shows the graphical model for Bayesian PMF.

tors are assumed to be Gaussian:

$$p(U|\mu_U, \Lambda_U) = \prod_{i=1}^{N} \mathcal{N}(U_i|\mu_U, \Lambda_U^{-1}), \tag{5}$$

$$p(V|\mu_V, \Lambda_V) = \prod_{i=1}^{M} \mathcal{N}(V_i|\mu_V, \Lambda_V^{-1}). \tag{6}$$

We further place Gaussian-Wishart priors on the user and movie hyperparameters $\Theta_U = \{\mu_U, \Lambda_U\}$ and $\Theta_V = \{\mu_V, \Lambda_V\}$:

$$\begin{aligned} p(\Theta_U|\Theta_0) &= p(\mu_U|\Lambda_U)p(\Lambda_U) \\ &= \mathcal{N}(\mu_U|\mu_0, (\beta_0\Lambda_U)^{-1})\mathcal{W}(\Lambda_U|W_0, \nu_0), \end{aligned} \tag{7}$$

$$\begin{aligned} p(\Theta_V|\Theta_0) &= p(\mu_V|\Lambda_V)p(\Lambda_V) \\ &= \mathcal{N}(\mu_V|\mu_0, (\beta_0\Lambda_V)^{-1})\mathcal{W}(\Lambda_V|W_0, \nu_0). \end{aligned} \tag{8}$$

Here $\mathcal{W}$ is the Wishart distribution with ν_0 degrees of freedom and a $D \times D$ scale matrix W_0:

$$\mathcal{W}(\Lambda|W_0, \nu_0) = \frac{1}{C}|\Lambda|^{(\nu_0 - D - 1)/2} \exp\left(-\frac{1}{2}\mathrm{Tr}(W_0^{-1}\Lambda)\right),$$

where C is the normalizing constant. For convenience we also define $\Theta_0 = \{\mu_0, \nu_0, W_0\}$. In our experiments we also set $\nu_0 = D$ and W_0 to the identity matrix for both user and movie hyperparameters and choose $\mu_0 = 0$ by symmetry.

3.2. Predictions

The predictive distribution of the rating value R_{ij}^* for user i and query movie j is obtained by marginalizing over model parameters and hyperparameters:

$$\begin{aligned} p(R_{ij}^*|R, \Theta_0) = \iint p(R_{ij}^*|U_i, V_j)p(U, V|R, \Theta_U, \Theta_V) \\ p(\Theta_U, \Theta_V|\Theta_0)\mathrm{d}\{U, V\}\mathrm{d}\{\Theta_U, \Theta_V\}. \end{aligned} \tag{9}$$

Since exact evaluation of this predictive distribution is analytically intractable due to the complexity of the posterior we need to resort to approximate inference.

One choice would be to use variational methods (Hinton & van Camp, 1993; Jordan et al., 1999) that provide deterministic approximation schemes for posteriors. In particular, we could approximate the true posterior $p(U, V, \Theta_U, \Theta_V|R)$ by a distribution that factors, with each factor having a specific parametric form such as a Gaussian distribution. This approximate posterior would allow us to approximate the integrals in Eq. 9. Variational methods have become the methodology of choice, since they typically scale well to large applications. However, they can produce inaccurate results because they tend to involve overly simple approximations to the posterior.

MCMC-based methods (Neal, 1993), on the other hand, use the Monte Carlo approximation to the predictive distribution of Eq. 9 given by:

$$p(R_{ij}^*|R, \Theta_0) \approx \frac{1}{K}\sum_{k=1}^{K} p(R_{ij}^*|U_i^{(k)}, V_j^{(k)}). \tag{10}$$

The samples $\{U_i^{(k)}, V_j^{(k)}\}$ are generated by running a Markov chain whose stationary distribution is the posterior distribution over the model parameters and hyperparameters $\{U, V, \Theta_U, \Theta_V\}$. The advantage of

the Monte Carlo-based methods is that asymptotically they produce exact results. In practice, however, MCMC methods are usually perceived to be so computationally demanding that their use is limited to small-scale problems.

3.3. Inference

One of the simplest MCMC algorithms is the Gibbs sampling algorithm, which cycles through the latent variables, sampling each one from its distribution conditional on the current values of all other variables. Gibbs sampling is typically used when these conditional distributions can be sampled from easily.

Due to the use of conjugate priors for the parameters and hyperparameters in the Bayesian PMF model, the conditional distributions derived from the posterior distribution are easy to sample from. In particular, the conditional distribution over the user feature vector U_i, conditioned on the movie features, observed user rating matrix R, and the values of the hyperparameters is Gaussian:

$$p(U_i|R,V,\Theta_U,\alpha) = \mathcal{N}\big(U_i|\mu_i^*,\left[\Lambda_i^*\right]^{-1}\big) \sim \prod_{j=1}^{M}\left[\mathcal{N}(R_{ij}|U_i^TV_j,\alpha^{-1})\right]^{I_{ij}} p(U_i|\mu_U,\Lambda_U), \tag{11}$$

where

$$\Lambda_i^* = \Lambda_U + \alpha\sum_{j=1}^{M}\left[V_jV_j^T\right]^{I_{ij}} \tag{12}$$

$$\mu_i^* = [\Lambda_i^*]^{-1}\left(\alpha\sum_{j=1}^{M}\left[V_jR_{ij}\right]^{I_{ij}} + \Lambda_U\mu_U\right). \tag{13}$$

Note that the conditional distribution over the user latent feature matrix U factorizes into the product of conditional distributions over the individual user feature vectors:

$$p(U|R,V,\Theta_U) = \prod_{i=1}^{N} p(U_i|R,V,\Theta_U).$$

Therefore we can easily speed up the sampler by sampling from these conditional distributions in parallel. The speedup could be substantial, particularly when the number of users is large.

The conditional distribution over the user hyperparameters conditioned on the user feature matrix U is given by the Gaussian-Wishart distribution:

$$p(\mu_U,\Lambda_U|U,\Theta_0) = \mathcal{N}(\mu_U|\mu_0^*,(\beta_0^*\Lambda_U)^{-1})\mathcal{W}(\Lambda_U|W_0^*,\nu_0^*), \tag{14}$$

where

$$\mu_0^* = \frac{\beta_0\mu_0 + N\bar{U}}{\beta_0+N}, \quad \beta_0^* = \beta_0+N, \quad \nu_0^* = \nu_0+N,$$

$$\left[W_0^*\right]^{-1} = W_0^{-1} + N\bar{S} + \frac{\beta_0 N}{\beta_0+N}(\mu_0-\bar{U})(\mu_0-\bar{U})^T$$

$$\bar{U} = \frac{1}{N}\sum_{i=1}^{N}U_i \quad \bar{S} = \frac{1}{N}\sum_{i=1}^{N}U_iU_i^T.$$

The conditional distributions over the movie feature vectors and the movie hyperparameters have exactly the same form. The Gibbs sampling algorithm then takes the following form:

Gibbs sampling for Bayesian PMF

1. Initialize model parameters $\{U^1, V^1\}$
2. For t=1,...,T
   - Sample the hyperparameters (Eq. 14):
     $$\Theta_U^t \sim p(\Theta_U|U^t,\Theta_0)$$
     $$\Theta_V^t \sim p(\Theta_V|V^t,\Theta_0)$$
   - For each $i = 1,...,N$ sample user features in parallel (Eq. 11):
     $$U_i^{t+1} \sim p(U_i|R,V^t,\Theta_U^t)$$
   - For each $i = 1,...,M$ sample movie features in parallel:
     $$V_i^{t+1} \sim p(V_i|R,U^{t+1},\Theta_V^t)$$

4. Experimental Results

4.1. Description of the dataset

The data, collected by Netflix, represent the distribution of all ratings Netflix obtained between October, 1998 and December, 2005. The training data set consists of 100,480,507 ratings from 480,189 randomly-chosen, anonymous users on 17,770 movie titles. As part of the training data, Netflix also provides validation data, containing 1,408,395 ratings. In addition, Netflix also provides a test set containing 2,817,131 user/movie pairs with the ratings withheld. The pairs were selected from the most recent ratings from a subset of the users in the training data set. Performance is assessed by submitting predicted ratings to Netflix which then posts the root mean squared error (RMSE) on an unknown half of the test set. As a baseline, Netflix provided the test score of its own system trained on the same data, which is 0.9514.

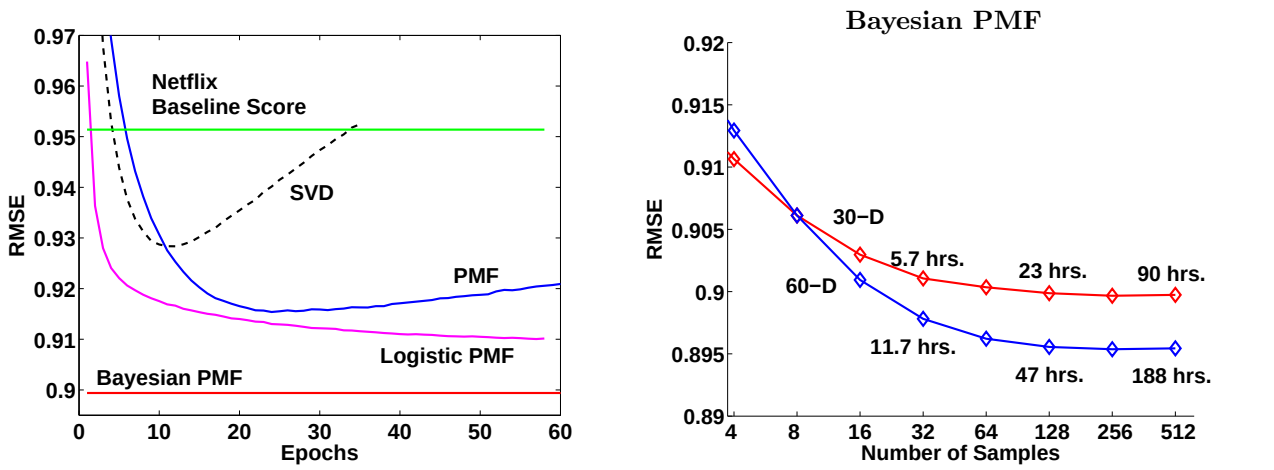

Figure 2. Left panel: Performance of SVD, PMF, logistic PMF, and Bayesian PMF using 30D feature vectors, on the Netflix validation data. The y-axis displays RMSE (root mean squared error), and the x-axis shows the number of epochs, or passes, through the entire training set. Right panel: RMSE for the Bayesian PMF models on the validation set as a function of the number of samples generated. The two curves are for the models with 30D and 60D feature vectors.

4.2. Training PMF models

For comparison, we have trained a variety of linear PMF models using MAP, choosing their regularization parameters using the validation set. In addition to linear PMF models, we also trained logistic PMF models, in which we pass the dot product between user- and movie-specific feature vectors through the logistic function $\sigma(x) = 1/(1 + \exp(-x))$ to bound the range of predictions:

$$p(R|U, V, \alpha) = \prod_{i=1}^{N} \prod_{j=1}^{M} \left[\mathcal{N}(R_{ij}|\sigma(U_i^T V_j), \alpha^{-1}) \right]^{I_{ij}}. \quad (15)$$

The ratings $1, ..., 5$ are mapped to the interval $[0, 1]$ using the function $t(x) = (x - 1)/4$, so that the range of valid rating values matches the range of predictions our model can make. Logistic PMF models can sometimes provide slightly better results than their linear counterparts.

To speed up training, instead of performing full batch learning, we subdivided the Netflix data into mini-batches of size 100,000 (user/movie/rating triples) and updated the feature vectors after each mini-batch. We used a learning rate of 0.005 and a momentum of 0.9 for training the linear as well as logistic PMF models.

4.3. Training Bayesian PMF models

We initialized the Gibbs sampler by setting the model parameters U and V to their MAP estimates obtained by training a linear PMF model. We also set $\mu_0 = 0$, $\nu_0 = D$, and W_0 to the identity matrix, for both user and movie hyperpriors. The observation noise precision α was fixed at 2. The predictive distribution was computed using Eq. 10 by running the Gibbs sampler with samples $\{U_i^{(k)}, V_j^{(k)}\}$ collected after each full Gibbs step.

4.4. Results

In our first experiment, we compared a Bayesian PMF model to an SVD model, a linear PMF model, and a logistic PMF model, all using 30D feature vectors. The SVD model was trained to minimize the sum-squared distance to the observed entries of the target matrix, with no regularization applied to the feature vectors. Note that this model can be seen as a PMF model trained using maximum likelihood (ML). For the PMF models, the regularization parameters λ_U and λ_V were set to 0.002. Predictive performance of these models on the validation set is shown in Fig. 2 (left panel). The mean of the predictive distribution of the Bayesian PMF model achieves an RMSE of 0.8994, compared to an RMSE of 0.9174 of a moderately regularized linear PMF model, an improvement of over 1.7%.

The logistic PMF model does slightly outperform its linear counterpart, achieving an RMSE of 0.9097. However, its performance is still considerably worse than that of the Bayesian PMF model. A simple SVD achieves an RMSE of about 0.9280 and after about 10 epochs begins to overfit heavily. This experiment clearly demonstrates that SVD and MAP-trained PMF models can overfit and that the predictive accuracy can be improved by integrating out model parameters and hyperparameters.

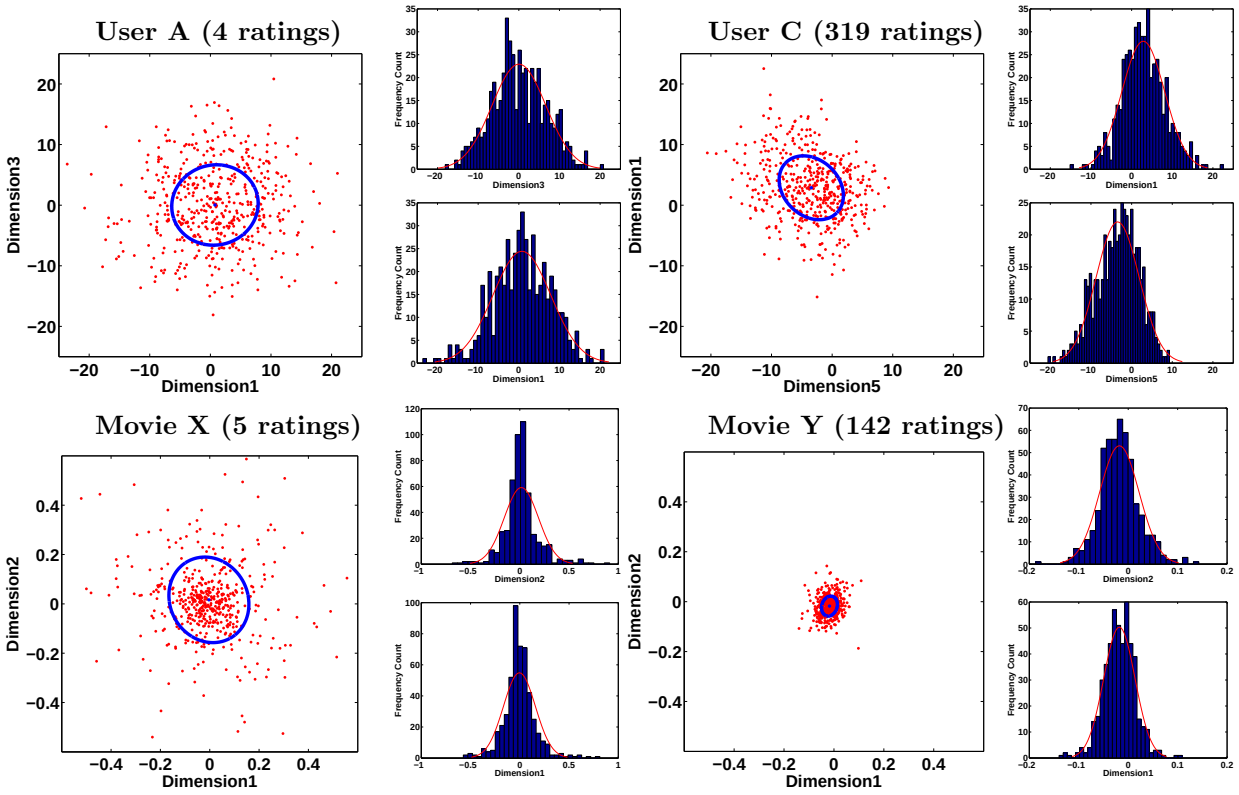

Figure 3. Samples from the posterior over the user and movie feature vectors generated by each step of the Gibbs sampler. The two dimensions with the highest variance are shown for two users and two movies. The first 800 samples were discarded as "burn-in".

D	Valid. RMSE		%	Test RMSE		%
	PMF	BPMF	Inc.	PMF	BPMF	Inc.
30	0.9154	0.8994	1.74	0.9188	0.9029	1.73
40	0.9135	0.8968	1.83	0.9170	0.9002	1.83
60	0.9150	0.8954	2.14	0.9185	0.8989	2.13
150	0.9178	0.8931	2.69	0.9211	0.8965	2.67
300	0.9231	0.8920	3.37	0.9265	0.8954	3.36

Table 1. Performance of Bayesian PMF (BPMF) and linear PMF on Netflix validation and test sets.

We than trained larger PMF models with $D = 40$ and $D = 60$. Capacity control for such models becomes a rather challenging task. For example, a PMF model with $D = 60$ has approximately 30 million parameters. Searching for appropriate values of the regularization coefficients becomes a very computationally expensive task. Table 1 further shows that for the 60-dimensional feature vectors, Bayesian PMF outperforms its MAP counterpart by over 2%. We should also point out that even the simplest possible Bayesian extension of the PMF model, where Gamma priors are placed over the precision hyperparameters α_U and α_V (see Fig. 1, left panel), significantly outperforms the MAP-trained PMF models, even though it does not perform as well as the Bayesian PMF models.

It is interesting to observe that as the feature dimensionality grows, the performance accuracy for the MAP-trained PMF models does not improve, and controlling overfitting becomes a critical issue. The predictive accuracy of the Bayesian PMF models, however, steadily improves as the model complexity grows. Inspired by this result, we experimented with Bayesian PMF models with $D = 150$ and $D = 300$ feature vectors. Note that these models have about 75 and 150 million parameters, and running the Gibbs sampler becomes computationally much more expensive. Nonetheless, the validation set RMSEs for the two models were 0.8931 and 0.8920. Table 1 shows that these models not only significantly outperform their MAP counterparts but also outperform Bayesian PMF models that have fewer parameters. These results clearly show that the Bayesian approach does not require limiting the complexity of the model based on the number of the training samples. In practice, however, we will be limited by the available computer resources.

For completeness, we also report the performance results on the Netflix *test set*. These numbers were ob-

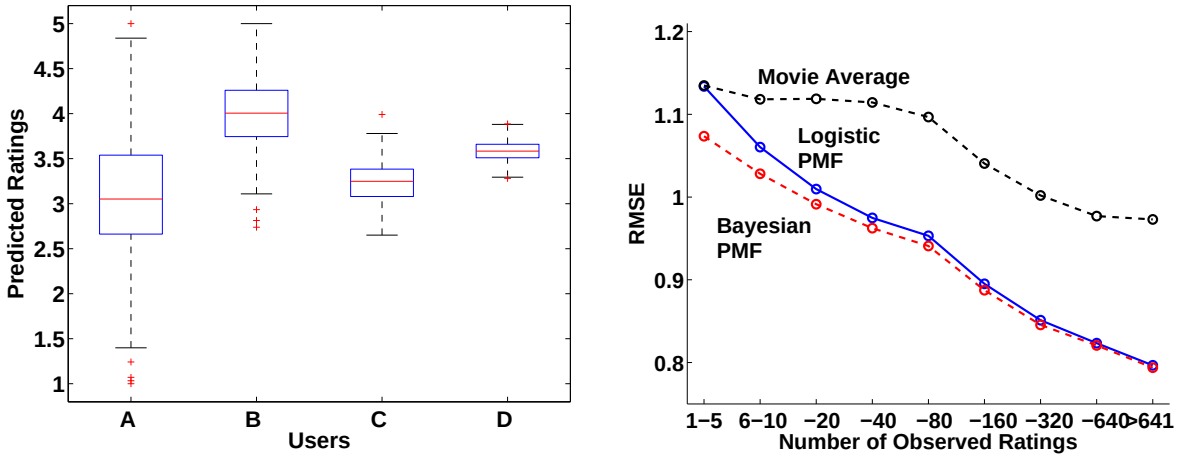

Figure 4. Left panel: Box plot of predictions, obtained after each full Gibbs step, for 4 users on a randomly chosen test movies. Users A,B,C, and D have 4, 23, 319 and 660 ratings respectively. Right panel: Performance of Bayesian PMF, logistic PMF, and the movie average algorithm that always predicts the average rating of each movie. The users were grouped by the number of observed ratings in the training data. The linear PMF model performed slightly worse than the logistic PMF model.

tained by submitting the predicted ratings to Netflix who then provided us with the test score on an unknown half of the test set. The test scores are slightly worse than the validation scores, but the relative behavior across all models remains the same.

To diagnose the convergence of the Gibbs sampler, we monitored the behaviour of the Frobenius norms of the model parameters and hyperparameters: U, V, Λ, and μ. Typically, after a few hundred samples these quantities stabilize. Fig. 2 (right panel) shows the RMSE error on the Netflix validation set for Bayesian PMF models as the number of samples increases. After obtaining a few hundred samples[1] the predictive accuracy does not significantly improve. Note that the initial predictive accuracy is already high because the Markov chain is initialized using the MAP values of the model parameters.

For the Bayesian PMF model with $D = 30$ we also collected samples over the user and movie feature vectors generated by each full step of the Gibbs sampler. The first 800 samples were discarded as "burn-in". Figure 3 shows these samples for two users and two movies projected onto the two dimensions of the highest variance. Users A and C were chosen by randomly picking among rare users who have fewer than 10 ratings and more frequent users who have more than 100 ratings in the training set. Movies X and Y were chosen in the same way. Note that the empirical distribution of the samples from the posterior appear to be non-Gaussian.

Using these samples from the posterior we also looked at the uncertainty of the predictions of four users on randomly chosen test movies. Figure 4 (left panel) shows results for users A,B,C, and D who have 4, 23, 319 and 660 ratings respectively. Note that there is much more uncertainty about the prediction of user A than about the prediction of user D, whose feature vector is well-determined. Figure 4 (right panel) shows that the Bayesian PMF model considerably outperforms the logistic PMF model on users with few ratings. As the number of ratings increases, both the logistic PMF and the Bayesian PMF exhibit similar performance.

The advantage of Bayesian PMF models is that by averaging over all settings of parameters that are compatible with the data as well as the prior they deal with uncertainty more effectively than the non-Bayesian PMF models, which commit to a single most probable setting.

Since the main concern when applying Bayesian methods to large datasets is their running time, we provide the times for our simple Matlab Bayesian PMF implementation. One full Gibbs step on a single core of a recent Pentium Xeon 3.00GHz machine for models with $D = 10, 30, 60, 300$ takes 6.6, 12.9 , 31.6, and 220 minutes respectively. Note that the most expensive aspect of training Bayesian PMF models is the inversion of a $D \times D$ matrix per feature vector[2] (see Eq. 13),

[1] We store the model parameters after each full Gibbs step as a sample. The fact that these samples are not independent does not matter for making predictions.

[2] In our implementation, we solve a system of D equa-

which is an $O(D^3)$ operation.

5. Conclusions

We have presented a fully Bayesian treatment of Probabilistic Matrix Factorization by placing hyperpriors over the hyperparameters and using MCMC methods to perform approximate inference. We have also demonstrated that Bayesian PMF models can be successfully applied to a large dataset containing over 100 million movie ratings, and achieve significantly higher predictive accuracy compared to the MAP-trained PMF models with carefully tuned regularization parameters. An additional advantage of using a Bayesian model is that it provides a predictive distribution instead of just a single number, allowing the confidence in the prediction to be quantified and taken into account when making recommendations using the model.

Using MCMC instead of variational methods for approximate inference in Bayesian matrix factorization models leads to much larger improvements over the MAP trained models, which suggests that the assumptions made by the variational methods about the structure of the posterior are not entirely reasonable. This conclusion is confirmed by inspecting the empirical distribution of the samples from the posterior, which appears to be significantly non-Gaussian.

A major problem of MCMC methods is that it is hard to determine when the Markov chain has converged to the desired distribution. In practice, we have to rely on rules of thumb to diagnose convergence, which means that there is a risk of using samples from a distribution that differs from the true posterior distribution, potentially leading to suboptimal predictions. Our results show that this problem is not a sufficient reason to reject MCMC methods.

For our models, the number of samples from the posterior that can be generated within a reasonable amount of time will typically be constrained by the available computer resources. However, as mentioned above, sampling the feature vectors for multiple users or movies in parallel provides an easy way to greatly speed up the process of generating samples using multiple cores.

Accurate Max-Margin Training for Structured Output Spaces

Sunita Sarawagi SUNITA@IITB.AC.IN
Rahul Gupta GRAHUL@CSE.IITB.AC.IN
IIT Bombay, India

Abstract

Tsochantaridis et al. (2005) proposed two formulations for maximum margin training of structured spaces: margin scaling and slack scaling. While margin scaling has been extensively used since it requires the same kind of MAP inference as normal structured prediction, slack scaling is believed to be more accurate and better-behaved. We present an efficient variational approximation to the slack scaling method that solves its inference bottleneck while retaining its accuracy advantage over margin scaling.

We further argue that existing scaling approaches do not separate the true labeling comprehensively while generating violating constraints. We propose a new max-margin trainer PosLearn that generates violators to ensure separation at each position of a decomposable loss function. Empirical results on real datasets illustrate that PosLearn can reduce test error by up to 25% over margin scaling and 10% over slack scaling. Further, PosLearn violators can be generated more efficiently than slack violators; for many structured tasks the time required is just twice that of MAP inference.

1. Introduction

The max-margin framework for training structured prediction models generalizes the benefits of support vector machines (SVMs) to predicting complex objects. A popular member of this framework is the margin scaling method (Tsochantaridis et al., 2005; Taskar, 2004; LeCun et al., 2006; Crammer & Singer, 2003) that tries to ensure that the score of the correct prediction is separated from the score of an incorrect prediction by a margin equal to the error of the prediction. This method has been used extensively in many applications, including sequence labeling (Taskar, 2004; Tsochantaridis et al., 2005), image segmentation (Taskar, 2004; Ratliff et al., 2007), grammar parsing (Taskar et al., 2004), dependency parsing (McDonald et al., 2005b), bipartite matching (Taskar, 2004) and text segmentation (McDonald et al., 2005a). A reason for its wide-spread use is that it can exploit the decomposability of the error function to find the most violating constraint using the maximum a-posteriori (MAP) inference algorithm used for prediction.

An alternative formulation (Tsochantaridis et al., 2005) is to ensure that all labelings are separated by a fixed margin of one but penalize violations in proportion to their errors. This method, called slack scaling, generally provides higher accuracy than margin scaling which gives too much importance to labelings with large errors even after they are well-separated, sometimes at the expense of instances that are not even separated. Another shortcoming of margin scaling is that it requires an error function that is linearly comparable with the feature values, whereas slack scaling is invariant to scaling of the error function. In spite of the advantages, slack scaling is not popular because it requires inferring the labeling which maximizes a non-decomposable metric – difference of score and error inverse.

In this paper we make two contributions in max-margin training of structured models.

First, we address the computational challenge of infering the labelings required when training via slack scaling. We propose a variational approximation of the slack loss so that the most violating labeling is found using the same loss augmented MAP inference as in margin scaling. We demonstrate that accuracy-wise our slack approximation is much better than margin scaling and close to the more expensive slack scaling.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Second, we propose a new max-margin framework for training models with decomposable error functions that, like the slack scaling method, is scale invariant and discounts labelings well-separated from the margin. The inference step it requires is much simpler than required by slack scaling. In particular, for Markov models we show that the inference of the most violating labelings is only a factor of two more expensive than in margin scaling. The basic idea of the new learner, that we call PosLearn, is to associate a different slack variable for each error position of a decomposable error function. We show that this leads to a better characterization of the loss than both the slack and margin scaling methods that define loss in terms of a *single* most violating labeling. Empirically, PosLearn reduces error by up to 25% over margin scaling and 10% over slack scaling in various tasks.

2. Existing Methods for Max-Margin Training

We consider structured prediction problems that associate a score $\mathrm{s}(\mathbf{x}, \mathbf{y})$ for each output $\mathbf{y} \in \mathcal{Y}$ of an input $\mathbf{x}$, and predict the output $\mathbf{y}^*$ with maximum score. The scoring function $\mathrm{s}(\mathbf{x}, \mathbf{y})$ is a dot product of a feature vector $\mathbf{f}(\mathbf{x}, \mathbf{y})$ defined jointly over the input $\mathbf{x}$ and output $\mathbf{y}$, and the corresponding parameter vector $\mathbf{w}$. The space of possible outputs $\mathcal{Y}$ can be exponentially large. Thus, efficient solutions for $\mathbf{y}^* = \mathrm{argmax}_{\mathbf{y} \in \mathcal{Y}} \mathbf{w}^T \mathbf{f}(\mathbf{x}, \mathbf{y})$ crucially depend on the decomposability of the feature vector $\mathbf{f}$ over components of $\mathbf{y}$. During training the goal is to find a $\mathbf{w}$ using a set of labeled input-output pairs $(\mathbf{x}_i, \mathbf{y}_i) : i = 1 \ldots N$ so as to minimize prediction error. The error of predicting $\mathbf{y}$ for an instance $\mathbf{x}_i$ whose correct label is $\mathbf{y}_i$ is user-provided. We denote it by $L_i(\mathbf{y})$. In max-margin methods, the training goal is translated to finding a $\mathbf{w}$ that minimizes the sum of the loss on the labeled data while imposing a regularization penalty for overfitting. The loss is a computationally convenient combination of the user-provided error function and feature-derived scores so as to both minimize training error and maximize the margin between correct and incorrect outputs. There are two popular loss functions for structured learning tasks: margin scaler and slack scaler. We review them briefly.

2.1. Margin Scaling

In margin scaling, the goal is to find $\mathbf{w}$ such that the difference in score $\mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y}) = \mathbf{w}^T \mathbf{f}(\mathbf{x}_i, \mathbf{y}_i) - \mathbf{w}^T \mathbf{f}(\mathbf{x}_i, \mathbf{y})$ of the correct output $\mathbf{y}_i$ from an incorrect labeling $\mathbf{y}$ is at least $L_i(\mathbf{y})$. This is formulated as:

$$\begin{aligned} &\min_{\mathbf{w},\xi} \frac{1}{2}||\mathbf{w}||^2 + C\sum_{i=1}^{N} \xi_i \\ &\text{s.t. } \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y}) \geq L_i(\mathbf{y}) - \xi_i \quad \forall \mathbf{y} \neq \mathbf{y}_i, i : 1 \ldots N \\ &\xi_i \geq 0 \quad i : 1 \ldots N \end{aligned}$$

Two category of methods have been proposed to optimize the above QP. The first category is based on the cutting plane algorithm to avoid generating the exponentially many constraints. This involves incrementally finding the output $\mathbf{y}^M = \mathrm{argmax}_{\mathbf{y}}(\mathbf{w}^T \mathbf{f}(\mathbf{x}_i, \mathbf{y}) + L_i(\mathbf{y}))$ which most violates the constraint. $\mathbf{y}^M$ can be found using the same inference algorithm as MAP $\mathbf{y}^* = \mathrm{argmax}_{\mathbf{y}} \mathbf{w}^T \mathbf{f}(\mathbf{x}_i, \mathbf{y})$ when $L_i(\mathbf{y})$ decomposes over variable subsets no larger than the subsets in the decomposition of $\mathbf{f}(\mathbf{x}_i, \mathbf{y})$. This category includes exact gradient ascent methods (Tsochantaridis et al., 2005), stochastic gradient methods (Bordes et al., 2007) and online sub-gradient methods (Ratliff et al., 2007). The online structured learning methods of (Crammer & Singer, 2003) follow a perceptron based framework but their constraints are identical to the margin scaling method described here. The second category of methods (Taskar, 2004; Taskar et al., 2006) exploit the decomposability of the error function to create a combined program for the inference and parameter learning task.

2.2. Slack Scaling

Slack scaling demands a margin of one but scales the slacks of violating outputs in proportion to their errors. The corresponding optimization problem is:

$$\begin{aligned} &\min_{\mathbf{w},\xi} \frac{1}{2}||\mathbf{w}||^2 + C\sum_{i=1}^{N} \xi_i \\ &\text{s.t. } \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y}) \geq 1 - \frac{\xi_i}{L_i(\mathbf{y})} \quad \forall \mathbf{y} \neq \mathbf{y}_i, i : 1 \ldots N \\ &\xi_i \geq 0 \quad i : 1 \ldots N \end{aligned}$$

The optimization of the above QP via the cutting plane algorithm requires the inference of the labeling $\mathbf{y}^S = \mathrm{argmax}_{\mathbf{y}}(1 - \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y}) - \frac{\xi_i}{L_i(\mathbf{y})})$. Unlike for margin scaling, even with decomposable loss and scoring functions, it is not easy to find $\mathbf{y}^S$ efficiently. For this reason, the slack scaling approach is not popular.

However, the slack loss is in many ways better behaved than margin loss (Tsochantaridis et al., 2005). Margin scaling gives too much importance to instances which are already well-separated from the margin. This hurts because the loss ξ_i is determined by a single most violating labeling. If a labeling imposes a difficult margin

requirement because of its large error, the optimizer will appropriately increase ξ_i. After that, there is no incentive to improving separability of any other labeling of that instance. In contrast, the slack scaling loss will ignore instances that are separated by a margin of 1, and ξ_i is determined by labelings that matter because of their being close to the margin. Empirically, we found slack scaling to give better accuracy than margin scaling (Section 5). Slack scaling also makes it convenient for an end-user to define an error function and a feature vector and tune C because the error function can be arbitrarily scaled vis-a-vis the feature vector.

3. Approximate Slack Scaling

We present a variational approximation to the slack inference problem that is applicable for any structured model for which we can only solve for the MAP efficiently. The slack inference problem is to find

$$\begin{aligned}\mathbf{y}^S &= \text{argmax}_{\mathbf{y}\in\overline{\mathcal{Y}}}\left(1-\mathbf{w}^T\delta\mathbf{f}_i(\mathbf{y})-\frac{\xi_i}{L_i(\mathbf{y})}\right)\\ &= \text{argmax}_{\mathbf{y}\in\overline{\mathcal{Y}}}\left(\text{s}_i(\mathbf{y})-\frac{\xi_i}{L_i(\mathbf{y})}\right) \quad (1)\end{aligned}$$

where $\text{s}_i(\mathbf{y}) = \mathbf{w}^T\mathbf{f}(\mathbf{x}_i,\mathbf{y})$, $\overline{\mathcal{Y}} = \{\mathbf{y} : \mathbf{y}\neq\mathbf{y}_i,\ \text{s}_i(\mathbf{y}) - \frac{\xi_i}{L_i(\mathbf{y})} > \text{s}_i(\mathbf{y}_i)-1\}$ is the set of all violating labelings.

We approximate $\mathbf{y}^S$ with another labeling $\mathbf{y}^A$. Our approximation is based on the observation that $\text{s}_i(\mathbf{y}) - \frac{\xi_i}{L_i(\mathbf{y})}$ is concave in $L_i(\mathbf{y})$ and its variational approximation can be written as a linear function of $L_i(\mathbf{y})$ (Jordan et al., 1999). Here on, we drop the subscript i wherever possible.

Claim 3.1. $s(\mathbf{y})-\frac{\xi}{L(\mathbf{y})} = \min_{\lambda\geq 0} s(\mathbf{y})+\lambda L(\mathbf{y})-2\sqrt{\xi\lambda}$

Proof. Any concave function $f(z)$ can be expressed as $\min_{\lambda\geq 0}(z\lambda - f^*(\lambda))$ where $f^*(\lambda) = \min_z(z\lambda - f(z))$ is the conjugate function of $f(z)$. The result follows from the fact that the conjugate function of $\frac{-\xi}{z}$ is $2\sqrt{\xi\lambda}$. □

Let $F'(\mathbf{y};\lambda) \triangleq \text{s}(\mathbf{y}) + \lambda L(\mathbf{y}) - 2\sqrt{\xi\lambda}$ and $F(\lambda) \triangleq \max_{\mathbf{y}\neq\mathbf{y}_i} F'(\mathbf{y};\lambda)$

We now approximate the exact slack MAP objective with an upper bound as follows:

$$\begin{aligned}\max_{\mathbf{y}\in\overline{\mathcal{Y}}}\left(\text{s}(\mathbf{y})-\frac{\xi}{L(\mathbf{y})}\right) &= \max_{\mathbf{y}\in\overline{\mathcal{Y}}}\min_{\lambda\geq 0} F'(\mathbf{y};\lambda) \quad (2)\\ &\leq \min_{\lambda\geq 0}\max_{\mathbf{y}\in\overline{\mathcal{Y}}} F'(\mathbf{y};\lambda) \quad (3)\\ &\leq \min_{\lambda\geq 0} F(\lambda) \quad (4)\end{aligned}$$

For a fixed λ, we can compute $F(\lambda)$ using the loss augmented MAP algorithm employed in margin scaling to first find $\mathbf{y}_\lambda = \text{argmax}_{\mathbf{y}\neq\mathbf{y}_i} s(\mathbf{y}) + \lambda L(\mathbf{y})$ and then setting $F(\lambda) = F'(\mathbf{y}_\lambda;\lambda)$. The constraint $\mathbf{y}\neq\mathbf{y}_i$ can be met by asking the loss augmented MAP algorithm to return top two MAPs. The algorithmic extension to return top two MAPs is straight forward in many structured tasks.

We search for the λ for which the upper bound $F(\lambda)$ is minimized by exploiting the fact that $F(\lambda)$ is convex in λ.

Claim 3.2. *$F(\lambda)$ is convex in λ.*

Proof. It can be seen that $F'(\mathbf{y};\lambda)$ is convex in λ. Since $F(\lambda)$ is a max of finitely many convex functions, and max is also convex, $F(\lambda)$ is convex. □

We can compute $\min_{\lambda\geq 0} F(\lambda)$ using efficient line search algorithms such as Golden Search. During the search phase, for each λ that we encounter, we evaluate $F(\lambda)$ and thus get one labeling. Of all these labelings, we return the one with the highest $\text{s}(\mathbf{y}) - \frac{\xi}{L(\mathbf{y})}$ as $\mathbf{y}^A$. We show in the next section the range $[\lambda_l, \lambda_u]$ within which it is sufficient to perform the line search.

3.1. Upper and Lower Bounds for λ

Since $\lambda \geq 0$, we can use $\lambda_l = 0$ as the lower limit. However, with $\lambda = 0$, $F'(\mathbf{y};\lambda)$ is not able to distinguish between high and loss labelings with same scores commonly seen in early training iterations. It can be shown that with $\lambda_l = \frac{\epsilon}{L_{max}}$ where L_{max} is the maximum possible loss, $F(\lambda)$ for any $\lambda < \lambda_l$ will not return any violating labeling with slack score more than ϵ of the score of a labeling returned with $\lambda \geq \lambda_l$. By setting ϵ to the tolerance of the cutting-plane algorithm, we get a provably correct lower bound.

For the upper bound, it is sufficient to pick a λ_u such that for any $\lambda \geq \lambda_u$, either $F(\lambda)$ gets the same violator as $F(\lambda_u)$ or a non-violator that we are not interested in. It is sufficient to pick a λ_u such that $\text{argmax}_{\mathbf{y}\in\overline{\mathcal{Y}}} F'(\mathbf{y};\lambda_u)$ ($= \mathbf{y}'$ say) has the maximum loss among all violators in $\overline{\mathcal{Y}}$. Hence we need:

$$\text{s}(\mathbf{y}') + \lambda_u L(\mathbf{y}') \geq \max_{\mathbf{y}\in\overline{\mathcal{Y}},\ L(\mathbf{y})<L(\mathbf{y}')} \text{s}(\mathbf{y}) + \lambda_u L(\mathbf{y})$$

Let $\mathbf{y}_1 \triangleq \text{argmax}_{\mathbf{y}} s(\mathbf{y})$ and L_ε be the minimum difference between two distinct loss values (e.g. $L_\varepsilon = 1$ for Hamming loss). Then the right side can be atmost $\text{s}(\mathbf{y}_1) + \lambda_u(L(\mathbf{y}') - L_\varepsilon)$. So we require $\lambda_u \geq \frac{\text{s}(\mathbf{y}_1)-\text{s}(\mathbf{y}')}{L_\varepsilon}$.

Now, $\mathbf{y}' \in \overline{\mathcal{Y}} \Rightarrow \text{s}(\mathbf{y}') \geq \text{s}(\mathbf{y}_i) - 1 + \frac{\xi}{L(\mathbf{y}')} \geq$

$\mathrm{s}(\mathbf{y}_i) - 1 + \frac{\xi}{L_{max}}$, so we can conservatively set $\lambda_u = \frac{1}{L_\varepsilon}\left(\mathrm{s}(\mathbf{y}_1) - \mathrm{s}(\mathbf{y}_i) + 1 - \frac{\xi}{L_{max}}\right)$.

3.2. Limitation of Approximate Slack

In the worst case, it is possible that the exact slack MAP $\mathbf{y}^S$ violates the inequality but $\mathbf{y}^A$ does not, as we show next.

Claim 3.3. $s(\mathbf{y}^A) - \frac{\xi}{L(\mathbf{y}^A)} < s(\mathbf{y}_i) - 1 + \epsilon \not\Rightarrow s(\mathbf{y}^S) - \frac{\xi}{L(\mathbf{y}^S)} < s(\mathbf{y}_i) - 1 + \epsilon$

Proof. We prove the claim with a counter example. Let $\mathbf{y}_j, j = 1, 2, 3$ be three labelings with scores $s_j = -\frac{1}{2}, -\frac{13}{18}, -\frac{5}{6}$ and losses $L_j = 1, 2, 3$. Note that $s_1 > s_2 > s_3$ and $L_1 < L_2 < L_3$. Let the score of the true labeling be $s = 0$, the slack be $\xi = \frac{19}{36}$, and let $\epsilon \approx 0$. By computing $\mathrm{sgn}(s_j - \frac{\xi}{L_j} - s + 1 - \epsilon)$, we can see that labelings $\mathbf{y}_1$ and $\mathbf{y}_3$ are not violators but $\mathbf{y}_2$ is. In order to return $\mathbf{y}_2$ as the worst violator, there must exist λ such that $s_2 + \lambda L_2 \geq s_j + \lambda L_j,\ j = 1, 3$. This translates to the constraints $\lambda > \frac{2}{9}$ and $\lambda < \frac{1}{9}$, which are infeasible. □

The above counter example showed that it is impossible to approximate the slack scaled constraint by any method that depends on finding MAP with varying weights on error. This limitation though seemingly restrictive, only slightly hampers the performance in practice, as evident in our experimental results.

4. Position Learner

We next propose a new formulation for max-margin training that directly exposes the decomposability of the error function so as to require solving a considerably simpler inference problem. We show that this new formulation not only addresses the computational problem of slack scaling inference, but also provides a more accurate characterization of the loss of scoring functions.

The basic premise of the new learner, which we call PosLearn, is that when error is additive over a set of positions, the loss should also additively reflect margin violations at each possible error position. This is in contrast to both the margin and slack scaling where loss is in terms of a single most violating labeling.

Let $L_i(\mathbf{y}) = \sum_{c \in C} L_{i,c}(\mathbf{y}_c)$ denote a decomposition of the error function. Our goal during training is to ensure that at each possible error position c, the correct labeling has a margin over all labelings where c is incorrectly labeled. If not, we add a hinge loss on the difference in score between the correct labeling $\mathbf{y}_i$ and the best labeling $\mathrm{argmax}_{\mathbf{y}:\mathbf{y}_c \neq \mathbf{y}_{i,c}} \mathbf{w}^T \mathbf{f}(\mathbf{x}_i, \mathbf{y})$ incorrect at c. This yields the following constrained optimization

$$\begin{aligned} \min_{\mathbf{w},\xi} \quad & \frac{1}{2}||\mathbf{w}||^2 + C \sum_{i=1}^{N} \sum_{c} \xi_{i,c} \\ \text{s.t} \quad & \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y}) \geq 1 - \frac{\xi_{i,c}}{L_{i,c}(\mathbf{y}_c)} \quad \forall \mathbf{y} : \mathbf{y}_c \neq \mathbf{y}_{i,c} \\ & \xi_{i,c} \geq 0 \quad i : 1 \ldots N, \forall c \end{aligned}$$

In the above program, the number of slack variables is equal to the total number of error positions over all instances. Otherwise, the form of the QP is the same as in Section 2.2 and therefore can be solved via similar cutting plane algorithms. For a given position c of an instance i, the most violating constraint is the labeling

$$\mathbf{y}^{P:c} \triangleq \mathrm{argmax}_{\mathbf{y}:\mathbf{y}_c \neq \mathbf{y}_{i,c}} \left(\mathrm{s}_i(\mathbf{y}) - \frac{\xi_{i,c}}{L_{i,c}(\mathbf{y}_c)}\right) \qquad (5)$$

This inference problem can be solved efficiently by any structured learning task in which MAP can be found efficiently since

$$\max_{\mathbf{y}:\mathbf{y}_c \neq \mathbf{y}_{i,c}} \mathrm{s}_i(\mathbf{y}) - \frac{\xi_{i,c}}{L_{i,c}(\mathbf{y}_c)} = \max_{\mathbf{y}_c \neq \mathbf{y}_{i,c}} \left(\max_{\mathbf{y} \sim \mathbf{y}_c} \mathrm{s}_i(\mathbf{y}) - \frac{\xi_{i,c}}{L_{i,c}(\mathbf{y}_c)}\right)$$

where the outer max is over a small number of values as the size of c is typically small and the inner max is MAP inference with label of c constrained to $\mathbf{y}_c$. The MAPs $\mathbf{y}^{P:c}$ will typically be evaluated simultaneously for each c. In many structured learning tasks, all these MAPs can be found in just twice the amount of time it takes to compute a single unrestricted MAP, as we show in Section 4.3.1.

In addition to these computational advantages, PosLearn also provides better loss characterization than slack scaling.

4.1. Comparison with Slack Scaling

First, we claim that the PosLearn loss is an upper bound of the slack loss.

Claim 4.1. *The slack loss* $\sum_i \max_{\mathbf{y}} L_i(\mathbf{y})[1 - \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y})]_+$ *is upper bounded by the PosLearn loss* $\sum_i \sum_c \max_{\mathbf{y}:\mathbf{y}_c \neq \mathbf{y}_{i,c}} L_{i,c}(\mathbf{y}_c)[1 - \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y})]_+$

Proof. Let $\mathbf{y}^S = \mathrm{argmax}_{\mathbf{y} \neq \mathbf{y}_i} L_i(\mathbf{y})[1 - \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y})]_+$.

$$\begin{aligned} & L_i(\mathbf{y}^S)[1 - \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y}^S)]_+ \\ & \quad = \sum_c L_{i,c}(\mathbf{y}^S_c)[1 - \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y}^S)]_+ \\ & \quad \leq \sum_c \max_{\mathbf{y}:\mathbf{y}_c \neq \mathbf{y}_{i,c}} L_{i,c}(\mathbf{y}_c)[1 - \mathbf{w}^T \delta\mathbf{f}_i(\mathbf{y})]_+ \end{aligned}$$

□

Next, we show that slack scaling by defining the total loss in terms of a *single* most violating labeling, cannot discriminate amongst scoring functions as well as the PosLearn loss that involves different labelings at different error positions.

Consider one example where $\mathbf{w}$ is such that three labelings $\mathbf{y}_0 = [0\ 0\ 0\ 0], \mathbf{y}_1 = [1\ 1\ 0\ 0], \mathbf{y}_2 = [0\ 0\ 1\ 0]$, all have the same score of 1. Let $\mathbf{y}_0$ be the correct labeling, then $L(\mathbf{y}_1) = 2, L(\mathbf{y}_2) = 1$, assuming Hamming error. Let the score of all remaining labelings be 0. The total slack loss in this case is 2 whereas the PosLearn loss is 3. Now consider the case where $\mathbf{y}_2$ has score 0. The slack loss remains unchanged whereas PosLearn loss reduces to 2.

An important consequence of the reduced error coverage is that, when the cutting plane algorithm terminates in slack scaling, PosLearn could continue to find violating constraints. The reverse is not true.

4.2. Comparison with M^3N Training

The PosLearn program appears similar to the M^3N program of (Taskar, 2004) because both decompose the slack variable over multiple positions. However, the similarity is only superficial. The training objective of M^3N is Margin scaling and the position specific slack variables are for integrating training with inference for loss augmented MAP. In PosLearn the position specific slacks lead to a very different training objective.

4.3. Common Decomposable Error Functions

We show examples of decomposable error functions in several structured learning tasks and show how to efficiently find the most violating constraints over all error positions simultaneously.

4.3.1. Markov Models

Many structured prediction tasks can be modeled as Markov models. Popular examples are sequence labeling for information extraction (Lafferty et al., 2001), and grid models for image segmentation (Taskar, 2004; Boykov et al., 2001). A natural error function here is Hamming loss that decomposes over the nodes of the Markov network. Typical MAP inference algorithms based on belief propagation also give max-marginals at each node. The max-marginals gives us at each (node c, label y) pair, the best labeling $\mathbf{y}^{c:y}$ with node c labeled y. We can now find the most violating labeling at each position c via

$$\max_{y \neq \mathbf{y}_{i,c}} (1 - \mathbf{w}^T \delta \mathbf{f}_i(\mathbf{y}^{c:y})) L_{i,c}(y)$$

where $L_{i,c}(y) = 1$ when $y \neq \mathbf{y}_{i,c}$ for Hamming loss. In general $L_{i,c}(y)$ can be any arbitrary real-value, for example a mis-classification matrix $M(y', y)$ could give the cost of misclassifying a y' node as y.

4.3.2. Segmentation

The output space $\mathcal{Y}$ consists of all possible labeled segmentations of an input sequence $\mathbf{x}$. A segmentation $\mathbf{y}$ consists of a sequence of segments $s_1 \ldots s_p$ where each $s_j = (t_j, u_j, y_j)$ with t_j = segment start position, u_j = segment end position, and y_j= segment label. Segmentation models have been proposed as alternative models for information extraction that allows for more effective use of entity-level features (McDonald et al., 2005a; Sarawagi & Cohen, 2004).

The feature vector decomposes over segments and is a function of the segment and the label of the previous segment. Thus $\mathbf{f}(\mathbf{x}, \mathbf{y}) = \sum_{j=1}^{p} \mathbf{f}(\mathbf{x}, s_j, y_{j-1})$. The error function also decomposes over segments as $L_i(\mathbf{y}) = \sum_{s \in \mathbf{y}} L_i(s)$ where for a segment $s = (t, u, y)$, $L_i((t, u, y))$ is defined as

$$L_i((t,u,y)) = \begin{cases} p_y + \sum_{(l',u',y') \in \mathbf{y}_i, \ t \leq u' \leq u} r_{y'} & (t,u) \notin \mathbf{y}_i \\ M(y', y) & (t,u,y') \in \mathbf{y}_i \end{cases}$$

where p_y is the precision penalty of labeling a segment as y and $r_{y'}$ is the recall penalty of missing a true segment of label y' and $M(y', y)$ is the misclassification cost matrix applicable when the same span appears in both segmentations.

The number of slack variables is the number of possible segment spans (t, u), which is $O(nm)$ for a sequence of length n and maximum segment size m.

The MAP segmentation can be found using an extension of the Viterbi algorithm (Sarawagi & Cohen, 2004). Viterbi also gives the highest scoring segmentation of the sequence from 1 to i with the last segment ending at i with label y for all possible i and y. Call this $\gamma(i, y)$. Similarly, we can use a backward Viterbi pass to get $\beta(i, y)$ the highest scoring segmentation from $i + 1$ to n with label y on the segment ending at i. These can be combined to find the most violating constraint for a slack variable corresponding to segment (t, u) as:

$$\max_{y', y:(t,u,y) \notin \mathbf{y}_i} L_i((t,u,y))[1 - \mathrm{s}(\mathbf{y}_i) + \gamma(t-1, y') + \mathbf{w}^T \mathbf{f}(\mathbf{x}, (t,u,y), y') + \beta(u, y)]_+$$

4.3.3. Unlabeled Dependency Parsing

In unlabeled dependency parsing, the goal is to assign each token to its 'head' token (or to a dummy token),

such that the head links form a directed spanning tree. The feature vector for a tree $\mathbf{y}$ over a sentence $\mathbf{x}$ is decomposable over the edges (McDonald et al., 2005b): $\mathbf{f}(\mathbf{x}, \mathbf{y}) = \sum_t \mathbf{f}(y_t, \mathbf{x}, t)$ where t is a token and y_t is its head. A natural error function for a dependency parse tree is then the number of words that are assigned an incorrect head word. In this case, the error and features decompose in exactly the same way, over individual words. The only coupling amongst the predictions of different words is that they need to form a tree.

We use the combinatorial non-projective parsing algorithm of (McDonald et al., 2005b), which cannot be easily extended to simultaneously return MAP for each position. For PosLearn we return the worst violator for each position by first finding the unrestricted MAP $\mathbf{y}^*$. Then, for each position where $\mathbf{y}^*$ is correct, we re-invoke MAP with the correct assignment disabled. In the worse case, this will lead to n MAP invocations.

5. Experiments

We present experimental results on three tasks — sequence labeling, text segmentation and dependency parsing, performed on the following datasets and settings:

CoNLL'03: We use the English benchmark from the CoNLL'03 shared task on named entity recognition. The corpus consists of train, development and test sets of $\approx$ 14000, 3200 and 3400 sentences respectively. We used exactly the same features as in the trained model from Stanford's Named Entity Recognizer [1].

Cora: This is a database of $\approx$ 500 citations (McCallum et al., 2000), containing entities such as Author, Journal, Title, Year and Volume. We used standard extraction features defined over the neighborhoods of each token and the label of the previous token (Peng & McCallum, 2004). For the segmentation task on this dataset, we also used the segment length feature.

Address: This is a collection of $\approx$ 400 non-US postal addresses. Unlike US addresses, these addresses are highly irregular and relatively difficult to segment. The features for sequence labeling and segmentation tasks are as defined in (Sarawagi & Cohen, 2004).

CoNLL-X: We use the freely available treebanks for Swedish, Dutch and Danish from the CoNLL X Shared Task for unlabeled dependency parsing. The training sets contain $\approx$ 11000, 13350, and 5200 sentences respectively. We use the first-order features, the online MIRA trainer (Crammer & Singer, 2003), and the non-projective parsing algorithm provided in the MSTParser package[2].

5.1. Results

Table 1 shows test errors (as defined in Section 4.3) and Span F1 (where ever applicable) of all four training approaches on all the tasks. For Cora and Address results are averaged over ten splits of 25% train — 75% test, the rest are with the standard training and test files as available in the benchmark. For sequence and segmentation tasks, we are able to solve the Slack inference problem exactly using a quadratic algorithm that finds the MAP for each possible error value. For dependency parsing, it was not easy to find MAP with a pre-specified error. Hence, numbers for Slack scaling methods are missing for this task.

Sequence labeling

We note that the errors go down in the order Margin > Slack > ApproxSlack > PosLearn, and PosLearn achieves $\approx$ 20% error reduction over Margin and 5-10% over Slack. The difference between PosLearn and Margin is statistically significant (p-value from paired t-test is < 0.001), while that between ApproxSlack and Slack is not. This confirms that the approximations done in ApproxSlack are empirically good.

We also reports the entity span F1 values in Table 1 (numbers after the "/"). PosLearn provides signifi-

[2] http://sourceforge.net/mstparser

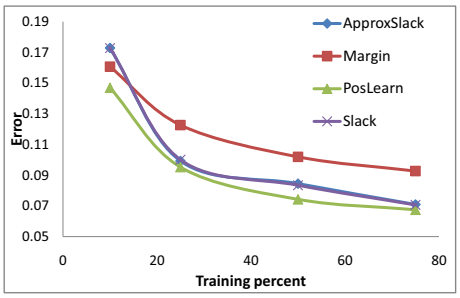

Figure 1. Sequence labeling error (in %) of all approaches on Cora as training size is increased.

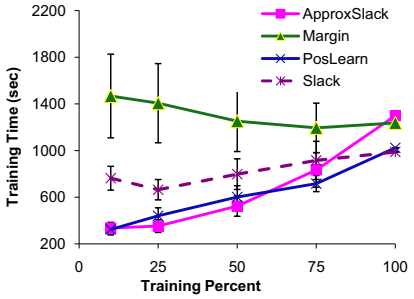

Figure 2. Comparison of training times on Cora over various training percentages. The error bars denote one standard deviation over ten random splits.

cant improvements over Margin for Cora and Address, going from 75 to 83 and 71 to 78 respectively. This shows that optimizing for the error directly translates to significantly better span F1 scores. For CoNLL'03 the gains are modest both for error and Span F1 for reasons we will highlight in Section 5.2. Figure 1 investigates the effect of increasing training size on the sequence labeling errors of all the approaches on Cora. PosLearn remains the best approach for all training sizes, with a 25% error reduction over Margin even for 75% training data. ApproxSlack and Slack are almost identical for all training sizes.

Figure 2 compares the training time of the four approaches on Cora over various training sizes. PosLearn and ApproxSlack turn out to be the cheapest of all the approaches. Two key observations here are (a) PosLearn is up to five times faster than Margin in spite of generating many more constraints, and (b) The training time of Margin reduces with an increase in data. These can be attributed to two reasons. First, PosLearn quickly generates a lot of relevant constraints and terminates in much fewer iterations, whereas Margin spends too much time in separating high loss labelings which are already far enough. Second, when data is scarce, Margin is not able to find good support vectors early on and takes many more iterations. This provides another empirical support for the recent observations in (Bottou & Bousquet, 2008) on the inverse dependence of training time on data sizes.

Segmentation

The results for segmentation are similar to sequence labeling. Again, PosLearn provides 7-10% decrease in error over Margin and Slack. ApproxSlack again turns out to be a close approximation to Slack.

Unlabeled dependency parsing

The difference between PosLearn and Margin turns out to be very insignificant in this case. We cannot evaluate Slack as its MAP inference algorithm is not feasible in this setting. Our discussion in the next section shows that we do not expect ApproxSlack to score over Margin either.

Note our baseline numbers are competitive with the state of the art for these tasks. For Swedish and Danish, the errors for Margin scaling are significantly lower than the average errors of the CoNLL X Shared Task participants — 15.8% and 15.5% respectively . For Dutch, Margin scaling model is better than the best model in the Shared Task (error 16.4%).

5.2. Discussion

We observed that Margin scaling was significantly worse than other loss functions for tasks like sequence labeling on the Address and Cora datasets, while being the highest performing on tasks like dependency parsing. We explain the reasons behind the varying gains of Margin relative to other loss functions, in particular PosLearn, based on the decomposition of the error function compared to the feature function.

We argue that margin scaling is a bad loss function only when the model comprises of features that strongly couple larger subset of variables than the error function. Consider the case when the feature function decomposes over each position of $\mathbf{y}$, exactly as in the error function. This is true for dependency parsing, and for sequence labeling models with no edge features. In such cases, a structured formulation adds little value, and a multi-class SVM with independent constraints over the local features and loss at each position, is just as adequate. The constraints of structured margin scaling turn out to be a summation of the constraints of multi-class SVM and the two solve equivalent objectives as shown in (Joachims, 2006). Interestingly, (McDonald et al., 2005b) indeed finds that such a model (which they call the factored model) is very close to the structured model using margin scal-

ing. We verify that for sequence labeling, if we disable all edge features, then for the Address dataset, span F1 drops from 71 to 62 and for Cora from 75 to 44 with Margin scaling. This indicates the strong importance of structured features for these datasets. In contrast, for CoNLL'03 where Margin is competitive with PosLearn, removal of edge features causes only a small drop in Span F1, from 84.7 to 81. Without edge features, PosLearn shows little or negative improvement over Margin scaling for all three datasets.

This indicates that in domains where the feature function does not induce strong coupling amongst variables, there is no reward in going beyond simple margin scaling, and possibly even multiclass SVMs. In truly structured problems where features strongly couple multiple variables, margin scaling gets adversely affected by the unnecessary margin requirements of high error labelings due to shared slack variables. PosLearn ignores labelings separated from the margin, and by defining per-position slacks instead of a single shared slack, handles such structured cases better.

6. Conclusion

We presented an efficient variational approximation to the slack scaling approach, which only requires a slightly modified loss augmented MAP algorithm, instead of the inefficient slack scaling inference algorithm. We demonstrated that in practice it performs much better than margin scaling and closely approximates slack scaling.

Next, we argued that all existing approaches that define loss in terms of a single most violating labeling achieve inadequate separation from the correct labeling. We proposed a new trainer, PosLearn that involves multiple labelings in trying to ensure max-margin separation at each possible error position in the structured output. The PosLearn constraints can be generated using only the MAP algorithm, and for many structured models the time required is no more than twice the time taken to find MAP. Empirically, this leads to significant error reduction over Margin scaling on structured models that induce strong coupling amongst output variables.

A compelling future direction is theoretically analyzing the generalizability of PosLearn vis-a-vis other loss scaling methods.

Abstract

In this paper we investigate two aspects of ranking problems on large graphs. First, we augment the deterministic pruning algorithm in Sarkar and Moore (2007) with sampling techniques to compute approximately correct rankings with high probability under random walk based proximity measures *at query time*. Second, we prove some surprising locality properties of these proximity measures by examining the short term behavior of random walks. The proposed algorithm can answer queries *on the fly without caching any information about the entire graph*. We present empirical results on a 600,000 node author-word-citation graph from the Citeseer domain on a single CPU machine where the average query processing time is around 4 seconds. We present quantifiable link prediction tasks. On most of them our techniques outperform Personalized Pagerank, a well-known diffusion based proximity measure.

1. Introduction

Link prediction in social networks, personalized graph search techniques, fraud detection and collaborative filtering in recommender networks are important practical problems that greatly rely on graph theoretic measures of similarity. Given a node in a graph we would like to ask which other nodes are most similar to this node. Ideally we would like this similarity measure to capture the graph structure such as having many common neighbors or having several short paths between two nodes. This kind of structural information can be easily quantified using random walks on graphs: diffusion of information from one node to another. Most random-walk based ranking algorithms can be categorized into two broad categories.

Probability of reaching a node: This is the basis of measures like *personalized page rank*. Personalized page-rank vectors (PPV) have been used for keyword search in databases (Balmin et al., 2004) and entity-relation graphs (Chakrabarti, 2007). These approaches focus on computing approximate PPV at query time (details in section 6), and quantify the performance in terms of the deviation of the approximation from the exact. However, it is not clear if PPV itself has good predictive power.

Expected number of hops to reach a node: This is also called the hitting time (Aldous & Fill, 2001). The symmetric version of this is the *commute time* between two nodes. These metrics have been shown to be empirically effective for ranking in recommender networks (Brand, 2005) and link prediction problems (Liben-Nowell & Kleinberg, 2003). These measures usually require $O(n^3)$ computation. Recently Spielman and Srivastava (2008) have come up with a novel approximation algorithm for efficiently computing commute times by random projections. However it is only applicable to undirected graphs.

Sarkar and Moore (2007) introduced the notion of truncated commute times and demonstrated that it had good predictive power for link prediction tasks. However their algorithm (GRANCH) required storing potential nearest neighbors of all nodes in the graph in order to answer nearest neighbor queries. The key contribution in this paper are: 1) we combine sampling with deterministic pruning to design an algorithm which retrieves top k neighbors of a query in truncated commute time incrementally without caching information about all nodes in the graph. 2) We investigate locality properties of truncated hitting and commute times. 3) We show that on several link prediction tasks these measures outperform PPV in terms of predictive

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

power, while on others they do comparably. 4) Our algorithm can process queries at around 4 seconds on average on graphs of the order of 600,000 nodes on a single CPU machine.

The rest of the paper is organized as follows: in section 2 we provide relevant background. In section 3 we introduce our hybrid algorithm, and provide sample complexity results for random sampling. The locality properties of truncated hitting and commute times are investigated in section 4. We present empirical results in section 5, and conclude with related work in section 6.

2. Background

A graph $G = (V, E)$ is defined as a set of vertices V edges E. The ij^{th} entry of the adjacency matrix W denotes the weight on edge (i, j), and is zero if the edge does not exist. $P = p_{ij}, i, j \in V$ denotes the transition probability matrix of this Markov chain, so that $p_{ij} = w_{ij}/\sum_j W_{ij}$ if $(i, j) \in E$ and zero otherwise.

Hitting time h_{ij}: The hitting time from node i to node j is defined as the expected number of steps in a random walk starting from i before node j is visited for the first time. Recursively h_{ij} can be written as $h_{ij} = 1 + \sum_k p_{ik}h_{kj}$, if $i \neq j$ and zero otherwise.

Commute time c_{ij}: Commute time between a pair of nodes is defined as $c_{ij} = h_{ij} + h_{ji}$.

2.1. Truncated Hitting Time

The hitting and commute times are sensitive to long range paths (Liben-Nowell & Kleinberg, 2003) which result in non-local nature. They are also prone to be small if one of the nodes is of large degree (Brand, 2005). This renders them ineffective for personalization purposes. In order to overcome these shortcomings, Sarkar and Moore (2007) define a *T-truncated hitting time*, where only paths of length less than T are considered. We shall use h, h^T interchangeably to denote truncated hitting time. h^T_{ij} can be defined recursively as

$$h^T_{ij} = 1 + \sum_k p_{ik} h^{T-1}_{kj} \quad (1)$$

where h^T is defined to be zero if $i = j$ or if $T = 0$. The above equation expresses h^T in a one step look-ahead fashion. The expected time to reach a destination within T timesteps is equivalent to one step plus the average over the hitting times of it's neighbors to the destination in $T - 1$ hops. If there is no path of length smaller than T from i to j, this automatically sets $h^T(i, j)$ to T.

2.2. GRANCH (Sarkar & Moore, 2007)

The truncated hitting time from all nodes to a destination node can be computed in $O(ET)$ time using dynamic programming. However in order to compute the hitting time from a query node to a destination, one has to compute the hitting time of all nodes to the destination, thus computing the entire matrix which takes $O(NET)$ time (N and E are the number of nodes and edges respectively).

In order to get around the above problem the graph is decomposed into N overlapping neighborhoods for each node. Each neighborhood is computed in a way to include potential nearest neighbors and prune away the rest. The authors provide bounds on the hitting time from all nodes within the neighborhood of i to i. The hitting time from any node outside the boundary to the destination is quantified by only two numbers: a lower and an upper bound. As the neighborhoods are expanded more the bounds become tighter. This way each column of the truncated hitting time (H^T) matrix is filled up **partially**. After iterating over all nodes it is possible to look at one row and obtain ranking from the bounds on hitting time from a node.

GRANCH computes all pairs of nearest neighbors by caching information for all nodes in the graph. This does not work when the graph is changing continuously. We introduce a hybrid algorithm which essentially combines the above branch and bound trick with sampling techniques to obtain nearest neighbors of a query node in commute time with high probability.

3. Hybrid Algorithm

We present an algorithm to compute approximate nearest neighbors in commute times, without iterating over the entire graph. We combine random sampling with the branch and bound pruning scheme mentioned before, in order to obtain upper and lower bounds on *commute times* from a node. This lets us compute the k nearest neighbors from a query node *on the fly*.

For any query node we compute hitting time from it using sampling. We maintain a bounded neighborhood for the query node at a given time-step. We compute estimated bounds on the commute time from the nodes within the neighborhood to the query. Commute time of nodes outside the neighborhood to the query are characterized by a single upper and lower bound. We expand this neighborhood until this lower bound exceeds $2T'$, which guarantees that with high probability we are excluding nodes which are more than $2T'$ commute distance away. These bounds are then used for ranking the nodes inside the neighborhood.

We will first describe a simple sampling scheme to obtain ϵ-approximate truncated hitting times **from** a query node with high probability.

3.1. Sampling Scheme

We propose a sampling scheme to estimate the truncated hitting time from a given query node i in a graph. We run M independent T-length random walks from i. Lets say out of these M runs m random walks hit j for the first time at $\{t_{k_1}, ...t_{k_m}\}$ time-steps. From these we can estimate the following

1. The probability of hitting any node j *for the first time* from the given source node within T steps can be estimated by $\frac{m}{M}$.
2. The first hitting time can be estimated by

$$\hat{h}^T(i,j) = \frac{\sum_r t_{k_r}}{M} + (1 - \frac{m}{M})T$$

We provide bounds (details in Appendix) similar to Fogaras et al. (2004)

1. The number of samples M required in order to give an ϵ- correct answer with probability $1 -$.
2. The number of samples M required in order to get the top k neighbors correct.

Theorem 3.1 *For a given node i, in order to obtain $P(\exists u \in \{1,\ldots,n\}, |\hat{h}^T(i,u) - h^T(i,u)| \geq \epsilon T) \leq$, number of samples M should be at least $\frac{1}{2\epsilon^2}\log(\frac{2n}{\delta})$.*

Theorem 3.2 *Let $v_j, j = 1:k$ be the top k neighbors of i in exact T-truncated hitting time. Let $\alpha = h^T(i,v_{k+1}) - h^T(i,v_k)$. Then number of samples M should be at least $\frac{2T^2}{\alpha^2}\log(nk/\ )$ in order to have $Pr(\exists j \leq k, q > k, \hat{h}^T(i,v_j) > \hat{h}^T(i,v_q)) \leq$.*

The details are provided in the appendix. The above theorem says nothing about the order of the top k neighbors, only that if the gap between the hitting times from i to the k^{th} and $k+1^{th}$ nearest neighbors is large, then it is easy to retrieve the top k nearest neighbors. We could change the statement slightly to obtain a sample complexity bound to guarantee the exact order of the top k neighbors with high probability. The main difference will be that it will depend on $\min_{j \leq k} h^T(i,v_{j+1}) - h^T(i,v_j)$.

3.2. Lower and Upper Bounds on c_{ij}^T

Let us denote the neighborhood of node j by $NBS(j)$. The boundary of this is denoted by (j).In Eqn (1) $h^t(i,j)$ is computed using the hitting time from its direct neighbors to j, which are computed in the $t-1^{th}$ iteration. Since only the hitting times of nodes within $NBS(j)$ are stored, a boundary node would not have access to the hitting time of at least one of its neighbors. Those values can be upper and lower bounded as follows. The fastest possible way to reach node j from any node outside $NBS(j)$ would be by jumping to the node on the boundary (j) which has the closest optimistic hitting time to j. This gives us a lower bound on the hitting time of all nodes outside $NBS(j)$ to j.

$$lb(j) = 1 + \min_{p \in \delta(j)} ho_{pj}^{T-1} \tag{2}$$

The pessimistic bound is T. Plugging in these bounds in equation (1) whenever the neighbors are outside the neighborhood of the destination gives the expressions for optimistic (ho_{ij}^T) and pessimistic (hp_{ij}^T) bounds on hitting times (details in Sarkar and Moore (2007)).

Now we have the expressions for the lower and upper bounds for the hitting times of the nodes in $NBS(j)$ to j (ho and hp values). The hitting time from j to nodes within $NBS(j)$ can be estimated using the sampling scheme described in section 3.1. Combining the two leads to the following.

Theorem 3.3 *The truncated commute time between nodes $i \in NBS(j)$ and j will be lower and upper bounded by co_{ij}^T and cp_{ij}^T with probability $1 -$ if the number of samples for estimating $\hat{h}_{ij}^T$ exceeds the lower bound in theorem 3.1, where*

$$co_{ij}^T = \hat{h}_{ji}^T + ho_{ij}^T - \epsilon T \tag{3}$$

$$cp_{ij}^T = \hat{h}_{ji}^T + hp_{ij}^T + \epsilon T \tag{4}$$

We would use $\widehat{co}_{ij} = \hat{h}_{ji}^T + ho_{ij}^T$ and similarly $\widehat{cp}_{ij}$ to denote estimates of these bounds. In order to prune away nodes which are not potential nearest neighbors we also need to obtain a lower bound on the commute time between j and any node outside $NBS(j)$. The incoming lower bound is given by equation 2. Now note that for the outgoing lower bound we need the minimum of $h_{jk}^T, \forall k \notin NBS(j)$.

Lemma 3.4 *The number of samples M should be at least $\frac{1}{2\epsilon^2}\log(\frac{2n}{\delta})$ in order to obtain $Pr(|\min_{k \notin NBS(j)} \hat{h}_{jk}^T - \min_{k \notin NBS(j)} h_{jk}^T| \geq \epsilon T) \leq 2$.*

Thus an estimate of the outgoing lower bound can be computed from the hitting times obtained from sampling. Combining the two we obtain an estimate on the lower bound on $2T$-truncated commute time $\widehat{lb\text{-}ct}(j)$ from j to any node outside $NBS(j)$.

$$\widehat{lb\text{-}ct}(j) = 1 + \min_{p \in \delta(j)} ho_{pj}^{T-1} + \min_{k \notin NBS(j)} \hat{h}_{jk}^T \tag{5}$$

For our implementation, we always used estimated, not the exact bounds. This introduces an additive error in our results (proof excluded for lack of space).

3.3. Expanding Neighborhood

Now we need to find a heuristic to expand the neighborhood such that both the outgoing and incoming

components of the lower bound increase quickly so that the threshold of $2T'$ is reached soon.

For the incoming lower bound we just find the x closest nodes on the boundary which have small optimistic hitting time to the query. We add the neighbors of these nodes to the neighborhood of j. For the outgoing lower bound, we compute the nodes outside the boundary which a random walk is most probable to hit. We do this by maintaining a set of paths from j which stop at the boundary. These paths are augmented one step at a time. This enables one step look-ahead in order to figure out which nodes outside the boundary are the most probable nodes to be hit. We add y of these nodes to the current boundary.

3.3.1. Ranking

The ranking scheme is similar to GRANCH and is rather intuitive. So far we only have lower and upper bounds for commute times from node j to the nodes in $NBS(j)$. Lets denote this set as S. The commute time from j to any node outside S is guaranteed to be bigger than $2T'$. The true k^{th} nearest neighbor will have commute time larger than the k^{th} smallest lower bound i.e. *co* value. Lets denote the k^{th} smallest *co* value by X. Now consider the nodes which have upper bounds (*cp* values) smaller than X. These are guaranteed to have commute time smaller than the true k^{th} nearest neighbor. Adding a multiplicative slack of α to X allows one to return the α-approximate k nearest neighbors which have commute time within $2T'$. Note that the fact that no node outside set S has hitting time smaller than $2T'$ is crucial for ranking, since that guarantees the *true k^{th} nearest neighbor* within $2T'$ commute distance to be within S. Since all our bounds are probabilistic, i.e. are true with high probability (because of the sampling), we return α-approximate k nearest neighbors with high probability. Also the use of estimated bounds ($\widehat{co}$,$\widehat{cp}$) will introduce an additive error of $2\epsilon T$ (ignoring a small factor of $\epsilon\alpha T$).

3.4. The Algorithm at a Glance

In this section we describe how to use the results in the last subsections to compute nearest neighbors in truncated commute time from a node. *Given T, α, k our goal is to return the top k α-approximate nearest neighbors (within $2\epsilon T$ additive error) w.h.p.*

First we compute the outgoing hitting times from a node using sampling. We initialize the neighborhood with the direct neighbors of the query node (We have set up our graph so that there are links in both directions of an edge, only the weights are different). At any stage of the algorithm we maintain a bounded neighborhood for the query node. For each node inside the neighborhood the hitting times *to* the query can be bounded using dynamic programming. Combining these with the sampled hitting times gives us the estimated $\widehat{co}$, and $\widehat{cp}$ values. We also keep track of the lower bound $\widehat{lb\text{-}ct}$ of the commute time from any node outside the neighborhood to the query node. At each step we expand the neighborhood using the heuristic in section 3.3. Similar to GRANCH we recompute the bounds again, and keep expanding until $\widehat{lb\text{-}ct}$ exceeds $2T'$. W.h.p this guarantees that all nodes outside the neighborhood have commute time larger than $2T'-\epsilon T$.

Then we use the ranking as in section 3.3.1 to obtain k α-approximate nearest neighbors (with an additive slack of $2\epsilon T$) in commute time. We start with a small value of T' and increase it until all k neighbors can be returned. As in Sarkar and Moore (2007) it is easy to observe that the lower bound can only increase, and hence at some point it will exceed $2T'$ and the algorithm will stop. The question is how many nodes can be within $2T'$ commute distance from the query node. In section 4 we prove that this quantity is not too large for most query nodes.

4. Locality Properties of h^T

In this section we analyze the locality properties of truncated hitting times. We show that *most* nodes in a graph will have only a *small* number of neighbors within $2T'$ T-truncated commute time. We would do this in three steps. First we show that number of nodes within hitting time T' **from** a node i is small. Then we would make a similar argument that the number of nodes within T'- hitting distance **to** i is also small. Finally we would make an argument about the neighbors of i in commute time.

Theorem 4.1 *For any graph G and constants T and T', the number of nodes within a truncated hitting distance of T' from any node is at most $T^2/(T-T')$.*

Let $P_{ij}^{<T}$ denote the probability of hitting node j starting at i within T steps and $\tilde{P}_{ij}^{t}$ the probability of hitting j in exactly t steps for the first time from i.

$$T' \geq h_{ij} \geq T(1-P_{ij}^{<T}) \implies P_{ij}^{<T} \geq \frac{T-T'}{T} \qquad (6)$$

Define S_i as the neighborhood of i which consists of only the nodes within hitting time T' **from** i.

$$\sum_{j\in S_i} P_{ij}^{<T} = \sum_{j\in S_i}\sum_{t=1}^{T-1} \tilde{P}_{ij}^{t} \leq \sum_{t=1}^{T-1}\sum_{j\in S_i} P_{ij}^{t} \leq T-1$$

However the left hand side is lower bounded by $|S_i|\frac{T-T'}{T}$ using (6). Which leads us to the upper bound

$|S_i| \leq \frac{T^2}{T-T'}$. So all total there are only $N\frac{T^2}{T-T'}$ pairs within T' hitting distance. If T and T' are constant w.r.t n, then using the above bound and counting arguments we can also show that there can be at most $O(\sqrt{n})$ nodes with more than $\sqrt{n}$ nodes within T' hitting time *to them*.

We have shown that not more than $O(\sqrt{n})$ nodes can have more than $O(\sqrt{n})$ nodes with hitting time smaller than T' **to** them. We already have a bound of $T^2/(T-T')$ on the number of nodes with hitting time smaller than T' **from** a node. We want to bound the number of nodes within commute time $2T'$.

In other words we have proven that $\{j|h_{ij}^T \leq T'\}$ and $\{j|h_{ji}^T \leq T'\}$ are small. Now we need to prove that $\{j|h_{ij}^T + h_{ji}^T \leq 2T'\}$ is also small. Note that the above set consists of

1. $S_1 = \{j|h_{ij}^T \leq T' \bigcap h_{ij}^T + h_{ji}^T \leq 2T'\}$
2. $S_2 = \{j|h_{ij}^T > T' \bigcap h_{ij}^T + h_{ji}^T \leq 2T'\}$

S_1 can have at most $T^2/(T-T')$ nodes. Now consider S_2. S_2 will have size smaller than $|\{j|h_{ji}^T \leq T'\}|$. Using our result from before we can say the following

Lemma 4.2 *Let T be constant w.r.t n. If T' is bounded away from T by a* ***constant*** *w.r.t n, i.e. $T^2/(T-T')$ is constant w.r.t n, then not more than $O(\sqrt{n})$ nodes will have more than $O(\sqrt{n})$ neighbors with truncated commute time smaller than $2T'$.*

The impact of lemma 4.2 is that in a sequence of $O(\sqrt{n})$ nearest neighbor queries (each selected at random), for each node, there would be at most $O(\sqrt{n})$ other nodes within $2T'$ commute distance on average.

5. Empirical Results

We have examined our algorithm on Entity Relation (ER) datasets extracted from the Citeseer corpus, as in Chakrabarti (2007). This is a graph of authors, papers and title-words extracted from Citeseer.

5.1. Dataset and Link Structure

The link structure is obvious:

1. Between a paper and a word appearing in its title.
2. From a paper to the paper it cites, and one with one-tenth the strength the other way.
3. Between a paper and each of its authors.

As observed by Chakrabarti (2007), the weights on these links are of crucial importance. Unlike some other approaches (Balmin et al., 2004; Chakrabarti, 2007) we also put links *from* the paper layer *to* the word layer. This allows flow of information from one paper to another via the common words they use. The links between an author and a paper are undirected. The links within the paper layer are directed. We use the convention in Chakrabarti (2007) to put a directed edge from the cited paper to the citing paper with one-tenth the strength.

For any paper we assign a total weight of W to the words in its title, a total weight of P to the papers it cites and A to the authors on it. We use an inverse frequency scheme for the paper-to-word link weight, i.e. the weight on link from paper p to word w is $W \times 1/f_w/(\sum_{p\to u} 1/f_u)$, where f_w is the number of times word w has appeared in the dataset. We set $W = 1, A = 10, P = 10$ so that the word layer to paper layer connection is almost directed. We add a self loop to the leaf nodes, with the same weight as its single edge, so that the hitting times from these leaf nodes are not very small.

We use two subgraphs of Citeseer. The small one has around $75,000$ nodes and $260,000$ edges: $16,445$ words, $28,719$ papers and $29,713$ authors. The big one has around $600,000$ nodes with 3 million edges : $81,664$ words, $372,495$ papers and $173,971$ authors.

5.2. Preprocessing

We remove the stopwords and all words which appear in more than 1000 papers from both the datasets. The number of such words was around 30 in the smaller dataset and 360 in the larger one. We will make the exact dataset used available on the web.

5.3. Experiments

The tasks we consider are as follows,

1. Paper prediction for words (Word task): We pick a paper X at random, remove the links between it and its title words. Given a query of exactly those words we rank the papers in the training graph. For different values of y the algorithm has a score of 1 if X appears in the closest y papers. *For any search engine, it is most desirable that the paper appears in the top k results, $k \leq 10$.*
2. Paper prediction for authors (Author task): Exactly the above, only the link between the paper and its authors are removed.

The hybrid algorithm is compared with: 1) Exact truncated hitting time from the query, 2) Sampled truncated hitting time from the query, 3) Exact truncated commute time from the query, 4) Exact truncated hitting time to the query, 5) Personalized Pagerank Vector and 6) Random predictor. Note that we can compute a high accuracy estimate of the *exact* hitting time *from* a query node by using a huge number of

samples. We can also compute the exact hitting time *to* a node by using dynamic programming by iterating over all nodes. Both of these will be slower than the sampling or the hybrid algorithm as in Table 1.

Distance from a set of nodes Hitting and commute times are classic measures of proximity from a single node. We extend these definitions in a very simple fashion in order to find near-neighbors of a set of nodes. The necessity of this is clear, since a query often consists of more than one word. We define the hitting time from a set of nodes as an weighted average of the hitting times from the single nodes. For hitting time to a set, we can change the stopping condition of a random walk to "stop when it hits any of the nodes in the set". We achieve this via a simple scheme: for any query q, we *merge* the nodes in the query in a new mega node Q as follows. For any node $v \notin Q$ $P(Q, v) = \sum_{q \in Q} w(q)P(q, v)$, where $P(q, v)$ is the probability of transitioning to node v from node q in the original graph. $\sum_{q \in Q} w(q) = 1$. We use a uniform weighing function, i.e. $w(q) = 1/|Q|$. The hitting/commute time is computed on this modified graph from Q. These modifications to the graph are local and can be done at query time, and then we undo the changes for the next query.

Our **average query size** is the average number of words (authors) per paper for the word (author) task. These numbers are around 3 (2) for the big subgraph, and 5 (2) for the small subgraph.

Figure 1 has the performance of all the algorithms for the author task on the (A) smaller, (B) larger dataset and the word task on the (C) smaller and (D) larger dataset, and Table 1 has the average runtime. As mentioned before for any paper in the testset, we remove all the edges between it and the words (authors) and then use the different algorithms to rank all papers within 3 hops of the words (5 for authors, since authors have smaller degree and we want to have a large enough candidate set) in the new graph and the removed paper. For any algorithm the percentage of papers in the testset which get ranked within the top k neighbors of the query nodes is plotted on the y axis vs. k on the x axis. We plot the performances for six values of k: $1, 3, 5, 10, 20$ and 40.

The results are extremely interesting. Before going into much detail let us examine the performance of the exact algorithms. Note that for the author task the *exact hitting time* ***to a node*** and the *exact commute time from a node* consistently beats the *exact hitting time* ***from a node***, and PPV. However for the word task the outcome of our experiments are **the opposite**. This can be explained in terms of the inherent directionality of a task. The distance *from* the word-layer to the paper-layer gives more information than the distance from the paper layer to the word layer, whereas both directions are important for the author task, which is why commute times, and hitting time to a node outperform all other tasks.

We only compare the predictive power of PPV with our measures, not the *runtime*. Hence we use the exact version of it. We used $c = 0.1$, so that the average path-length for PPV is around 10, since we use $T = 10$ for all our algorithms (however, much longer paths can be used for the exact version of PPV). PPV and hitting time from a node essentially relies on the probability of reaching the destination from the source. Even though hitting time uses information only from a truncated path, in all of our experiments it performs better than PPV, save one, where it behaves comparably.

Word task: The sampling based hitting time beats PPV consistently by a small margin on the bigger dataset, whereas it performs comparably on the smaller one. Hitting times and PPV beat the hitting time to nodes for the word task. In fact for $k = 1, 3, 5$, for the smaller dataset the hitting time *to* a query node isn't much of an improvement over the random predictor (which is zero). This emphasizes our claim that the hitting time *to* the word layer does not provide significant information for the word task. As a result the performance of the exact and hybrid commute times deteriorates.

Author task: The hitting time *to the query* and the exact commute time *from a query* have the best performance by a large margin. The hybrid algorithm has almost similar performance. Hitting time from the query is beaten by these. PPV does worse than all the algorithms except of course the random predictor.

Number of samples: For the small graph, we use $100,000$ samples for computing the high accuracy approximation of hitting time from a node; 5000 samples for the word task and 1000 samples for the author task. We use 1.5 times each for the larger graph. We will like to point out that our derived sample complexity bounds are interesting for their asymptotic behavior. In practice we expect much fewer samples to achieve low probability of error. In Figure 1 sometimes the exact hitting (commute) times does worse than the sampled hitting time (hybrid algorithm). This might happen by chance, with a small probability.

6. Related Work

In this section we briefly examine algorithms which have been developed using random walks on graphs, and their applications. Brand (2005) uses different random walk based measures to compute the top k rec-

ommendations for a particular customer in a customer-movie graph from the movielens dataset. The submatrices of the hitting and commute times matrices are computed by iterative sparse matrix multiplications (details in Sarkar and Moore (2007)). However it is only tractable to compute these measures on graphs with a few thousand nodes for most purposes.

Liben-Nowell and Kleinberg (2003) showed that the hitting and commute times perform poorly for link prediction tasks, because of their sensitivity to long paths. The most effective measure was shown to be the Katz measure (Katz, 1953) which directly sums over the collection of paths between two nodes with exponentially decaying weights. However, ranking under the Katz score would require solving for a row of the matrix $(I-\gamma A)^{-1}-I$, where I and A are the identity and adjacency matrices of the graph and γ is the decay factor. Even if A is sparse the fast linear solvers will take at least $O(E)$ time.

Tong et al. (2007) uses escape probability from node i to node j to compute *direction aware proximity* in graphs. A fast matrix solver is used to compute this between *one pair of nodes*, in $O(E)$ time. Multiple pairs of proximity require computation and storage of the inverse of the matrix $I-\gamma P$, which would be intractable for large graphs ($10K$ nodes). Jeh and Widom (2002b) use the notion of *expected f-hitting distance*, which is the hitting time (in a random walk with restart) between a set of nodes in a product graph with N^2 nodes. The quadratic time complexity is reduced by limiting the computation between source and destination pairs within distance of r.

The main idea of *personalized pagerank* is to bias the probability distribution towards a set of webpages particular to a certain user, resulting in a user-specific view of the web. It has been proven (Jeh & Widom, 2002a) that the PPV for a set of webpages can be computed by linearly combining those for each individual webpage. However it is hard to store all possible personalization vectors or compute the personalized pagerank vector at query time because of the sheer size of the internet graph. There have been many novel algorithms for efficiently computing PPV (Jeh & Widom, 2002a; Haveliwala, 2002; Fogaras et al., 2004). Most of these algorithms compute partial PPVs offline and combine them at query time.

The *ObjectRank* algorithm (Balmin et al., 2004) computes keyword-specific ranking in a publication database of authors and papers, where papers are connected via citations and co-authors. The personalized pagerank for each word is computed and stored offline, and at query time combined linearly. Chakrabarti

(2007) et al. show how to compute approximate personalized pagerank vectors using clever neighborhood expansion schemes which would drastically reduce the amount of offline storage and computation.

7. Conclusion

Many graph-based learning algorithms rely on computing proximity measures in graphs. These graphs can be very large and undergoing continuous change, hence fast *incremental* algorithms are needed. In this paper we have combined sampling techniques with branch and bound pruning to compute near neighbors of a query node with high probability. Our proximity measures have been empirically shown to often outperform a popular alternative, namely personalized pagerank on link-prediction tasks.

Appendix

Proof of Theorem 3.1: We provide a bound on the number of samples M required in order to give an ϵ-correct answer with probability $1-\delta$. We denote the estimate of a random variable x by $\hat{x}$ from now on. Lets denote by $X^r(i,u)$ the first arrival time at node u from node i on the r^{th} trial. Define $X^r(i,u)=T$ if the path does not hit u on trial r. Note that $\hat{h}^T(i,u)=\sum_r X^r(i,u)/M$, and $E[\hat{h}^T(i,u)]=h^T(i,u)$. $\{X^r(i,u)\in[1,T], r=1:M\}$ are i.i.d. random variables. The Hoeffding bound gives

$$P(|\hat{h}^T(i,u)-h^T(i,u)|\geq\epsilon T)\leq 2\exp(-\tfrac{2M(\epsilon T)^2}{T^2})$$
$$=2\exp(-2M\epsilon^2)$$

Now we want the probability of a bad estimate for any u to be low. We upper bound this error probability using union and Hoeffding bounds and set the upper bound to be less than a small value δ. Hence we have $P(\exists u\in\{1,\ldots,n\}, |\hat{h}^T(i,u)-h^T(i,u)|\geq\epsilon T)\leq 2n\exp(-2M\epsilon^2)\leq\delta$. This gives the lower bound of $\frac{1}{2\epsilon^2}\log(\frac{2n}{\delta})$.

Proof of Theorem 3.2: Consider a sampled path of length T starting from i. We define $X^r(i,u)$ as before. For two arbitrary nodes u and v, WLOG let $h^T(i,u)>h^T(i,v)$. The idea is to define a random variable whose expected value will equal $h^T(i,u)-h^T(i,v)$. We define a random variable $Z^r=X^r(i,u)-X^r(i,v)$. $\{Z^r\in[-(T-1),T-1], r=1:M\}$ are i.i.d. random variables. Note that $E(Z^r)=h^T(i,u)-h^T(i,v)$.

The probability that the ranking of u and v will be exchanged in the estimated h^T values from M samples equals $P(\hat{h}^T(i,u)<\hat{h}^T(i,v))$. This probability equals $P(\sum_{r=1}^M Z_r/M<0)$ which using the Hoeffding bound is smaller than $\exp(-2M(h^T(i,u)-h^T(i,v))^2/(2T)^2)=\exp(-M(h^T(i,u)-h^T(i,v))^2/2T^2)$. Let $v_1,v_2,\ldots,v_k$ be the top k neighbors of i in exact truncated hitting time.

$$Pr(\exists j\leq k, q>k, \hat{h}^T(i,v_j)>\hat{h}^T(i,v_q))$$
$$\leq\sum_{j\leq k}\sum_{q>k}Pr(\hat{h}^T(i,v_j)>\hat{h}^T(i,v_q))$$
$$\leq\sum_{j\leq k}\sum_{q>k}\exp(-\tfrac{M(h^T(i,v_q)-h^T(i,v_j))^2}{2T^2})$$
$$\leq nk\exp(-\tfrac{M(h^T(i,v_{k+1})-h^T(i,v_k))^2}{2T^2})$$

Let $\alpha=h^T(i,v_{k+1})-h^T(i,v_k)$. Setting the above probability to be less than δ gives us the desired lower bound of $\frac{2T^2}{\alpha^2}\log(nk/\delta)$ on M.

Proof of lemma 3.4: Let S be a set of nodes. Let $q=\arg\min_{k\in S}h(j,k)$. Let $m=\arg\min_{k\in S}\hat{h}(j,k)$. We know that $h(j,q)\leq h(j,m)$, since q is the true minimum, and $\hat{h}(j,m)\leq\hat{h}(j,q)$, since m is the node which has the minimum estimated h-value. Using the sample complexity bounds from theorem 3.1, we have $\hat{h}(j,m)\leq\hat{h}(j,q)\leq^{w.h.p}h(j,q)+\epsilon T$. For the other part of the inequality we have $\hat{h}(j,m)\geq^{w.h.p}h(j,m)-\epsilon T\geq h(j,q)-\epsilon T$. Using both sides we get $h(j,q)-\epsilon T\leq^{w.h.p}\hat{h}(j,m)\leq^{w.h.p}h(j,q)+\epsilon T$. Using S to be the set of nodes outside the neighborhood of j yields lemma 3.4.

Abstract

Probabilistic grammatical formalisms such as hidden Markov models (HMMs) and stochastic context-free grammars (SCFGs) have been extensively studied and widely applied in a number of fields. Here, we introduce a new algorithmic problem on HMMs and SCFGs that arises naturally from protein and RNA design, and which has not been previously studied. The problem can be viewed as an inverse to the one solved by the Viterbi algorithm on HMMs or by the CKY algorithm on SCFGs. We study this problem theoretically and obtain the first algorithmic results. We prove that the problem is NP-complete, even for a 3-letter emission alphabet, via a reduction from 3-SAT, a result that has implications for the hardness of RNA secondary structure design. We then develop a number of approaches for making the problem tractable. In particular, for HMMs we develop a branch-and-bound algorithm, which can be shown to have fixed-parameter tractable worst-case running time, exponential in the number of states of the HMM but linear in the length of the structure. We also show how to cast the problem as a Mixed Integer Linear Program.

1. Introduction

Probabilistic grammatical formalisms such as hidden Markov models (HMMs) and stochastic context-free grammars (SCFGs) have found many applications in areas such as computational biology and natural language processing. Because of their intuitive representation, their power to capture some of the essential relationships present in data, and the existence of polynomial-time algorithms (such as the Viterbi algorithm) and practical training procedures (such as the Baum-Welch algorithm), these formalisms have enjoyed tremendous popularity in the past decades.

Three natural problems for a model have been described: the decoding problem (given a model and a sequence, find the most likely derivation), the evaluation problem (given a model and a sequence, find the likelihood of the sequence being generated), and the learning problem (given a set of sequences, learn the parameters of the underlying model). In this paper, we identify another natural problem on HMMs and SCFGs, which is the inverse of the decoding problem: given a derivation and a model, find a sequence for which this derivation is the most likely one. Because the decoding problem is solved by the Viterbi algorithm in HMMs and by the CKY algorithm in SCFGs, we refer to our problem for these two models as the Inverse-Viterbi and the Inverse-CKY problem, respectively.

The motivation for our problem comes from protein and RNA design. The design of biological molecules with a desired structure is a long sought-after goal in computational biology. While a number of achievements have been made in protein structure design, the problem remains difficult (Butterfoss & Kuhlman, 2005; Park et al., 2004; Pokala & M., 2001). For RNA, there has been recent interest in secondary structure design (Breaker, 1996), and a number of fairly successful heuristics have been developed to solve this problem (Hofacker, 1994; Andronescu, 2004; Busch & Backofen, 2006). Generally, structure design can be divided into two goals: the positive-design aspect of finding a sequence that has low energy in the desired structure, and the negative-design aspect of blocking the sequence from having low energy in other struc-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1]To whom correspondence should be addressed

tures. While some work has explored the negative-design aspect in protein structure design (Butterfoss & Kuhlman, 2005), most work has focused solely on the positive-design aspect. In RNA secondary structure design, the positive-design aspect is largely trivial (desired paired positions in the secondary structure can simply be chosen to be complementary bases) and the negative-design aspect, which involves attempting to block erroneous base pairings in other structures, is central to solving the problem.

Our goal in formulating the Inverse-Viterbi and Inverse-CKY problems is to simultaneously capture the positive-design and negative-design aspects of the design problem. Our framework for viewing design within the context of HMMs or SCFGs is the following. When HMMs (SCFGs) are used for structure prediction, the emitted string represents the biological sequence and the goal is to find the hidden state-path (derivation tree for SCFGs) that represents the structure this sequence will adopt. A state-path of high probability for that sequence is the analogue of a structure with low energy. By inverting this problem, we can use the same HMM (SCFG) for design. Now, a state-path (derivation tree) representing the desired structure is known and the goal is to find a sequence which will adopt this structure (i.e. a string for which this state-path is optimal).

Our Contribution. We have defined a novel problem (the Inverse-Viterbi problem) on HMMs and its analogue on SCFGs, that as far as we know has never been studied before. We show that the problem is NP-hard for HMMs (and as a result for SCFGs). We then give approaches for making the problem tractable. In particular, for HMMs we give a branch-and-bound algorithm. This algorithm can be shown to have fixed-parameter tractable running time: if there are K states, the emission alphabet is Σ, the path length is n, and all of the log-probabilities in the model are greater than $-B$ (so that there are no 0 transition probabilities and all the probabilities in the model are greater than e^{-B}) and are defined to a precision δ, then the branch-and-bound algorithm has worst-case running time $O((2B/\delta)^{K-2}nK^2|\Sigma|)$, which is exponential in the number of states but linear in the path length. We also show how to cast the problem as a simple Mixed Integer Linear Program.

Our hardness proof shows that the RNA secondary structure design problem is hard in a certain sense: a polynomial-time algorithm that only depends on the energy model for RNA secondary structure being SCFG-like, as is the case for the Zuker energy model (the most successful model curently available for RNA secondary structure prediction (Zuker & Stiegler, 1981)), without making additional assumptions on the particular form of the energy model, is not possible unless $P = NP$.

In presenting an abstract formulation of the design problem and giving the theoretical results derived in this paper, our goal is not to provide methods that will necessarily be immediately applied to the protein or RNA structure design problems. Instead, we believe that the abstract framework given in this paper may prove to be useful in understanding the design problem and facilitating the development of new methods for design. The Inverse-Viterbi and Inverse-CKY problems are novel and natural problems on HMMs and SCFGs, and so we believe a theoretical exploration is interesting in its own right.

2. Problem Description and Hardness Results

2.1. Definition of the Models

An HMM consists of a set $\mathcal{N}$ of K states and an alphabet Σ, with $\mathcal{N} \cap \Sigma = \emptyset$. The symbols in Σ are emitted on transitions between the states. The probability of emitting the symbol a when transitioning from the state s_k to the state s_l is specified by the value of the parameter $p^a_{s_k,s_l}$. These parameters determine the HMM. We assume (without loss of generality) that there is a unique initial state S.

The normalization condition requires that

$$\sum_{s_l \in \mathcal{N}} \sum_{a \in \Sigma} p^a_{s_k,s_l} = 1 \text{ for } k = 1, \ldots, K$$

Similarly, an SCFG consists of a set $\mathcal{N}$ of K non-terminal symbols, and a set Σ of terminal symbols, with $\mathcal{N} \cap \Sigma = \emptyset$. The non-terminals are rewritten according to a set $\mathcal{R}$ of rewriting rules. The probability of applying each rewriting rule α is specified by the value of the parameter p_α. These parameters determine the SCFG. We assume (without loss of generality) that there is a unique starting non-terminal symbol S.

Every rule α replaces a single non-terminal with a string γ of non-terminals and terminals:

$$\alpha = N_k \rightarrow \gamma$$

Here N_k (the terminal symbol being rewritten) is referred to as the left-hand side of the rule, abbreviated as $l(\alpha)$.

The normalization condition requires that

$$\sum_{\{\alpha \in \mathcal{R} | l(\alpha) = N_k\}} p_\alpha = 1, \text{ for } k = 1 \ldots, , K$$

We do not insist that the SCFG be in Chomsky Normal Form (CNF) because in some applications (such as RNA secondary structure design), the correspondence between the design and inverse problem defined in this paper may only be natural if the SCFG is not converted to CNF.

We use boldface letters to indicate sequences of symbols. A state-path of length n in the HMM is written as $\boldsymbol{\pi} = \pi_1 \ldots \pi_n$, where each π_i is a state in the HMM. Such a path emits a sequence of $n-1$ emission symbols, $\boldsymbol{\omega} = \omega_1 \ldots \omega_{n-1}$ where each ω_i is a symbol from Σ. The joint probability of a state-path $\boldsymbol{\pi}$ and an emission sequence $\boldsymbol{\omega}$ is given by $\Pr(\boldsymbol{\pi}, \boldsymbol{\omega}) = \prod_{i=1}^{n-1} p^{\omega_i}_{\pi_i, \pi_{i+1}}$. It is frequently more convenient to deal with sums rather than products, and so we work in log-space, taking $q^a_{s_1,s_2} := \log(p^a_{s_1,s_2})$ and therefore $\log(\Pr(\boldsymbol{\pi}, \boldsymbol{\omega})) = \sum_{i=1}^{n-1} q^{\omega_i}_{\pi_i, \pi_{i+1}}$.

A derivation of length n in the SCFG is the successive application of rewriting rules, beginning with the starting symbol S, which generates a yield $\boldsymbol{\omega} = \omega_1 \ldots \omega_n$ where each ω_i is a symbol from Σ. The derivation can be summarized in the form of a tree $\mathcal{T}$. The joint probability of a derivation tree $\mathcal{T}$ and a yield $\boldsymbol{\omega}$ is given by $\Pr(\mathcal{T}, \boldsymbol{\omega}) = \prod_{\alpha \in \mathcal{R}(\mathcal{T})} p_\alpha$, where $\mathcal{R}(\mathcal{T})$ denotes the multiset of rewriting rules used to derive $\mathcal{T}$. As with HMMs, it is convenient to work instead with the log-probabilities, $q_\alpha := \log p_\alpha$, which gives $\log(\Pr(\mathcal{T}, \boldsymbol{\omega})) = \sum_{\alpha \in \mathcal{R}(\mathcal{T})} q_\alpha$.

2.2. Definition of the Direct Problem

In the original Viterbi problem, one is given an emission sequence $\boldsymbol{\omega_0}$ from an HMM and the goal is to find the most likely state-path to have generated $\boldsymbol{\omega_0}$: the $\boldsymbol{\pi}$ that maximizes the conditional probability given the emission $\Pr(\boldsymbol{\pi} | \boldsymbol{\omega_0})$. Since $\Pr(\boldsymbol{\pi} | \boldsymbol{\omega_0}) = \frac{\Pr(\boldsymbol{\pi}, \boldsymbol{\omega_0})}{\Pr(\boldsymbol{\omega_0})}$, and $\boldsymbol{\omega_0}$ is fixed, it is equivalent to simply maximize the joint probability $\Pr(\boldsymbol{\pi}, \boldsymbol{\omega_0})$. The Viterbi problem can therefore be expressed as: given $\boldsymbol{\omega_0}$, find an element of $\arg\max_{\boldsymbol{\pi}} \Pr(\boldsymbol{\pi}, \boldsymbol{\omega_0})$ (we consider arg max as the *set* of all arguments maximizing the function). For an HMM with K states and an emission of length n, the Viterbi algorithm finds the best state-path using dynamic programming in time $O(nK^2|\Sigma|)$ (Viterbi, 1967).

Similarly, the direct problem for an SCFG is formulated as follows: given a yield $\boldsymbol{\omega}$, find the derivation tree $\mathcal{T}$ which maximizes the joint probability $\Pr(\mathcal{T}, \boldsymbol{\omega})$. In other words, given $\boldsymbol{\omega}$, we find an element of $\arg\max_{\mathcal{T}} \Pr(\mathcal{T}, \boldsymbol{\omega})$. The optimal derivation is referred to as the Viterbi parse of $\boldsymbol{\omega}$. For a derivation of length n in an SCFG with rewriting rules $\mathcal{R}$ in Chomsky Normal Form, the CKY algorithm finds the Viterbi parse in time $O(n^3|\mathcal{R}|)$ (Durbin et al., 1999). Modified versions of the CKY algorithm can also handle SCFGs in similar forms, such as those used in RNA structure prediction, with the same time complexity (for example see (Dowell & Eddy, 2004)).

2.3. Definition of the Inverse Problem

In the Inverse-Viterbi problem, a desired output of the Viterbi algorithm is known and the goal is to design an input to the Viterbi algorithm that will return this output. In mathematical terms the problem is: given a state-path $\boldsymbol{\pi_0}$, find an $\boldsymbol{\omega}$ so that $\boldsymbol{\pi_0}$ is in $\arg\max_{\boldsymbol{\pi}} \Pr(\boldsymbol{\pi}, \boldsymbol{\omega})$, or determine that none exists.

In an HMM used for structure prediction, the above definition of the inverse problem captures what it means to do structure design: one knows the structure (state-path) and tries to find a sequence that has a higher score with that structure than with any other structure. It is important to emphasize that for many $\boldsymbol{\pi}$ there will be no such $\boldsymbol{\omega}$. In fact, it can be shown that only polynomially many paths are designable (Elizalde & Woods, 2006). This captures the notion that many structures are not designable: there is no sequence that will lead to these structures.

To illustrate this distinction, consider the 2-state HMM shown in Figure 1. Say that the desired state-path to design is $B^n = B \ldots B$. The most likely emission given this state-path is $a^{n-1} = a \ldots a$, but when run on such a path the Viterbi algorithm will not return B^n. In fact, the only sequence that the Viterbi algorithm will return B^n on is b^{n-1}. This simple case illustrates that to design a path of all B's it is important not just to pick emissions likely given this path, but to simulatenously block other possible paths, in this case those paths containing A's. Note further that the probability of b^{n-1} being emitted from B^n at random is $(0.2)^{n-1}$. Therefore, neither picking the most likely emission sequence nor randomly generating sequences from the state-path will in general solve the Inverse-Viterbi problem with probability greater than exponentially small in the length of the state-path.

We incorporate one generalization into our definition of the problem of inverting the Viterbi algorithm, because it seems natural to the design problem. We allow constraints on the emissions that can be chosen in any position (given as the Σ_i below). The algorithms we develop in this paper handle this generalization without any added complexity.

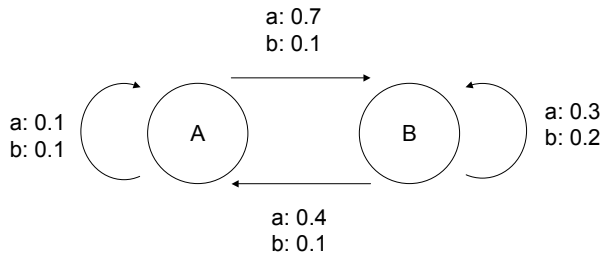

Figure 1. A 2-state HMM illustrating the distinction between the Inverse-Viterbi problem and the trivial problem of finding the most likely emission from a given state-path. The 2 states are A and B, while the 2 possible emissions are a and b. Each transition is marked with the possible emissions followed by their corresponding probabilities. In order to design B^n the only possible sequence is b^{n-1}, which is the least likely sequence to be produced by B^n.

INVERSE-VITERBI:
Input: An HMM, a state-path $\boldsymbol{\pi_0}$ of length n and for every position i in $1, \ldots, n$ a set $\Sigma_i \subseteq \Sigma$ giving allowed emissions at position i.
Output: An $\boldsymbol{\omega}$ where each $\omega_i \in \Sigma_i$ so that $\boldsymbol{\pi_0}$ is in $\arg\max_{\boldsymbol{\pi}} \Pr(\boldsymbol{\pi}, \boldsymbol{\omega})$, or $\emptyset$ if no such $\boldsymbol{\omega}$ exists.

Similarly, the inverse problem for an SCFG requires one to find an input that corresponds to a given output. In other words, given a derivation $\mathcal{T}_0$, we would like to find an $\boldsymbol{\omega}$ such that $\mathcal{T}_0$ is in $\arg\max_{\mathcal{T}} \Pr(\mathcal{T}, \boldsymbol{\omega})$, or determine that none exists. Note that this problem only makes sense if the tree $\mathcal{T}_0$ has had all of its leaves removed (we will call such a tree "naked"); in other words, the tree includes the specification of non-terminals but not the terminal symbols produced.

INVERSE-CKY:
Input: An SCFG, a naked derivation tree $\mathcal{T}_0$ that corresponds to an emitted string of n terminals and for every position i in $1, \ldots, n$ a set $\Sigma_i \subseteq \Sigma$ giving the allowed emissions at position i.
Output: An $\boldsymbol{\omega}$ where each $\omega_i \in \Sigma_i$ so that $\mathcal{T}_0$ is in $\arg\max_{\mathcal{T}} \Pr(\mathcal{T}, \boldsymbol{\omega})$, or $\emptyset$ if no such $\boldsymbol{\omega}$ exists.

2.4. NP-hardness of the Inverse Problem

We now prove that the Inverse-Viterbi problem is NP-hard. To do so, we introduce the decision problem corresponding to Inverse-Viterbi:

DESIGNABLE:
Input: An HMM and a state-path $\boldsymbol{\pi_0}$
Output: YES if there is an $\boldsymbol{\omega}$ so that $\boldsymbol{\pi_0}$ is in $\arg\max_{\boldsymbol{\pi}} \Pr(\boldsymbol{\pi}, \boldsymbol{\omega})$, otherwise NO.

An algorithm that solves Inverse-Viterbi would also solve Designable and so by proving Designable is NP-complete, we show that Inverse-Viterbi is NP-hard.

Theorem 1. *Designable is NP-Complete.*

Proof. Clearly Designable is in NP so we just need to show Designable is NP-hard. We do so by presenting a polynomial-time reduction from 3-SAT to Designable.

In outline, the construction is achieved by creating an HMM with one component that can emit all possible non-satisfying assignments for the 3-SAT problem along with a special state outside of this component that can emit all binary strings, but that does so with smaller probability. Because this probability is small, the path consisting of repeatedly being in the special state is only designable if a specific sequence of 0's and 1's could not possibly be emitted by the component corresponding to the 3-SAT formula. And such a sequence is, by the construction, a satisfying assignment of the 3-SAT formula.

In full detail, the construction is as follows (see Figure 2 for an illustration). Assume the 3-SAT formula consists of m variables and r clauses. The HMM consists of a begin state B, two special states S and T and $r(m+1)$ states labelled $X_{i,j}$ where $1 \leq i \leq r$ and $1 \leq j \leq m+1$. The emission alphabet consists of 0, 1, and the special symbol #. The state B transitions to either S or any of $X_{i,1}$ with equal probability, $\frac{1}{r+1}$, while emitting #. The state S transitions to itself while emitting 0 or 1, each with probability $\frac{1}{2}$. The state T transitions to itself with probability 1 while emitting #. The r sets of states $X_{i,1}, \ldots, X_{i,m+1}$ for $1 \leq i \leq r$ are arranged in independent chains, each corresponding to the ith clause, that emit all strings $\{0,1\}^m$ that do not satisfy the ith clause. Such a chain is constructed by the following: if the ith clause contains the jth variable un-negated then $X_{i,j}$ transitions to $X_{i,j+1}$ while emitting 0 with probabilty 1, if the ith clause contains the jth variable negated then $X_{i,j}$ transitions to $X_{i,j+1}$ while emitting 1 with probabilty 1, and if the ith clause doesn't contain the jth variable then $X_{i,j}$ transitions to $X_{i,j+1}$ while emitting 0 or 1 each with probability $\frac{1}{2}$. Finally, $X_{i,m+1}$ transitions to T while emitting # with probability 1.

The state-path to design is BS^{m+1}. We observe that the joint probability of this state-path and an emission sequence of the form $\#\{0,1\}^m$ is $(\frac{1}{r+1})(\frac{1}{2})^m$, and that only emissions of this form have non-zero probability for this state-path. We further observe that the only other state-path that could emit such a sequence must be of the form $BX_{i,1} \ldots X_{i,m+1}$, and the joint

probability of such a sequence and such a state-path is $(\frac{1}{r+1})(\frac{1}{2})^{m-3}$ if the emission sequence contains a # followed by a non-satisfying assignment to the 3-SAT formula, but the joint probability is zero if the emission sequence contains a # followed by a satisfying assignment. Since $(\frac{1}{r+1})(\frac{1}{2})^{m-3} > (\frac{1}{r+1})(\frac{1}{2})^{m}$, the only sequence that could design BS^{m+1} is a # followed by a satisfying assignment and therefore BS^{m+1} is designable if and only if there is a satisfying assignment to the 3-SAT formula.

The above construction is done in polynomial time, and therefore we have successfully given a polynomial reduction from 3-SAT to Designable. □

Corollary 1. *Inverse-CKY is NP-hard.*

Proof. An HMM can be thought of as an SCFG with a non-terminal corresponding to each state and a terminal to each letter in the emission alphabet. Every branching rule rewrites a state as a letter and another state, so that all derivation trees are right-branching. Since the problem is hard on HMMs it is also hard on the extended class of SCFGs. □

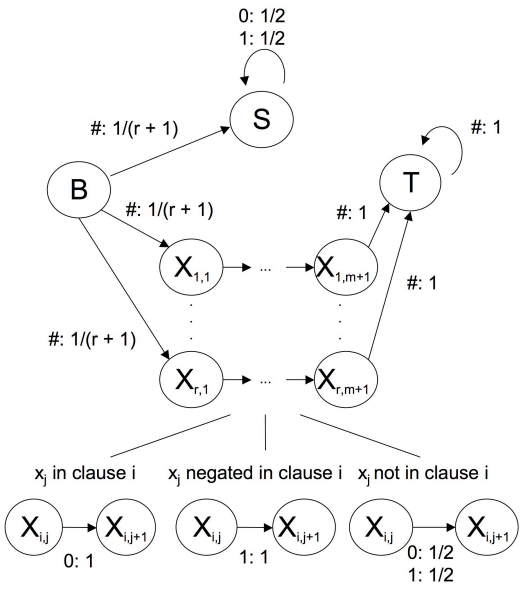

Figure 2. The reduction from 3-SAT to DESIGNABLE. Each transition is marked with all non-zero probability emissions followed by their corresponding probabilities.

3. Algorithmic Results

In this section, we give two approaches for finding a solution to the inverse problem, a branch-and-bound algorithm and a formulation of the problem as a Mixed Integer Linear Program. Both of these are derived from the same basic approach, based on a set of constraints we develop that are satisfied by an $\boldsymbol{\omega}$ if and only if it is a solution to the inverse problem. Below we first develop these constraints. Similar constraints and a Mixed Integer Linear Program can be developed for SCFGs. For reasons of space and simplicity of presentation, we only give the details for HMMs in this section. We illustrate the formulation of constraints and a Mixed Integer Linear Program for an SCFG used for RNA secondary structure prediction in a supplement.[2]

3.1. Constraint Formulation

Conceptually, the set of inequalities for HMMs is derived by looking at how the Viterbi algorithm works and enforcing constraints on $\boldsymbol{\omega}$ so that the Viterbi algorithm is forced to return the desired state-path $\boldsymbol{\pi_0}$.

The Viterbi algorithm calculates an n by K table of values $M_{i,s}$ of the best log-probability scores for the state-path from positions 1 to i with final state s. Because of the special form of the HMM score, this table can be filled in iteratively:
(1) $M_{1,S} = 0$ and $M_{1,s} = -\infty$ for all $s \neq S$
(2) $M_{i,s} = \max_{s'}(M_{i-1,s'} + q_{s',s}^{\omega_{i-1}})$ for $2 \leq i \leq n$ and all s

The best state in the nth position is then read off as $\pi_n \in \arg\max_s(M_{n,s})$, and the earlier ones are read off by a traceback routine: the best state in position $n-1$ is an s' that maximized $(M_{n-1,s'} + q_{s',\pi_n}^{\omega_{n-1}})$, and so on.

From the above we can directly read off the constraints on the emission symbol ω_i in position i for $1 \leq i \leq n-1$, that need to be satisfied in order to design a state-path with states π_i. For the Viterbi algorithm to return the desired path, we need for every state in this path to traceback to the previous state in the desired path and for the last state in this path to have the best log-probability score:
(3) $M_{i,\pi_i} + q_{\pi_i,\pi_{i+1}}^{\omega_i} \geq \max_{s \neq \pi_i}(M_{i,s} + q_{s,\pi_{i+1}}^{\omega_i})$ for $1 \leq i \leq n-1$
(4) $M_{n,\pi_n} \geq \max_{s \neq \pi_n}(M_{n,s})$

3.2. Branch-and-Bound Algorithm

What is particularly nice about inequalities (1)-(4) is that they allow for an inductive method for choosing possible ω_i in an emission sequence based only on the choices of ω_j for $1 \leq j \leq i-1$. This is because the inequality constraining the choice of ω_i (inequality 3 above) only depends on the values for $M_{i,s}$. And the

[2]See http://groups.csail.mit.edu/cb/inv_viterbi/scfg.pdf

values for $M_{i,s}$ only depend on the choices made for ω_1 through ω_{i-1}. This naturally leads to a branch-and-bound algorithm. Branch-and-bound algorithms are frequently useful in solving computationally hard problems. A branch-and-bound algorithm is complete (it always finds the correct answer) and frequently efficient on many problem instances.

The branch-and-bound algorithm steps through position i from 1 to $n-1$, at each step maintaining a list of emission sequences of length i that could be extended to possible length $n-1$ sequences the algorithm will ultimately return. At each step i, the algorithm forms emission sequences of length i from the emission sequences of length $i-1$ stored in the previous stage by appending possible emission symbols onto the sequences from the previous stage. In order to avoid performing an exhaustive search, at every stage the algorithm prunes the search space by applying two elimination rules. The first elimination rule ensures that for a given length $i-1$ sequence from the previous stage, an ω_i is only appended onto this sequence to form a length i sequence if the traceback constraint (constraint 3) is satisfied by the choice ω_i. The second elimination rule examines pairs $\boldsymbol{\omega}$ and $\tilde{\boldsymbol{\omega}}$ of partial strings of length i that remain after the application of the first elimination rule. It eliminates $\boldsymbol{\omega}$ due to $\tilde{\boldsymbol{\omega}}$, if given that $\boldsymbol{\omega}$ can be extended to a solution to the design problem, then $\tilde{\boldsymbol{\omega}}$ must also be able to be extended to a solution.

Specifically, the second elimination rule is based on the following observation. If for all states s, $M_{i+1,\pi_{i+1}} - M_{i+1,s}$ is at least as large under $\tilde{\boldsymbol{\omega}}$ as it is under $\boldsymbol{\omega}$ (i.e. if for all states s, the relative preference of $\tilde{\boldsymbol{\omega}}$ for π_i to state s is at least as large as that of $\boldsymbol{\omega}$), then the traceback constraints (inequality 3 above) on all positions j for $j > i$ and the ending constraints (inequality 4 above) can only be easier to satisfy when extending $\tilde{\boldsymbol{\omega}}$ than when extending $\boldsymbol{\omega}$.

It is important to note that for the case of a 2-state HMM the branch-and-bound is an exact polynomial-time algorithm. This is because there is only one $M_{i+1,\pi_{i+1}} - M_{i+1,s}$ value to compare the choices for ω_i on (there is only one state s other than π_i at every position since there are only 2 states to choose from), and so there is always a *best* choice for ω_i at every position based on the past choices.

The above branch-and-bound algorithm is exact for all HMMs, but has no guaranteed worst-case running time. If we make additional assumptions about our HMM, however, we can show that the algorithm also has fixed-parameter tractable running time. Specifically, we assume that all q values (the log-probabilities)

Algorithm 1 Branch-and-Bound Algorithm

Input: An HMM, a desired state-path $\boldsymbol{\pi_0}$ of length n, and for every position i in $1, \ldots, n$ a set $\Sigma_i \subseteq \Sigma$ giving the allowed emissions at position i
Output: A sequence $\boldsymbol{\omega}$ such that $\boldsymbol{\pi_0}$ is in $\arg\max_{\boldsymbol{\pi}} \Pr(\boldsymbol{\pi}, \boldsymbol{\omega})$ or $\emptyset$ if no such sequence exists.
Variables: A list L_i of all partial sequences of length i considered at the ith iteration each together with its corresponding K-vector of values $M_{i,s}$.
Initialize: $L_0 = \{(\epsilon, \mathbf{0})\}$
for $i = 1$ **to** $n-1$ **do**
  Set $L_i = \emptyset$
  for all $(\boldsymbol{\omega^{i-1}}, \boldsymbol{v^{i-1}}) \in L_{i-1}$ and all $\omega_i \in \Sigma_i$ **do**
    Form $\boldsymbol{\omega^i} = \boldsymbol{\omega^{i-1}}\omega_i$ by concatenation
    Compute the K-vector $\boldsymbol{v^i}$ of values $M_{i+1,s}$
    Add $(\boldsymbol{\omega^i}, \boldsymbol{v^i})$ to L_i iff Elim Rule 1 doesn't apply
  end for
  for all $(\boldsymbol{\omega^i}, \boldsymbol{v^i}) \in L_i$ **do**
    From $\boldsymbol{v^i}$ compute and store the $(K-1)$-vector $\boldsymbol{u}$ of values $M_{i+1,\pi_{i+1}} - M_{i+1,s}$ for $s \neq \pi_{i+1}$
  end for
  Apply Elim Rule 2 to all pairs of entries of L_i
end for
for all $(\boldsymbol{\omega^{n-1}}, \boldsymbol{v^{n-1}}) \in L_{n-1}$ **do**
  if $M_{n,\pi_n} < \max_{s \neq \pi_n}(M_{n,s})$ **then**
    Remove $(\boldsymbol{\omega^{n-1}}, \boldsymbol{v^{n-1}})$ from L_{n-1}
  end if
end for
Return: An element of L_{n-1} or $\emptyset$ if L_{n-1} is empty.
Elim Rule 1: Eliminate $\boldsymbol{\omega^i}$ if $M_{i,\pi_i} + q^{\omega_i}_{\pi_i,\pi_{i+1}} < \max_{s \neq \pi_i}(M_{i,s} + q^{\omega_i}_{s,\pi_{i+1}})$
Elim Rule 2: Eliminate $\boldsymbol{\omega^i}$ due to $\tilde{\boldsymbol{\omega}}^{\boldsymbol{i}}$ if $\tilde{\boldsymbol{\omega}}^{\boldsymbol{i}} \in L_i$ has $(K-1)$-vector $\boldsymbol{u}$ componentwise $\geq$ that of $\boldsymbol{w^i}$

satisfy $q \geq -B$ and that there are no zero probabilities in the model. Furthermore, we assume that these q values have been rounded off to precision δ.

Under these assumptions, we can see that any two values $M_{i,s}$ and $M_{i,s'}$ satisfy $|M_{i,s} - M_{i,s'}| \leq B$. This follows from the definitions:
$M_{i,s} = \max_{s'}(M_{i-1,s'} + q^{\omega_{i-1}}_{s',s})$ and
$M_{i,s'} = \max_{s}(M_{i-1,s} + q^{\omega_{i-1}}_{s,s'})$.
Let the maximum in the expression for $M_{i,s}$ be attained with s_0. Then

$$M_{i,s'} \geq M_{i-1,s_0} + q^{\omega_{i-1}}_{s_0,s'}$$

$$= M_{i-1,s_0} + q^{\omega_{i-1}}_{s_0,s} + (q^{\omega_{i-1}}_{s_0,s'} - q^{\omega_{i-1}}_{s_0,s})$$

$$= M_{i,s} + (q^{\omega_{i-1}}_{s_0,s'} - q^{\omega_{i-1}}_{s_0,s}),$$

so that, upon rearranging,

$$M_{i,s} - M_{i,s'} \leq q^{\omega_{i-1}}_{s_0,s} - q^{\omega_{i-1}}_{s_0,s'} \leq 0 - (-B) = B,$$

and by symmetry, we also get $M_{i,s'} - M_{i,s} \leq B$, so finally, $|M_{i,s} - M_{i,s'}| \leq B$.

In particular, only $2B/\delta$ distinct values are possible for each of the $(K-1)$ possible $M_{i,\pi_i} - M_{i,s}$ values. In the branch-and-bound algorithm, it is only impossible to remove either $\boldsymbol{\omega}$ or $\tilde{\boldsymbol{\omega}}$ (both of length i) due to the other if they are incomparable: the values one gives for $M_{i,\pi_i} - M_{i,s}$ are larger for some s and smaller for some other s. But there are only $(2B/\delta)^{K-2}$ incomparable values: for two sequences that share the first $(K-2)$ $M_{i,\pi_i} - M_{i,s}$ values, any values for the last $M_{i,\pi_i} - M_{i,s}$ will make them comparable.

Therefore, in the branch-and-bound algorithm there are at most $(2B/\delta)^{K-2}$ sequence possibilities that must be retained at any stage, and so with a careful implementation the running time of the algorithm is $O((2B/\delta)^{K-2} n K^2 |\Sigma|)$. This bound is exponential in the number of states, but linear in the length of the structure to be designed. (This bound is independent of the base used to get the q values (log-probabilities), because changing the base introduces a factor into both B and δ that cancels.)

For SCFGs in CNF, a similar idea allows one to obtain an exact algorithm that runs in polynomial time if there are only 2 non-terminal symbols. However, the idea used above for candidate string elimination does not immediately generalize to SCFGs because of their non-linear nature; an HMM outputs one symbol per state, but a non-terminal in an SCFG can generally end up producing any substring of the output string.

3.3. Casting the Problem as a Mixed Integer Linear Program

We can also start with the inequalities that must be satisfied for $\boldsymbol{\omega}$ and cast the inverse problem as the problem of finding a feasible solution to a Mixed Integer Linear Program. We provide this simple formulation because it allows both practical and theoretical tools developed for integer programming to be applied directly to our problem.

The formulation as a Mixed Integer Linear Program is done by defining 0-1 variables $\epsilon_{i,j}$, where $\epsilon_{i,j} = 1$ indicates that the jth emission symbol is chosen for ω_i. Enforcing that there is only one emission choice made at every position is equivalent to requiring $\sum_j \epsilon_{i,j} = 1$ for $i = 1$ to $n-1$. Each maximum in the constraints is replaced by $\geq$, while the traceback constraints are enforced by additional equalities.

Integer Linear Program For HMMs:
Objective: Feasible Solution

Variables:
$\epsilon_{i,j}$, 0-1 valued, for $1 \leq i \leq n-1$ and $1 \leq j \leq |\Sigma|$
$M_{i,s}$, for $1 \leq i \leq n$ and $1 \leq s \leq K$

Constraints:
$\sum_j \epsilon_{i,j} = 1$ for all $1 \leq i \leq n-1$
$\epsilon_{i,j} = 0$ if $j \notin \Sigma_i$ for all $1 \leq i \leq n-1$
$M_{1,S} = 0$ and $M_{1,s} = -\infty$ for all $s \neq S$
$M_{i,s} \geq \sum_j \epsilon_{i-1,j}(M_{i-1,s'} + q^j_{s',s})$ for all s, s' and all $i \geq 2$
$M_{i,\pi_i} = \sum_j \epsilon_{i-1,j}(M_{i-1,\pi_{i-1}} + q^j_{\pi_{i-1},\pi_i})$ for all $i \geq 2$
$M_{n,s} \leq M_{n,\pi_n}$ for all $s \neq \pi_n$

4. Simulations

We implemented our branch-and-bound algorithm and examined its running time on synthetic data in order to demonstrate that in practice the algorithm frequently runs fast when an exhaustive search would be infeasible. In order to do this, we randomly generated HMMs by drawing each-transition-emission pair probability from the uniform distribution and then normalizing the values, rounding off to precision $\delta = 0.01$. We then separately generated both arbitrary state-paths and designable state-paths at random from this HMM (the latter by randomly sampling emission sequences and running the Viterbi algorithm on these sequences) and timed our branch-and-bound algorithm on these instances. We found that our algorithm ran significantly faster on arbitrary paths, the majority of which are not designable, than on arbitrary designable paths (taking milliseconds rather than seconds per run).

Figure 3 shows running times of simulations on random designable state-paths for different numbers of states K and path lengths n, with fixed emission alphabet of size $|\Sigma| = 20$. For each pair of K and n values, 10 HMMs were generated at random and for each of these HMMs, 10 designable paths were generated at random, as described above. The branch-and-bound algorithm was then run and the average time to design a sequence over these 100 runs was recorded. On these problem instances, the running time of the algorithm scales roughly linearly with path length n. Interestingly, while the running times initially increased with increasing K values, the running times were lower for $K = 50$ and $K = 100$ than for $K = 20$, an observation that was repeated for multiple experiments. The longest run of the algorithm took 80 seconds. A solution by exhaustive search would require examining $|\Sigma|^n$ possible sequences, which for that run would have

been 20^{400} sequences. All code was implemented in Matlab and run on a 3.06 GHz Intel Xeon PC.

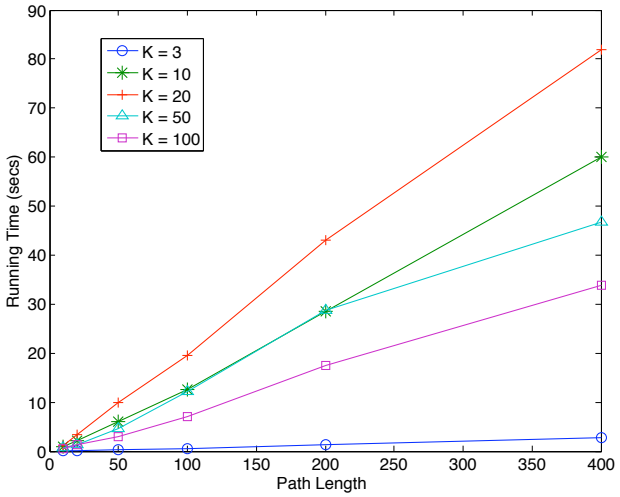

Figure 3. Running times of the branch-and-bound algorithm on designable paths. Simulations shown for number of states $K = 3$, 10, 20, 50, 100, path lengths $n = 10$, 20, 50, 100, 200, 400 and emission alphabet size $|\Sigma| = 20$.

5. Conclusions

We have introduced a novel problem on HMMs and SCFGs, the Inverse-Viterbi problem, inspired by protein and RNA structure design, and have given a number of theoretical results for the problem. In particular, our hardness result demonstrates that a polynomial time algorithm for RNA secondary structure design that only exploits the general form of the Zuker energy or similar SCFG models (and not the particulars of a specific model) is not possible unless $P = NP$.

There are a number of possible extensions to this work. Developing more efficient algorithms on both HMMs and SCFGs may be possible and in particular, extending our branch-and-bound algorithm to SCFGs would be useful. It is also possible to explore extensions of the problem to more general probabilistic models such as Markov Random Fields. The framework given here may also be useful for developing new algorithms for design in specific applications. Areas where the negative-design aspect plays a large role, such as RNA secondary structure design, are the most likely candidates to benefit from such an approach. Given the widespread use of grammars, the inverse problem we have defined here may find applications to other fields.

Compressed Sensing and Bayesian Experimental Design

Matthias W. Seeger SEEGER@TUEBINGEN.MPG.DE
Hannes Nickisch HN@TUEBINGEN.MPG.DE
Max Planck Institute for Biological Cybernetics, Spemannstr. 38, Tübingen, Germany

Abstract

We relate compressed sensing (CS) with Bayesian experimental design and provide a novel efficient approximate method for the latter, based on expectation propagation. In a large comparative study about linearly measuring natural images, we show that the simple standard heuristic of measuring wavelet coefficients top-down systematically outperforms CS methods using random measurements; the sequential projection optimisation approach of (Ji & Carin, 2007) performs even worse. We also show that our own approximate Bayesian method is able to learn measurement filters on full images efficiently which outperform the wavelet heuristic. To our knowledge, ours is the first successful attempt at "learning compressed sensing" for images of realistic size. In contrast to common CS methods, our framework is not restricted to sparse signals, but can readily be applied to other notions of signal complexity or noise models. We give concrete ideas how our method can be scaled up to large signal representations.

1. Introduction

There has been a lot of recent interest in the area of *compressed sensing* (CS) (Candès et al., 2006; Donoho, 2006), where it is argued that if signals can be expected to be compressible due to sparseness after some linear transform, then they can be reconstructed from a number of measurements significantly below the Nyquist/Shannon limit, if the measurement design is not too regular. In this paper, we relate CS to the more general notion of statistical (Bayesian) experimental design.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Through this view, characteristics of signals and algorithms, defined in an abstract mathematical way in the CS literature so far, become understandable and workable. The experimental design approach applies to signals of low complexity in general, not only to sparse ones. It has the potential to clearly outperform the randomised designs, favoured by theoretical CS arguments, in cases where signals are not well-described by common CS assumptions. For example, CS has been viewed with some scepticism so far by researchers in computer vision and image statistics (Weiss et al., 2007). While images exhibit transform sparsity to some degree, purely random measurement designs can be suboptimal for them. The reason is that there is more to low-level image statistics than sparsity. Much of this knowledge can be modeled tractably (Simoncelli, 1999) and could therefore be incorporated into a Bayesian experimental design architecture. To our knowledge, the current CS reconstruction schemes are purely estimation-based and lack proper representations of uncertainty (which is what fundamentally drives experimental design), and the theory deals exclusively with signals which are *unstructured except for random sparsity*. We present experimental results sheding more light on the relationship between CS and images. Similar to (Weiss et al., 2007), we find that standard approaches to linear image measurement (wavelet coefficients) give significantly better reconstruction results than using random measurements favoured by CS, even if modern CS reconstruction algorithms are applied. Yet, our experimental evidence is more substantial than theirs. Beyond that, we show that our efficient approximation to sequential Bayesian design can be used to learn measurements which indeed outperform measuring wavelet coefficients top-down. Our method provides a practically efficient solution to the problem posed in (Weiss et al., 2007), namely how to learn measurement filters automatically from data (using very little concrete knowledge about the signal class) which perform close to or even better than "standard" ones obtained through decades of research and experience. In contrast, the uncertain

components analysis algorithm suggested by them requires a large database of image patches to be run, and could hardly be scaled up to the realistic dimensions treated here[1].

An approximate Bayesian approach to compressed sensing has been presented in (Ji & Carin, 2007), making use of sparse Bayesian learning (SBL) (Tipping, 2001). Our method is based on a different, more general inference approximation, expectation propagation (Minka, 2001), and outperforms theirs very significantly, for prediction based on the same design and, even more so, for sequential design optimisation, as we show in comparative experiments below. Moreover, strongly underdetermined problems (many more variables than observations) are dealt with more efficiently in our framework. In addition, our framework is generalised easily to non-Gaussian observation likelihoods, skew prior terms, and generalised linear models (Gerwinn et al., 2008), and our methodology, our comparisons, as well as our discussion here have a broader scope. Our method is an extension of the scheme in (Seeger et al., 2007). However, the applications to images considered here are orders of magnitude larger than theirs, and several novel ideas are proposed here in order to increase computational efficiency substantially. While much work has been done in statistics on experimental design for the classical Gaussian-linear model, Gaussian priors are entirely inappropriate for images[2], and designs optimized for them are suboptimal (see also (Seeger et al., 2007)). We are not aware of existing methods for the model used here, which scale comparable to ours, with the exception of (Ji & Carin, 2007).

A different approach for optimising measurement design is given in (Elad, 2007), where $\boldsymbol{X}$ is designed *a priori* with the aim of making its rows maximally decoherent. In our setup, $\boldsymbol{X}$ is designed sequentially, using Bayesian information criteria.

The structure of the paper is as follows: The experimental design view on CS is detailed in Section 2. Our framework for approximate inference is described in Section 3, where we also show how to apply it to large problems, especially in sequential experimental design. Our approach is validated through a series of experiments, comparing it to (Ji & Carin, 2007) and common CS methods on artificial data (Section 4.1), and analysing the suitability of CS and Bayesian experimental design on natural images (Section 4.2).

[1]Their experiments are on 4×4 image patches, while ours run efficiently on 64×64 images.

[2]Reconstruction under the Gaussian-linear model is simply the method of least squares, often referred to as "linear reconstruction". Much of the improved performance through CS is due to the use of non-linear sparse reconstruction techniques.

2. Compressed Sensing and Experimental Design

Compressed sensing (CS) (Candès et al., 2006; Donoho, 2006) can be motivated as follows. Suppose a signal, such as an image or a sound waveform, is measured and then transferred over some channel or stored. Traditionally, the measurement obeys the Nyquist/Shannon theorem, allowing for an exact reconstruction of the (band-limited) signal if there is no measurement noise. However, what follows is usually some form of lossy compression, exploiting redundancies and non-perceptibility of losses. Given that, can the information needed for a satisfactory reconstruction not be measured below the Nyquist frequency (this is called undersampling)? In many key applications today, the measurement itself is the main bottleneck for cost reductions or higher temporal/spatial resolution. Recent theoretical results indicate that undersampling should work well if randomized designs are used, and if the signal reconstruction method specifically takes the "compressibility" into account.

Bayesian experimental design encompasses the CS problem. Here, the "compressibility" of signals is encoded in a *prior distribution*, under which signals of low complexity in general, or high (transform) sparsity in particular, have most mass. While an undersampling violates the Nyquist theorem, signals can often still be reconstructed if they are sufficiently likely under the prior. But not every way of undersampling will do. Experimental design is concerned with optimising the measurement structure (called design), so as to obtain the desired information at the lowest possible cost. This is easily explained by considering the model of interest here. Let $\boldsymbol{u} \in \mathbb{R}^n$ be latent variables (pixels of an image), and let $\boldsymbol{y} \in \mathbb{R}^m$ be noisy measurements thereof. The model class of interest is

$$P(\boldsymbol{u}|\boldsymbol{y}) \propto N(\boldsymbol{y}|\boldsymbol{X}\boldsymbol{u}, \sigma^2\boldsymbol{I}) \prod_{i=1}^{q} t_i(s_i), \quad \boldsymbol{s} = \boldsymbol{B}\boldsymbol{u}. \quad (1)$$

The likelihood $P(\boldsymbol{y}|\boldsymbol{u})$ is Gaussian and underdetermined ($n > m$). The prior[3] is a product of univariate non-Gaussian potentials $t_i(s_i)$. It is computationally advantageous, yet not essential, that the $\log t_i$ be concave (Seeger, 2008), and in this paper we use Laplacian

[3]We do not require that the prior potential is actually a normalisable distribution over $\boldsymbol{u}$, the models of interest here are of the undirected Markov random field (or "energy-based") type.

potentials

$$t_i(s_i) = \frac{\tau}{2} e^{-\tau|s_i|}, \qquad (2)$$

which are of this sort. If number of image pixels n is large, it is important for computational efficiency that matrix-vector multiplications (MVMs) with $\boldsymbol{B}$ and $\boldsymbol{B}^T$ (less important: with $\boldsymbol{X}$, $\boldsymbol{X}^T$) can be done efficiently, and that $\boldsymbol{B}$ does not have to be stored explicitly.

The unknown signal $\boldsymbol{u}$ (an image for now) should be "compressible", *i.e.* it should exhibit *transform sparsity*[4]: after some fixed linear mapping $\boldsymbol{B}$, such as a wavelet transform, $\boldsymbol{s} = \boldsymbol{B}\boldsymbol{u}$ has many coefficients s_i close to zero. An image coder would set these to exactly zero, thereby compressing the image. "Expected transform sparsity" is encoded in a sparsity prior, in our case the product of Laplacians (2). As opposed to a Gaussian, a Laplace distribution concentrates more mass close to zero, forcing coefficients to be very small. On the other hand, the Laplacian also has more mass in the tails, which allows for occasional large values. These points are explained further in (Seeger, 2008; Tipping, 2001).

Next, the design is $\boldsymbol{X}$, the measurement matrix. In our example, each row of $\boldsymbol{X}$ is a linear filter specifying a single image measurement. In this paper, we assume that all rows of $\boldsymbol{X}$ have unit norm[5]. The problem of experimental design is how to choose $\boldsymbol{X}$ among many candidates of the same cost, so that subsequent measurements allow for the best reconstruction of $\boldsymbol{u}$. This decision has to be taken *without* doing real measurements for most candidates. In a Bayesian variant, the posterior distribution $P(\boldsymbol{u}|\boldsymbol{y})$ encodes all present knowledge. To score a candidate $\boldsymbol{X}_*$ (new rows of $\boldsymbol{X}$), assume for the moment that the outcome $\boldsymbol{y}_*$ is known. We can measure the decrease in uncertainty from $P(\boldsymbol{u}|\boldsymbol{y})$ to $P(\boldsymbol{u}|\boldsymbol{y}, \boldsymbol{y}_*)$ by the *entropy difference* $\mathrm{H}[P(\boldsymbol{u}|\boldsymbol{y})] - \mathrm{H}[P(\boldsymbol{u}|\boldsymbol{y}, \boldsymbol{y}_*)]$. Not knowing $\boldsymbol{y}_*$, we integrate it out using $P(\boldsymbol{y}_*|\boldsymbol{y}) = \int P(\boldsymbol{y}_*|\boldsymbol{u}) P(\boldsymbol{u}|\boldsymbol{y})\, d\boldsymbol{u}$. This expected information score drives the optimisation of the design. It is clear that such scores are fundamentally based on the posterior as representation of uncertainty, so that algorithms which merely estimate good solutions from given data cannot be used directly in order to compute them[6]. With such methods, either rough rules of thumb have to be followed to obtain a design ("make it random" in CS), or many measurements have to be taken in a trial-and-error fashion. In Bayesian experimental design, a permanently refined uncertainty representation is used to avoid uninformative data sampling, so often many fewer real measurements are required.

3. Approximate Inference

Bayesian inference is in general not analytically tractable for models of the form (1), and has to be approximated. Moreover, the applications of interest here demand a high efficiency in many dimensions ($n = 4096$ in the natural image experiments here). Importantly, Bayesian experimental design does not only require inference just once, but many times in a sequential fashion. We make use of the *expectation propagation* (EP) method (Minka, 2001), together with a robust and efficient representation for $Q(\boldsymbol{u}) \approx P(\boldsymbol{u}|\boldsymbol{y})$. Our framework has previously been used in a different context (Seeger, 2008), where details can be found which are omitted here. As a novelty, we will show here how the framework can be run efficiently for large n, and how sequential design optimisation can be done orders of magnitude faster.

In EP, the posterior $P(\boldsymbol{u}|\boldsymbol{y})$ is approximated by a Gaussian $Q(\boldsymbol{u})$ with free (variational) parameters $\boldsymbol{b}$, $\boldsymbol{\pi}$, which are formally introduced by replacing $t_i(s_i)$ by $\tilde{t}_i(s_i) = e^{b_i s_i - \pi_i s_i^2/2}$ in (1). The distribution $Q(\boldsymbol{u})$ is represented by lower triangular $\boldsymbol{L}$ and $\boldsymbol{\gamma}$,

$$\begin{aligned} \boldsymbol{L}\boldsymbol{L}^T &= \sigma^{-2}\boldsymbol{X}^T\boldsymbol{X} + \boldsymbol{B}^T\boldsymbol{\Pi}\boldsymbol{B} = \mathrm{Cov}_Q[\boldsymbol{u}]^{-1}, \\ \boldsymbol{\gamma} &= \boldsymbol{L}^{-1}(\sigma^{-2}\boldsymbol{X}^T\boldsymbol{y} + \boldsymbol{B}^T\boldsymbol{b}),\ \boldsymbol{\Pi} = \mathrm{diag}\,\boldsymbol{\pi}, \end{aligned}$$

so that $\mathrm{E}_Q[\boldsymbol{u}] = \boldsymbol{L}^{-T}\boldsymbol{\gamma}$. The (b_i, π_i) are then updated sequentially by matching the Gaussian moments of the *tilted distributions*

$$\hat{P}_i(\boldsymbol{u}) \propto N(\boldsymbol{y}|\boldsymbol{X}\boldsymbol{u}, \sigma^2\boldsymbol{I}) \prod_{j \neq i} \tilde{t}_j(s_j) \tilde{t}_i(s_i)^{1-\eta} t_i(s_i)^{\eta}$$

with the new $Q'(\boldsymbol{u})$. Here, $\eta \in (0, 1]$ is a fractional parameter[7]. In each local update, we need to compute the non-Gaussian moments of the marginal $\hat{P}_i(s_i)$, and to update the $Q(\boldsymbol{u})$ representation, which is done by an $O(n^2)$ Cholesky update of $\boldsymbol{L}$. Note that (Ji & Carin, 2007) employ the variational mean field approximation of (Tipping, 2001), which is specific to sparse linear models (more precisely, all t_i have to be Gaussian

[4] In our experiments, we use an extended notion of sparsity, see Section 3.2.

[5] When designing $\boldsymbol{X}$, it is important to keep its rows of the same scale. Otherwise, a measurement can always be improved (at fixed noise level σ^2) simply by increasing its norm. Put differently, we place a prior on $\boldsymbol{X}$ which is uniform over all matrices with rows of unit norm.

[6] It is one thing to learn to predict well, yet a different issue to estimate its own uncertainty well, and methods employing "premature sparsification" often perform badly w.r.t. the latter (see Section 4.1).

[7] $\eta = 1$ gives standard EP, but choosing $\eta < 1$ can increase the robustness of the algorithm on the sparse linear model significantly (Seeger, 2008). We use $\eta = 0.9$ in all our experiments.

scale mixtures, thus even functions), while EP can be applied with little modification to models with skew priors or non-Gaussian skew likelihoods as well (Gerwinn et al., 2008).

In our applications of sequential design, we need to score the informativeness of new candidates $\boldsymbol{x}_*$ (as row of $\boldsymbol{X}$), which we do by the entropy difference (see Section 2). If Q' is the approximate posterior after including $\boldsymbol{x}_*$, then $2\mathrm{H}[Q'] = \log|\mathrm{Cov}_{Q'}[\boldsymbol{u}]| + C$, where Q' differs from Q in that $(\boldsymbol{X}')^T\boldsymbol{X}' = \boldsymbol{X}^T\boldsymbol{X} + \boldsymbol{x}_*\boldsymbol{x}_*^T$, and $\boldsymbol{\pi} \to \boldsymbol{\pi}'$. We approximate the entropy difference by assuming that $\boldsymbol{\pi}' = \boldsymbol{\pi}$, whence

$$\mathrm{H}[Q] - \mathrm{H}[Q'] = \frac{1}{2}\log\left(1 + \sigma^{-2}\boldsymbol{x}_*^T\mathrm{Cov}_Q[\boldsymbol{u}]\boldsymbol{x}_*\right).$$

Since $\|\boldsymbol{x}_*\| = 1$ by assumption, this score is maximized by choosing $\boldsymbol{x}_*$ along the principal (leading) eigendirection[8] of $\mathrm{Cov}_Q[\boldsymbol{u}]$. The same score is used by (Ji & Carin, 2007).

3.1. Large-Scale Applications

There are two major issues with trying to apply our method for large sizes n. First, the EP site updates are done in random sweeps over n sites, because it is not clear which particular site ordering leads to fastest convergence. This problem is severe in our sequential design application to natural images, since there are many small changes to $\boldsymbol{X}$, $\boldsymbol{y}$ (individual new measurements), after each of which EP convergence has to be regained. We approach it by forward scoring many site candidates before each EP update, thereby always updating the one which gives the largest posterior change. This is detailed just below. Second, the robust Q representation of (Seeger, 2008) is of size $O(n^2)$, and each update costs $O(n^2)$. We sketch a different representation of size $O(m^2)$ below, which can be used to drive our framework as well. In contrast, (Ji & Carin, 2007) use a heuristic of setting many of the π_i to ∞ early in the iteration, which leads to much worse results than we obtain (see Section 4.1, Section 4.2).

Our selective updating scheme for EP hinges on the fact that we can maintain all site marginals $\boldsymbol{h}$, $\boldsymbol{\rho}$, $Q(s_i) = N(h_i, \rho_i)$, up to date at all times. For a site i, we can quantify the change of Q through an update there by $\mathrm{D}[Q'(s_i)\,\|\,Q(s_i)]$ (Q' the posterior after the update at i), which can be computed in $O(1)$. Importantly, $\mathrm{D}[Q'(\boldsymbol{u})\,\|\,Q(\boldsymbol{u})] = \mathrm{D}[Q'(s_i)\,\|\,Q(s_i)]$ (because $Q(\boldsymbol{u}|s_i) = Q'(\boldsymbol{u}|s_i)$), so the score precisely measures the global amount of change $Q \to Q'$. We maintain a list of candidate sites, which are scored before each EP update, and the update is done for the winner only. The list is then evolved by replacing the lower half of worst-scoring sites by others randomly drawn from $\{1, \ldots, q\}$. Importantly, the marginals $\boldsymbol{h}$, $\boldsymbol{\rho}$ can be updated along with the representation, at the expense of only *one* additional $\boldsymbol{L}$ backsubstitution and MVM with $\boldsymbol{B}$. Namely, if $\pi_i' = \pi_i + \Delta\pi_i$, $b_i' = b_i + \Delta b_i$, and $\boldsymbol{w} := \boldsymbol{B}\boldsymbol{L}^{-T}(\boldsymbol{L}^{-1}\boldsymbol{B}_{i,\cdot}^T)$, then

$$\boldsymbol{\rho}' = \boldsymbol{\rho} - \frac{\Delta\pi_i}{1 + \rho_i\Delta\pi_i}\boldsymbol{w} \circ \boldsymbol{w}, \quad \boldsymbol{h}' = \boldsymbol{h} + \frac{\Delta b_i - h_i\Delta\pi_i}{1 + \rho_i\Delta\pi_i}\boldsymbol{w}.$$

Here, $\boldsymbol{L}^{-1}\boldsymbol{B}_{i,\cdot}^T$ has to be computed for the $\boldsymbol{L}$ update anyway. This idea is used in the experiments described in Section 4.2.

For large n, storing an $n \times n$ matrix in memory becomes prohibitive. In a less costly representation, we exploit $m \ll n$. We require[9] that $\boldsymbol{B} = \boldsymbol{I}$. The Woodbury formula gives

$$\mathrm{Cov}_Q[\boldsymbol{u}] = \boldsymbol{\Pi}^{-1} - \boldsymbol{\Pi}^{-1}\boldsymbol{X}^T\boldsymbol{L}^{-T}\boldsymbol{L}^{-1}\boldsymbol{X}\boldsymbol{\Pi}^{-1},$$

where $\boldsymbol{L}\boldsymbol{L}^T = \boldsymbol{I} + \boldsymbol{X}\boldsymbol{\Pi}^{-1}\boldsymbol{X}^T$, so $\boldsymbol{L}$ (different from above) is of size m^2 only. An EP update requires $O(m^2)$ and two MVMs with $\boldsymbol{X}$, rather than $O(n^2)$ above. While this representation is exact, it is numerically less robust to update than the $O(n^2)$ one.

3.2. Image Model. Other Methods

In this section, we provide further details about the concrete model we use in our experiments with natural images. Our prior encourages two different notions of sparsity in an image. First, a multi-scale wavelet transform of $\boldsymbol{u}$ should be sparse, modeling the observation that natural images can be compressed well in a wavelet domain. Second, the finite differences in the horizontal and vertical direction should exhibit sparsity, accounting for spatial smoothness often found in images[10]. A frequently used penalty term for the latter is the L_1 norm of the image gradient, also known as *total variation*.

Our model is an instance of (1), where all t_i are Laplacian (2). $\boldsymbol{s}$, and therefore $\boldsymbol{B}$, decompose into two different parts: $\boldsymbol{B}^T = (\boldsymbol{B}^{(sp)T}\,\boldsymbol{B}^{(tv)T})$. Equivalently, the prior is the product of two potentials. The *transform sparsity* potential is a sparsity prior on the wavelet coefficients of $\boldsymbol{u}$. Note that the Laplace distribution is a sensible candidate to fit wavelet coefficient histograms from natural images (Simoncelli, 1999). Thus,

[8] We compute $\boldsymbol{x}_*$ by the Lanczos algorithm.

[9] More generally, $\boldsymbol{B}^T\boldsymbol{\Pi}\boldsymbol{B}$ must be easy to invert. If $\boldsymbol{B}$ is invertible and $\boldsymbol{B}^{-1}$-MVM feasible, we represent $Q(\boldsymbol{s})$ rather than $Q(\boldsymbol{u})$.

[10] Recall what we mean by sparsity from Section 2: *most* coefficients are forced to be small, by allowing *some* to be large. Occasional large components in the gradient correspond to edges in the image.

$\boldsymbol{B}^{(sp)} \in \mathbb{R}^{n\times n}$ is a multi-scale orthonormal wavelet transform, and the potential is $\exp(-\tau_{sp}\|\boldsymbol{B}^{(sp)}\boldsymbol{u}\|_1)$. The *total variation* potential is a Laplace prior on the image gradient, *i.e.* the differences between horizontal and vertical pixel neighbours[11]. $\boldsymbol{B}^{(tv)} \in \mathbb{R}^{2(n-\sqrt{n})\times n}$ is a sparse structured matrix, mapping the image $\boldsymbol{u}$ to its gradient. Here, we assume that $n = 2^{2k}$ for simplicity. The total variation potential is $\exp(-\tau_{tv}\|\boldsymbol{B}^{(tv)}\boldsymbol{u}\|_1)$.

Therefore, we have $q \approx 3n$ for the size of $\boldsymbol{s}$. Also, the potentials come with different scale parameters τ_{sp}, τ_{tv}. Importantly, neither of $\boldsymbol{B}^{(sp)}$, $\boldsymbol{B}^{(tv)}$ has to be stored in memory, and MVM with $\boldsymbol{B}$ or $\boldsymbol{B}^T$ can be done in $O(n)$.

We also briefly describe the methods we compare against. Most of them come with a transform sparsity potential only, so that $\boldsymbol{s} = \boldsymbol{B}^{(sp)}\boldsymbol{u}$. The method of (Ji & Carin, 2007) is called SBL here. In L_p reconstruction, $\hat{\boldsymbol{s}} = \mathrm{argmin}\{\|\boldsymbol{s}\|_p \,|\, \boldsymbol{X}\boldsymbol{B}^{(sp)T}\boldsymbol{s} = \boldsymbol{y}\}$, $\hat{\boldsymbol{u}} = \boldsymbol{B}^{(sp)T}\hat{\boldsymbol{s}}$. For L_2 we just solve the normal equations, while for L_1 this is a linear program. Note that the latter is used in many CS publications (Candès et al., 2006; Donoho, 2006). A method with transform sparsity *and* total variation potential, called $L_1 + TV$ here, is given by the following quadratic program: $\hat{\boldsymbol{u}} = \mathrm{argmin}\, \frac{1}{2}\|\boldsymbol{y} - \boldsymbol{X}\boldsymbol{u}\|_2^2 + \tau_{sp}\sigma^2\|\boldsymbol{B}^{(sp)}\boldsymbol{u}\|_1 + \tau_{tv}\sigma^2\|\boldsymbol{B}^{(tv)}\boldsymbol{u}\|_1$ (Candès & Romberg, 2004). We used the following code in our experiments:

SBL: `www.ece.duke.edu/~shji/BCS.html`
L_1: `www.acm.caltech.edu/l1magic/`
$L_1 + TV$: `www.stanford.edu/~mlustig/`

4. Experiments

In this section, we provide experimental results for different instances of our framework, comparing to CS and approximate Bayesian methods on synthetic data (Section 4.1), and on the task of measuring natural images (Section 4.2).

4.1. Artificial Setups

It is customary in the CS literature to test methods on synthetic data, generated following the "truly sparse and otherwise unstructured" assumptions under which asymptotic CS theorems are proven. We do the same here, explicitly using the "(non-)uniform spikes" (Ji & Carin, 2007), but cover some other heavy-tailed distributions as well. It seems that not many signals of real-world interest are strictly and randomly sparse, so that studies looking at the robustness of CS theoretical claims are highly important. In this section, signals are sparse as such, so that $\boldsymbol{B} = \boldsymbol{I}$ and $\boldsymbol{u} = \boldsymbol{s}$ here. We compare methods described in Section 3.2. It is important to stress that all methods compared here (except for L_2) are based on exactly the same underlying model (1) with $\boldsymbol{B} = \boldsymbol{I}$, and differences arise only in the nature of computations (approximate Bayesian versus maximum a-posteriori optimisation) and in whether $\boldsymbol{X}$ is sequentially designed (EP, SBL) or chosen at random (L_p reconstruction; we follow CS theory (Candès et al., 2006; Donoho, 2006) and sample rows of $\boldsymbol{X}$ uniformly of unit norm). Results are shown in Figure 1.

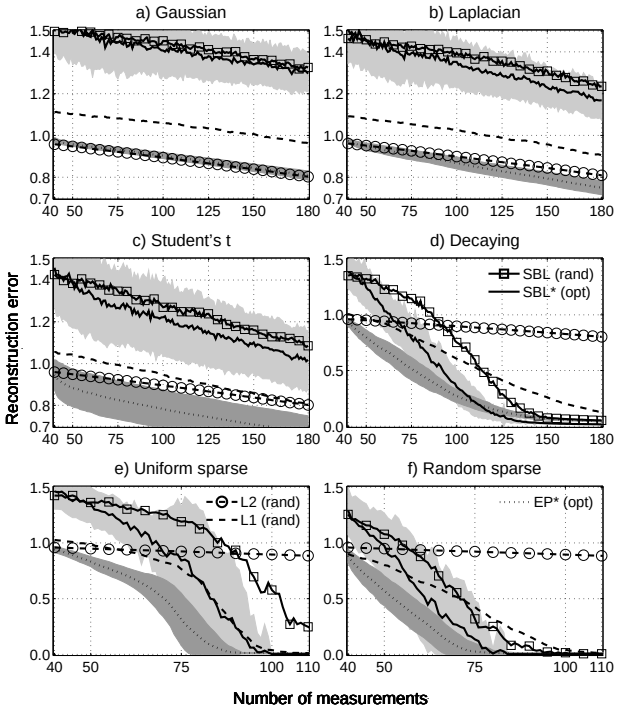

Figure 1. Comparison on 6 random synthetic signals $\boldsymbol{u} \in \mathbb{R}^{512}$. Shown are L_2-reconstruction errors (mean±std.dev. over 100 runs). All methods start with same random initial $\boldsymbol{X}$ ($m = 40$), then "(rand)" add random rows, "(opt)" optimise new rows sequentially. Noise variance $\sigma^2 = 0.005$, prior scale $\tau = 5$. SBL: (Ji & Carin, 2007), Lp: L_p reconstruction, EP: our method. (a-c): i.i.d. zero mean, unit variance Gaussian, Laplacian (Eq. 2), Student's t (3 d.o.f.). (d): $\frac{n}{2}$ of $u_i = 0$, $\frac{n}{4}$ exponential decay $1, \ldots, 0$, $\frac{n}{4}$ minus that, randomly permuted. (e-f): 20 $u_i \neq 0$ at random; (e) uniform spikes, $u_i \in \{\pm 1\}$; (f): non-uniform spikes, $u_i \sim \frac{1}{4} + |t|$, $t \sim N(0, 1)$; as in (Ji & Carin, 2007). Distributions in (d-f) normalised to unit variance.

The "sparsity" (or super-Gaussianity) of the signal distributions increases from (1a) to (1e-f). For Gaussian signals (1a), L_2 reconstruction based on random measurements is optimal. While all CS methods and SBL

[11] This potential on its own is not normalisable as distribution over $\boldsymbol{u}$, being invariant against adding a constant to all pixels.

(random and designed) lead to large errors, EP with design matches the L_2 results, thus shows robust behaviour. For Laplacian and Student's t signals (1b-c), designed EP outperforms L_2 reconstruction significantly, while even the CS L_1 method still does worse than simple least squares. SBL performs poorly in all three cases with signals not truly sparse, thus is not robust against rather modest violations of the strict CS assumptions. Its non-robustness is also witnessed by large variations across trials.

On the other hand, L_2 performs badly on truly sparse signals. In all cases (1d-f), EP with design significantly outperforms all other methods, including designed SBL, with special benefits at rather small numbers of measurements. SBL does better now with truly sparse signals, and is able to outperform L_1.

From the superior performance of EP with design on all signal classes, we conclude that experimental design can sequentially find measurements that are significantly better than random ones, even if signals are truly sparse. Moreover, the superior performance is robust against large deviations away from the underlying model, more so even than classical L_1 or L_2 estimation. The poor performance of SBL (Ji & Carin, 2007) seems to come from their desire for "premature sparsification". During their iterations, many π_i are clamped to $+\infty$ early for efficiency reasons. This does not hurt mean predictions from current observations much, but affects their covariance approximation drastically: most directions not supported by the data right now are somewhat ruled out for further measurements, since posterior variance along them (which should be large!) is shrunk in their method. In contrast, in our EP method, none of the π_i become very large with modest m, and our covariance approximation seems good enough to successfully drive experimental design. Without premature sparsification, our scheme is still efficient, since the most relevant site updates are found actively, and the need to eliminate variables does not arise.

4.2. Natural Images

In this section, we are concerned about finding linear filters which allow for good reconstruction of natural images from noisy measurements thereof. Since natural images exhibit sparsity in wavelet or Fourier domains, CS theory seems to suggest that random measurements should be well-suited for this purpose, and there have been considerable efforts to develop hardware which can perform such random measurements cost-efficiently (Duarte et al., 2008). On the other hand, much is known about low level natural image statistics, and powerful linear measurement transforms have emerged there, such as multi-scale wavelet transforms, based on which natural image reconstruction should be substantial better than for random measurements (Weiss et al., 2007).

The sparsity of images in a wavelet domain is highly structured, there is a clear ordering among the coefficients from coarse to fine scales: natural images typically have much more energy in the coarse-scale coefficients, and coefficients with very small values are predominantly found in the fine scales. In our experiments, we employ a simple heuristic for linearly measuring images, called *wavelet heuristic* in the sequel: every measurement computes a single wavelet coefficient, and the sequential ordering of the measurements is deterministic top-down, from coarse to fine scales[12]. This ordering is a pragmatic strategy: if mainly the coarse-scale coefficients are far from zero, they should be measured first[13]. Do state-of-the-art CS reconstruction algorithms, based on random linear image measurements, perform better than simple L_2 reconstruction based on the wavelet heuristic? And how does Bayesian sequential design perform on this task, if the model described in Section 3.2 is used? Note that no prior knowledge about typical ordering or dependence among wavelet coefficients in encoded in this model either. Results of our study are given in Figure 2.

In fact, we started our exploration with what is shown in (2a), where 100 initial filters are drawn at random (except for L_2(heur)). Intrigued by the fact that the wavelet heuristic method L_2(heur) outperformed all CS variants significantly, we tried to give them a head-start, supplying $m = 100, 200, 400$ wavelet heuristic measurements initially (2b-d). However, the systematic under-performance of methods which have sparsity regularizers built in, yet do *random* rather than wavelet measurements, remains consistently present. From these results we conclude, much as (Weiss et al., 2007) argued on theoretical grounds, that if natural images are to be measured successively by unit norm, but otherwise unconstrained linear filters, then *drawing these filters at random leads to significantly worse*

[12]This ordering follows the recursive definition of such transforms: downsampling by factor two (coarse), horizontal differences, vertical differences, diagonal corrections at each stage. Our ordering is coarse → horizontal → vertical → diagonal, descending just as the transform does.

[13]Note that another problem with common CS assumptions applied to images is that the typical scale of coefficients along a coarse-to-fine ordering follows a smooth power law, it does not exhibit the abrupt drop from "significantly above noise level" to "exactly zero" often required by CS theory.

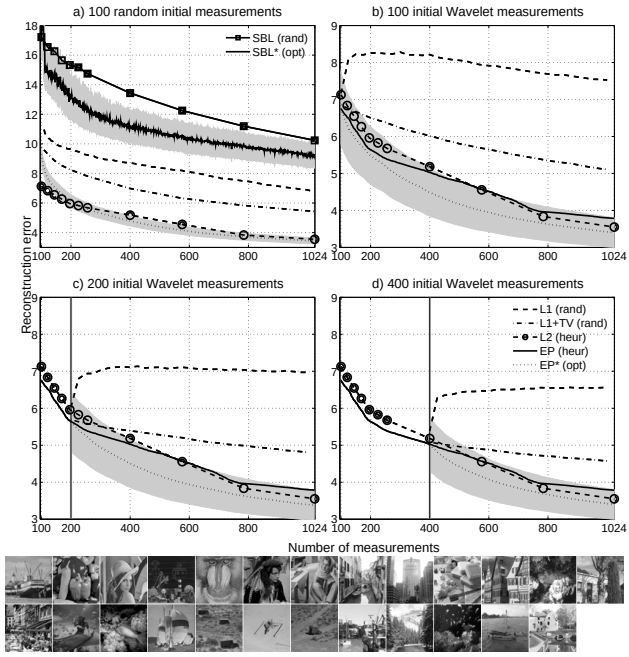

Figure 2. Experiments for measuring natural images ($64 \times 64 = 4096$ pixels). Shown are L_2-reconstruction errors averaged over 25 grayscale images typically used in computer vision research (from `decsai.ugr.es/cvg/dbimagenes/`) ($\pm\frac{1}{4}$std.dev. for "$*$"). Noise level $\sigma^2 = 0.005$. SBL: (Ji & Carin, 2007), Lp: L_p reconstruction, $L_1 + \mathrm{TV}$: Lasso with TV/wavelet penalties, EP: our method. True σ^2 supplied, τ parameters chosen optimally for each method individually: $\tau_{sp} = \tau_{tv} = 0.075$ ($L_1 + \mathrm{TV}$), $\tau_{sp} = 0.075$, $\tau_{tv} = 0.5$ (EP). New rows of $\boldsymbol{X}$ random unit norm (rand), actively designed (opt), acc. to wavelet heuristic (heur).
(a): Start with $m = 100$, $\boldsymbol{X}$ random unit norm. (b-d): Start with $m = 100, 200, 400$, $\boldsymbol{X}$ acc. to wavelet heuristic.

reconstructions than using standard wavelet coefficient filters top-down. While CS theorems are mathematically intriguing, and while there certainly are important applications that benefit from these results[14], linear image measurement is probably not among them.

On the other hand, the wavelet heuristic method is significantly outperformed by our EP method, where $\boldsymbol{X}$ is designed sequentially. In (2a), EP quickly recovers from the suboptimal initial random $\boldsymbol{X}$. Moreover, even when started from the same point as the wavelet heuristic (2b-d), the designed measurements lead to improvements over the heuristic immediately. EP(heur) is doing EP reconstruction, but based on the same measurements as L_2(heur). While it slightly outperforms L_2 reconstruction, the significant difference is due to the choice of the measurements. Our method therefore provides an efficient solution to the problem posed in (Weiss et al., 2007), namely how to learn measurements automatically from data, starting from little concrete domain knowledge. On the particular problem of measuring images linearly, our findings should be put into perspective, by noting that the L_2 wavelet heuristic is vastly faster to compute[15]. Moreover, $\boldsymbol{X}$ is optimised sequentially, particular to the image $\boldsymbol{u}$ (but without knowing the underlying $\boldsymbol{u}$), while the wavelet heuristic filters are always the same. Finally, the final $\boldsymbol{X}$ is is dense and unstructured. However, our method can be used in the same way to address applications where strong structural constraints on allowable $\boldsymbol{X}$ are present, and where wavelet (or purely random) measurements are not an option.

In this setting, SBL (Ji & Carin, 2007) performs much worse than all other methods tried, whether using random, wavelet or designed measurements. Results for SBL in cases (b-d) were even worse and are not included to facilitate comparison among the others. This is most probably an extreme instance of the problem noted in Section 4.1. Premature sparsification, in light of not strictly sparse signals, leads to poor results even with random $\boldsymbol{X}$. Their covariance estimates seem too bad to steer sequential design in a useful direction[16].

Finally, the deterioration of L_1, when adding random to initial wavelet measurements, is somewhat puzzling, especially since it does not happen for $L_1 + \mathrm{TV}$. These additional measurements provide novel information about the true $\boldsymbol{u}$, so a valid inference method should rather improve.

5. Discussion

We have shown how to address the compressive sensing problem with Bayesian experimental design, where designs are optimised to rapidly decrease uncertainty and do not have to be chosen at random. In a large study

[14]The theoretical CS setting is more extreme than what is really required here, in that there is no prior knowledge about where the non-zeros will lie. We speculate that more suitable applications could lie in steganography, spam or intrusion detection, where a signal has to be detected which has been hidden by an adversary.

[15]EP sequential design is still very efficient. A typical run on one image took 53 min (on 64bit 2.33GHz AMD), for $n = 4096$ and $q = 12160$ sites: 16785 initial EP updates, then 308 increments of $\boldsymbol{X}$ by 3 rows each, with on average only 8.8 site updates needed to regain EP convergence (up to 85 updates after *some* increments).

[16]In cases (b-d), top wavelet coefficients are measured initially, so their method confidently starts with a highly over-sparse solution and fails. Note that, as opposed to EP, we restarted the SBL code after each new measurement, so that poor current solutions are not inherited when new data is obtained.

about linearly measuring natural images, we show that CS reconstruction methods based on randomly drawn filters are outperformed significantly by standard least squares reconstruction measuring coarse-scale wavelet coefficients. Our findings suggest that the applicability of CS results (with their insistence on strict and unstructured signal sparsity) to natural image applications should be reconsidered. We also show that our Bayesian sequential design method, starting from a model with little domain knowledge built in, is able to find filters with significantly better reconstruction properties than top-down wavelet coefficients. Our findings indicate that efficient Bayesian experimental design techniques are highly promising for CS applications of different kinds just as well.

Why do random measurement filters enjoy good properties in CS theory, but are not useful in the case of natural images? We think that this seeming contradiction really comes from an erroneous "extrapolation" of what CS theorems really mean. Any structure apart from a randomly distributed sparsity pattern is ignored there. Also, they are *minimax* results, in that the reconstruction error for the worst sparsity pattern is bounded. But undersampled image reconstruction is not a worst-case problem, and much is known about the sparsity structure of natural images. It may be that L_1 or $L_1 + TV$ are minimax methods (for known $\boldsymbol{B}$), but that does not imply much about their *typical* performance. We suspect that our doubts about CS with random measurements extend beyond natural images to other signals of common interest in normal non-adversarial situations, since interest in a signal class implies that statistical knowledge about them beyond random sparsity has been obtained.

Our experience with the method of (Ji & Carin, 2007), which we compare against in our study, raises another more speculative, yet interesting point. Several methods very frequently used in machine learning today can loosely be summarised as trying to detect very sparse solutions early on, mainly with the aim of high computational efficiency. For example, SBL (Tipping, 2001) is much more aggressive in this respect than our EP method here. Early sparsification does not seem to hurt mean prediction performance much, and thus is embraced for efficiency. However, our experiences here indicate that it is the *covariance* (or uncertainty) estimates that can be badly hurt by such sparsity-by-elimination processes, and that in contexts such as experimental design, where covariances are more important than predictive means, their application should probably be avoided. The challenge is then to develop methods that run efficiently *without* eliminating many variables early on, and our selective site updating method for EP is a step in that direction.

Abstract

We derive a generalization bound for multi-classification schemes based on grid clustering in categorical parameter product spaces. Grid clustering partitions the parameter space in the form of a Cartesian product of partitions for each of the parameters. The derived bound provides a means to evaluate clustering solutions in terms of the generalization power of a built-on classifier. For classification based on a single feature the bound serves to find a globally optimal classification rule. Comparison of the generalization power of individual features can then be used for feature ranking. Our experiments show that in this role the bound is much more precise than mutual information or normalized correlation indices.

1. Introduction

Clustering is one of the basic tools for dimensionality reduction in categorical spaces. In this paper we study classifiers based on a soft grid clustering of categorical parameter product spaces. The grid clustering is defined by a set of stochastic mappings $\{q_i : \mathcal{X}_i \mapsto \{1, .., m_i\}\}$, one for each parameter i, which map the possible values $\mathcal{X}_i$ of the parameter X_i to a reduced set C_i of size m_i. A classifier based on the grid clustering then assigns a separate prediction strategy to each partition cell. For example, in collaborative filtering we can cluster a thousand by thousand space of viewers by movies into a five by five space of viewer clusters by movie clusters (here X_1 are the viewers and X_2 are the movies). Then we can predict a missing entry within some partition cell with an average of ratings in that cell.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Grid clustering or some other form of dimensionality reduction can be helpful and even essential when the sample size is limited. However, an appropriate choice of clustering resolution is crucial for good results. A coarse clustering may be highly imprecise - think of the extreme of putting all the data into one big cluster. On the other hand, a fine clustering may be statistically unreliable - at the opposite extreme, if we put every parameter value into a separate cluster, some parameter combinations may not occur in the training set at all. Thus, unification of parameter values amplifies the statistical reliability, but reduces the precision. In this paper we relate this tradeoff to generalization properties of a classifier based on the clustering.

Applications of grid clustering to data with intrinsically categorical features are abundant. Seldin, Slonim and Tishby (2007) consider grid clustering from an MDL perspective and demonstrate its success in predicting missing values in the context of collaborative filtering. The same work achieves state of the art performance in terms of coherence of obtained clusters with manual annotation in the context of gene expression and stock data analysis. Here we also suggest a new application of grid clustering for feature ranking.

We are not aware of any previous work on generalization properties of models based on grid clustering. A somewhat related work is (Srebro, 2004), which derives a generalization bound for matrix approximation with bounded norm factorization. However, matrix factorization is a different model and the proof is based on a different technique (Rademacher complexities).

The key point of this paper is a derivation of a generalization bound for classification based on grid clustering. The bound is derived by using the PAC-Bayesian technique (McAllester, 1999). The power of the PAC-Bayesian technique lies in its ability to handle heterogeneous hypothesis classes so that the generalization bound for a specific hypothesis depends on the complexity of that hypothesis rather than on the complexity of the whole class. A classical example of an appli-

cation of the PAC-Bayesian bound are SVMs (Langford, 2005). It is well known that the VC-dimension of separating hyperplanes in $\mathbb{R}^n$ is $n+1$. As well, the VC-dimension of separating hyperplanes with a margin γ, assuming all points are bounded in a unit sphere, is $min\{\frac{1}{\gamma^2}, n\} + 1$. The ability to slice the hypothesis space into infinitely many subspaces characterized by a finer notion of complexity (the size of the margin) rather than the coarse VC-dimension of the whole class makes it possible to derive a better bound that remains meaningful even for infinite dimensional spaces.

In this paper we propose a fine measure of complexity of a grid partition of a cardinal space. The proposed measure of complexity is related to the entropy of a partition along each dimension i. The bound enables us to consider all possible partitions of the product space and to choose one with better generalization properties. In the case of a single parameter it is easy to find a global optimum of the bound. The mapping rule achieving the optimum is shown to be the optimal classification rule from a generalization point of view. Although the bound is not perfectly tight, its shape follows an error on a validation set extremely well. In the experimental section we apply the bound to feature ranking and it is shown to be much more precise than standard mutual information or normalized correlation rankings.

2. A Brief Review of the PAC-Bayesian Generalization Bound

To set the stage, we start with a simplified version of the PAC-Bayesian bound, called Occam's razor. Let $\mathcal{H}$ be a countable hypothesis space. For a hypothesis $h \in \mathcal{H}$ denote by $L(h)$ an expected and by $\hat{L}(h)$ an empirical loss of h. We assume the loss is bounded by b.

Theorem 1 (Occam's razor)**.** *For any data generating distribution and for any "prior distribution" $P(h)$ over $\mathcal{H}$ with a probability greater than $1-\delta$ over drawing an i.i.d. sample of size N, for all $h \in \mathcal{H}$:*

$$L(h) \leq \hat{L}(h) + b\sqrt{\frac{-\ln P(h) - \ln \delta}{2N}}. \qquad (1)$$

Proof. The proof is fairly simple and provides a good illustration of what the "prior distribution" $P(h)$ is. By Hoeffding's inequality $P\{L(h) - \hat{L}(h) \geq \varepsilon(h)\} \leq e^{-2N\varepsilon(h)^2/b^2}$ for any given $h \in \mathcal{H}$. We require that $e^{-2N\varepsilon(h)^2/b^2} \leq P(h)\delta$ for some prior $P(h)$ that satisfies $\sum_{h\in\mathcal{H}} P(h) = 1$. Then, by the union bound $L(h) \leq \hat{L}(h) + \varepsilon(h)$ for all $h \in \mathcal{H}$ with a probability of $1-\delta$. The minimal value of ε that satisfies the requirement is $\varepsilon(h) = b\sqrt{\frac{-\ln P(h) - \ln \delta}{2N}}$, which completes the proof.

We now introduce the notion of a randomized classifier. Let Q be any (posterior) distribution over $\mathcal{H}$. A randomized classifier associated with Q works by choosing a new classifier h from $\mathcal{H}$ according to Q every time a classification is made. We denote the loss of a strategy Q by $L(Q) = \mathbb{E}_{h\sim Q} L(h)$ and similarly $\hat{L}(Q) = \mathbb{E}_{h\sim Q}\hat{L}(h)$. By taking an expectation of (1) over the choice of h and exploiting the concavity of the square root we obtain that with a probability greater than $1-\delta$:

$$L(Q) \leq \hat{L}(Q) + b\sqrt{\frac{-\mathbb{E}_{h\sim Q}\ln P(h) - \ln \delta}{2N}}. \qquad (2)$$

The PAC-Bayesian bound (McAllester, 1999) was derived to allow uncountably infinite hypothesis spaces, though in our case the hypothesis space is finite. We cite a slightly tighter version of the bound proved in (Maurer, 2004).

Theorem 2 (PAC-Bayesian Bound)**.** *For any data distribution and for any "prior" P over $\mathcal{H}$ fixed ahead of training with a probability greater than $1-\delta$ for all distributions Q over $\mathcal{H}$:*

$$L(Q) \leq \hat{L}(Q) + b\sqrt{\frac{D(Q\|P) + \frac{1}{2}\ln(4N) - \ln \delta}{2N}}, \qquad (3)$$

where $D(Q\|P) = \mathbb{E}_{h\sim Q} \ln \frac{Q(h)}{P(h)}$ is the Kullback-Leibler (KL) divergence between the distributions Q and P.

If the loss function is bounded by one (1), (2), and (3) may be written in the form of a bound on the KL-divergence between $\hat{L}(Q)$ and $L(Q)$. For example, (1) may be obtained as: $D(\hat{L}(h)\|L(h)) \leq \frac{-\ln P(h) - \ln \delta}{N}$ if we start from the $P\{L(h) - \hat{L}(h) \geq \varepsilon\} \leq e^{-ND(L(h)+\varepsilon\|L(h))}$ form of Hoeffding's inequality. This provides a better bound in cases when $\hat{L}(Q)$ is sufficiently small (less than $\frac{1}{8}$). The choice of the square root form of the bounds is based on their easier analytical tractability for subsequent minimization.

By writing $D(Q\|P) = -H(Q) - \mathbb{E}_{h\sim Q}\ln P(h)$ it is easy to see that (3) is an improvement over (2) when $H(Q) > \frac{1}{2}\ln(4N)$. In our experiments (2) is usually tighter. It is an open question whether $\frac{1}{2}\ln(4N)$ can be removed from (3), at least in the case of a countable $\mathcal{H}$. For example, (Blanchard & Fleuret, 2007) suggest a parameterized tradeoff $\frac{k+1}{k}D(Q\|P) + \ln(k+1) + 3.5 + \frac{1}{2k}$ instead of $D(Q\|P) + \frac{1}{2}\ln(4N)$. For our data the tradeoff does not improve the results and therefore we omit its discussion.

3. A Formal Definition of Grid Clustering

Before proceeding to the results we provide a formal definition of grid clustering as used in this paper.

Definition 1. Grid Clustering *of the parameter space* $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ *is a set of distributions* $q_i(C_i|X_i)$ *defining the probability of mapping* $X_i \in \mathcal{X}_i$ *to* $C_i \in \{1, .., m_i\}$. *If each of* $q_i(C_i|X_i)$ *is deterministic, we call the clustering a* deterministic grid clustering. *Otherwise it is a* stochastic grid clustering.

In the following sections we assume some unknown joint probability distribution $p(Y, X_1, .., X_d)$ of the parameters and the label exists. The set of all possible labels is denoted by $\mathcal{Y}$ and its size is denoted by n_y. The size of $\mathcal{X}_i$ is denoted by n_i. The cardinality of C_i is m_i. The value of each m_i can vary in the range of $1 \leq m_i \leq n_i$ for different partitions. A hypothesis h in a *deterministic* grid clustering is comprised of a set of deterministic mappings $q_i(C_i|X_i)$, for simplicity denoted by $q_i(X_i) : \mathcal{X}_i \to \{1, .., m\}$, and a set of $\prod_i m_i$ labels, one for each partition cell. We denote the hypothesis space by $\mathcal{H}$ and decompose it as $\mathcal{H} = \mathcal{H}|_1 \times .. \times \mathcal{H}|_d \times \mathcal{H}|_{\mathcal{Y}|\bar{m}}$. Here $\mathcal{H}|_i$ is a space of all possible partitions of $\mathcal{X}_i$, or, in other words, a projection of $\mathcal{H}$ onto dimension i. $\bar{m} = (m_1, .., m_d)$ is a vector of cardinalities of the partitions along each dimension and $\mathcal{H}|_{\mathcal{Y}|\bar{m}}$ is a space of all possible labelings of $\prod_i m_i$ partition cells. Similarly, $h \in \mathcal{H}$ is decomposed as $h = h|_1 \times .. \times h|_d \times h|_{y|\bar{m}}$. It is assumed that a loss function $l : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}^+$ is given. The loss of h, denoted by $L(h)$, is defined as an expectation over p of L: $L(h) = \mathbb{E}_p l(h(X_1, .., X_d), Y(X_1, .., X_d))$. The empirical loss of h on a sample S of size N is denoted by $\hat{L}(h)$ and equals the average loss on the sample.

For stochastic mappings $q_i(C_i|X_i)$ it is assumed that a random realization of the mapping is done prior to the prediction. In other words, we choose a hypothesis h at random by determining the values of $q_i(X_i)$ according to $q_i(C_i|X_i)$ before we make a prediction. $Q = \left\{\{q_i(C_i|X_i)\}_{i=1}^d, q(Y|C_1, .., C_d)\right\}$ collectively denotes a distribution over $\mathcal{H}$ associated with a randomized classifier called Q. The loss of Q is denoted by $L(Q)$ and equals $L(Q) = \mathbb{E}_{h\sim Q} L(h)$. The empirical loss of Q is denoted by $\hat{L}(Q)$.

We define $q_i(C_i) = \frac{1}{n_i} \sum_{x_i} q_i(C_i|x_i)$ to be a marginal distribution over C_i corresponding to a *uniform* distribution over $\mathcal{X}_i$ and the conditional distribution $q_i(C_i|X_i)$ of our choice. The entropy of a partition along a dimension i with respect to a uniform distribution over $\mathcal{X}_i$ is then $H_U(q_i) \equiv H_U(C_i) = -\sum_{c_i} q_i(c_i) \ln q_i(c_i)$. The mutual information between X_i and C_i with respect to a uniform distribution over $\mathcal{X}_i$ is $I_U(X_i; C_i) = \frac{1}{n_i} \sum_{x_i, c_i} q_i(c_i|x_i) \ln[q_i(c_i|x_i)/q_i(c_i)]$.

4. Generalization Bound for Multi-Classification with Grid Clustering

In this section we state and prove a generalization bound for multi-classification with stochastic grid clustering:

Theorem 3. *For any probability measure* p *over instances and for any loss function* l *bounded by* b, *with a probability of at least* $1-\delta$ *over a selection of an i.i.d. sample* S *of size* N *according to* p, *for all randomized classifiers* $Q = \left\{\{q_i(C_i|X_i)\}_{i=1}^d, q(Y|C_1, .., C_d)\right\}$:

$$L(Q) \leq \hat{L}(Q) + b\sqrt{\frac{\sum_i n_i H_U(C_i) + K}{2N}}, \qquad (4)$$

$$K = \sum_i (m_i \ln n_i + \frac{(\ln(n_i) + 1)^2}{4}) + (\prod_i m_i) \ln n_y - \ln \delta. \qquad (5)$$

It is also possible to replace (4) in the theorem with:

$$L(Q) \leq \hat{L}(Q) + b\sqrt{\frac{\sum_i n_i I_U(X_i; C_i) + \frac{1}{2}\ln(4N) + K}{2N}}. \qquad (6)$$

Proof. The bounds (4) and (6) are direct consequences of (2) and (3) respectively for an appropriate choice of a prior P over $\mathcal{H}$. The main part of the proof is to define a prior P that will provide a meaningful complexity-related slicing of $\mathcal{H}$ and then to calculate $-\mathbb{E}_Q \ln P(h)$ for (4) and $D(Q\|P)$ for (6).

To define the prior P over $\mathcal{H}$ we count the hypotheses in $\mathcal{H}$. For a fixed partition there are $n_y^{\prod_i m_i}$ possibilities to assign the labels to the partition cells. There are n_i possibilities to choose the number of clusters along a dimension i. There are at most $\binom{n_i+m_i-1}{m_i-1} \leq n_i^{m_i-1}$ possibilities to choose a cluster cardinality profile along a dimension i. (This is the number of possibilities to place $m_i - 1$ ones in a sequence of $n_i + m_i - 1$ ones and zeros, where ones symbolize a partition of zeros ("balls") into m_i bins.) We take the $n_i^{m_i-1}$ bound for simplicity. For a fixed cardinality profile $|c_{i1}|, .., |c_{im_i}|$ (over a single dimension) there are $\binom{n_i}{|c_{i1}|, .., |c_{im_i}|}$ possibilities to assign X_i-s to the clusters. This multinomial coefficient can be bounded from above by $e^{n_i H_U(C_i)}$ (see (Cover & Thomas, 1991, page 284) for an elegant proof). Putting all the combinatorial calculations together it is possible to define a distribution $P(h)$ over

$\mathcal{H}$ that satisfies:

$$P(h) \geq \frac{1}{\exp\left[\sum_i \left(n_i H_U(C_i) + m_i \ln n_i\right) + \left(\prod_i m_i\right) \ln n_y\right]}. \quad (7)$$

We pause to stress that unlike in most applications of the PAC-Bayesian bound, in our case the prior P and the posterior Q are defined over slightly different hypothesis spaces. The posterior Q is defined for *named* clusterings - we explicitly specify for each X_i the "name" of C_i it is mapped to. Whereas the prior P is defined over *unnamed* partitions - we only check the cardinality profile of C_i, but we cannot recover which X_i-s are mapped to a given C_i. Nevertheless, the "named" distribution Q induces a distribution over the "unnamed" space by summing up over all possible name permutations. This enables us to compute $-\mathbb{E}_Q \ln P(h)$ we need for the bound.

We now turn to bound $-\mathbb{E}_Q \ln P(h)$. This is done by showing that Q is concentrated around the hypotheses (hard partitions) h for which the entropies of the partitions are close to the entropies $H_U(q_i)$. By the decomposition property we can write: $P(h) = P(h|_1)..P(h|_d)P(h|_{y|\bar{m}})$, and similarly for Q. Then $-\mathbb{E}_Q \ln P(h) = -\sum_i \mathbb{E}_Q \ln P(h|_i) - \mathbb{E}_Q \ln P(h|_{y|\bar{m}})$, and similarly for $D(Q\|P)$. The last term is easy to compute since P is uniform over $\mathcal{H}_{\mathcal{Y}|\bar{m}}$ and Q is defined for a fixed $\bar{m}$. Therefore, $-\mathbb{E}_Q \ln P(h|_{y|\bar{m}}) = \left(\prod_i m_i\right) \ln n_y$. For the first d terms we need to compute or at least to bound $Q(h|_i)$.

Recall that $h|_i$ is obtained from Q by drawing a cluster C_i for each $X_i \in \mathcal{X}_i$ independently according to the distribution $q_i(C_i|X_i)$. Let $\hat{q}_i = \{\frac{|c_{i1}|}{n_i}, .., \frac{|c_{im_i}|}{n_i}\}$ denote an empirical cluster cardinality profile along a dimension i obtained by such assignment. Then:

$$\mathbb{E}_{q_i} H(\hat{q}_i) = H_U(q_i) - \mathbb{E}_{q_i} D(\hat{q}_i \| q_i) \leq H_U(q_i), \quad (8)$$

where $H(\hat{q}_i) = -\sum_{c_i} \hat{q}(c_i) \ln \hat{q}(c_i)$ and $D(\hat{q}_i\|q_i) = \sum_{c_i} \hat{q}_i(c_i) \ln \frac{\hat{q}_i(c_i)}{q_i(c_i)}$. And also:

$$P_{q_i}\left\{H(\hat{q}_i) - \mathbb{E}H(\hat{q}_i) \geq \varepsilon\right\} \leq e^{-2n_i\varepsilon^2/(\ln(n_i)+1)^2}. \quad (9)$$

The latter inequality follows from the fact that the empirical entropy $H(\hat{q}_i)$ satisfies a bounded differences property with a constant equal to $\frac{1}{\ln(n_i)+1}$. See (Paninski, 2003) for a more detailed proof of (8) and (9).

Now, if $\hat{q}_i$ is the cardinality profile of $h|_i$, then $Q(h|_i) = Q(\hat{q}_i) \equiv P_{q_i}\{\hat{q}_i\}$. Let $\varepsilon(\hat{q}_i) = \max\{0, H(\hat{q}_i) - H_U(q_i)\}$. Since $H(\hat{q}_i) - H_U(q_i) \leq H(\hat{q}_i) - \mathbb{E}H(\hat{q}_i)$ by (8), from (9) we have: $Q(\hat{q}_i) \leq e^{-2n_i\varepsilon(\hat{q}_i)^2/(\ln(n_i)+1)^2}$. Thus:

$$-\mathbb{E}_Q \ln P(h|_i) = -\sum_{h|_i \in \mathcal{H}|_i} Q(h|_i) \ln P(h|_i)$$

$$= \sum_{h|_i \in \mathcal{H}|_i} Q(\hat{q}_i)(n_i H(\hat{q}_i) + m_i \ln n_i)$$

$$= \sum_{h|_i \in \mathcal{H}|_i} Q(\hat{q}_i)[n_i H_U(q_i) + m_i \ln n_i + n_i(H(\hat{q}_i) - H_U(q_i))]$$

$$\leq n_i H_U(q_i) + m_i \ln n_i + \sum_{h|_i \in \mathcal{H}|_i} Q(\hat{q}_i) n_i \varepsilon(\hat{q}_i)$$

$$\leq n_i H_U(q_i) + m_i \ln n_i + \sum_{h|_i \in \mathcal{H}|_i} n_i \varepsilon(\hat{q}_i) e^{\frac{-2n_i\varepsilon(\hat{q}_i)^2}{(\ln(n_i)+1)^2}}$$

$$\leq n_i H_U(q_i) + m_i \ln n_i + \int_0^\infty n_i \varepsilon e^{-2n_i\varepsilon^2/(\ln(n_i)+1)^2} d\varepsilon$$

$$= n_i H_U(C_i) + m_i \ln n_i + \frac{1}{4}(\ln(n_i)+1)^2.$$

This completes the proof of (4).

For (6) what remains is to compute $\mathbb{E}_Q \ln Q(h|_i)$. To do so we bound $\ln Q(\hat{q}_i)$ from above. The bound follows from the fact that if we draw n_i values of C_i according to $q_i(C_i|X_i)$ the probability of the resulting type $\hat{q}_i$ is bounded from above by $e^{-n_i H_U(C_i|X_i)}$, where $H_U(C_i|X_i) = -\frac{1}{n_i}\sum_{x_i,c_i} q_i(c_i|x_i) \ln q_i(c_i|x_i)$ (see Theorem 12.1.2 in (Cover & Thomas, 1991)). Thus $\mathbb{E}_Q \ln Q(h|_i) \leq -n_i H_U(C_i|X_i)$, which together with the identity $I_U(X_i;C_i) = H_U(C_i) - H_U(C_i|X_i)$ completes the proof of (6).

5. An Optimal Solution for a Single Feature and Feature Ranking

In this section we show that if there is only one parameter X (i.e., $d = 1$) a globally optimal (from a generalization point of view) classification rule may be efficiently found by examining the "direct" mappings $q(Y|X)$. In other words, for a single parameter there is no need for intermediate clustering. The obtained result is used in the applications section for feature ranking. It is shown there that the bound follows extremely well the shape of the true error of a classifier based on a single feature and is much more precise than mutual information or normalized correlation indices.

To prove the optimality of direct mappings we start with the observation that for any clustering C a classification rule $q(Y|X)$ defined as

$$q(y|x) = \sum_c q(c|x) q(y|c) \quad (10)$$

achieves the same loss as the loss of a hypothesis h based on the clustering C. Therefore, the space of all direct mappings $q(Y|X)$ incorporates all possible solutions that may be achieved via intermediate clustering. It remains to show that the generalization power of the

direct mappings is not worse than the generalization power of clustering-based solutions and that the global optimum may be efficiently found.

To analyze the generalization power of a direct mapping we define n_y clusters c_y, one for each label $y \in \mathcal{Y}$, i.e., $C_y = \{c_y : y \in \mathcal{Y}\}$. All instances x mapped to a cluster c_y obtain the label y. Thus the clustering C_y is identified with the labeling Y, in particular $q(C_y|X) = q(Y|X)$, and we can replace $H_U(C_y)$ in (4) with $H_U(Y)$ and $I_U(X;C_y)$ in (6) with $I_U(X;Y)$. Moreover, in our construction there are only $(n_y!)$ possibilities to assign the labels to the clusters and not $n_y^{n_y}$ as in the case of general clustering. In addition, the cardinality of C_y is fixed at n_y and does not change from 1 to n, where n is the cardinality of X. This further reduces a $\ln(n)$ factor from the bound. Thus, the definition of K in (5) is improved to:

$$K_y = \ln[\binom{n+n_y-1}{n_y-1}] + \frac{(\ln n + 1)^2}{4} + \ln(n_y!) - \ln\delta. \tag{11}$$

(We used the tighter bound $\binom{n+n_y-1}{n_y-1}$ instead of n^{n_y-1} on the number of partitions.) And we get:

$$L(Q) \le \hat{L}(Q) + b\sqrt{\frac{nH_U(Y) + K_y}{2N}} \tag{12}$$

instead of (4) and

$$L(Q) \le \hat{L}(Q) + b\sqrt{\frac{nI_U(X;Y) + K'_y}{2N}} \tag{13}$$

instead of (6) for $K'_y = K_y + \frac{1}{2}\ln(4N)$.

For any other clustering C the direct mapping $q(Y|X)$ defined by (10) satisfies $I_U(X;C) \ge I_U(X;Y)$ by the information processing inequality (Cover & Thomas, 1991). Furthermore, since in $\mathcal{H}$ every partition cell gets a single label, $H_U(Y|C) = 0$. Therefore, $H_U(Y) \le H_U(C)$ because $H_U(Y) = H_U(Y) - H_U(Y|C) = I_U(C;Y) = H_U(C) - H_U(C|Y) \le H_U(C)$. Adding the fact that the empirical losses are equal for the clustering-based classification and the associated direct mapping we obtain that both (12) and (13) for the direct mapping are tighter than (4) and (6) for the corresponding clustering solution.

We can further optimize (13) by looking for an optimal classification rule $q^*(Y|X)$ that minimizes it. The minimum is achieved by iteration of the following self-consistent equations, where $\hat{p}(x,y)$ is the empirical joint distribution of X and Y (the derivation is done by taking a derivative of the bound with respect to $q(Y|X)$ and is omitted due to lack of space):

$$q(y|x) = \frac{q(y)}{Z(x)} e^{-\frac{2}{b}\left(\sum_{y'} \hat{p}(x,y')l(y',y)\right)\sqrt{2N(nI_U(X;Y)+K'_y)}}, \tag{14}$$

$q(y) = \frac{1}{n}\sum_x q(y|x)$, $Z(x) = \sum_y q(y|x)$, and $I_U(X;Y) = \frac{1}{n}\sum_{x,y} q(y|x)\ln[q(y|x)/q(y)]$. Although $\sqrt{I_U(X;Y)}$ is not necessarily convex, in our experiments the iterations always converged to a global optimum. It is also possible to optimize a parameterized tradeoff $\hat{L}(Q) + \beta I_U(X;Y)$, which is convex since both mutual information $I_U(X;Y)$ and the empirical loss $\hat{L}(Q)$ are convex with respect to $q(Y|X)$. A linear search over β then leads to a global optimum of (13).

Note that the direct mapping is no longer optimal when there is more than one parameter. For example, for two parameters X_1, X_2, each with a cardinality n, the conditional distribution $p(Y|X_1,X_2)$ is defined over the product space of size $n^2 n_y$. This requires at least an order of $n^2 n_y$ samples - a number quadratic in n - for the direct inference to be possible. However, from (4) and (6) it follows that with grid clustering for relatively small cluster cardinalities m_i it may be possible to achieve reliable estimations when the sample size N is linear in n. This is further discussed in the next section.

A related bound for generalization in prediction by a single feature is suggested in (Sabato & Shalev-Shwartz, 2007). Sabato and Shalev-Shwartz designed an estimator for the loss of a prediction rule based on the empirical frequencies $q_{emp}(y|x) = \hat{p}(y|x)$. They prove that their estimate is at most $O(\frac{\ln(N/\delta)\sqrt{\ln(1/\delta)}}{\sqrt{N}})$ far from the generalization error of q_{emp}. Compared to their work, a strong advantage of bounds (12) and (13) is that they hold for any prediction rule $q(Y|X)$. In particular, they hold for the maximum likelihood prediction $q_{ml}(x) = \arg\max_y \hat{p}(y|x)$ that performs much better than q_{emp} in practice.

6. A Bound for Estimation of a Joint Probability Distribution in Grid Clustering

For a fixed set of mappings $\{q_i(C_i|X_i)\}$ denote by $p(Y,\bar{C})$ the joint probability distribution of Y and $\bar{C}$, where $\bar{C}$ stays for $\langle C_1,..,C_d\rangle$ for brevity. Denote by $\hat{p}(Y,\bar{C})$ its empirical counterpart. Clearly, $p(Y,\bar{C})$ is determined by $p(Y,X_1,..,X_d)$ and the set $\{q_i(C_i|X_i)\}$. In this section we bound the deviation between $p(Y,\bar{C})$ and its empirical estimation.

Theorem 4. *For any probability measure p over instances and an i.i.d. sample S of size N according to p, with a probability of at least $1-\delta$ for all grid clusterings $Q = \{q_i(C_i|X_i)\}_{i=1}^d$ the following holds:*

$$D(\hat{p}(Y,\bar{C})\|p(Y,\bar{C})) \le \frac{\sum_i n_i H_U(C_i) + K_2}{N} \tag{15}$$

$$K_2 = \sum_i \left(m_i \ln n_i + \frac{(\ln(n_i)+1)^2}{4} \right) + n_y \left(\prod_i m_i \right) \ln(N+1) - \ln \delta. \quad (16)$$

Proof. The proof is based on the law of large numbers cited below (Cover & Thomas, 1991).

Theorem 5 (The Law of Large Numbers)**.** *Let $Z_1, .., Z_N$ be i.i.d. distributed by $p(Z)$. Then:*

$$P\{D(\hat{p}(Z)\|p(Z)) > \varepsilon\} \leq e^{-N\varepsilon + |Z| \ln(N+1)}, \quad (17)$$

where $|Z|$ stays for the cardinality of Z.

Note that the cardinality of the random variable $\langle Y, \bar{C} \rangle$ is $n_y \prod_i m_i$. For the proof of theorem 4 we require that the right hand side of (17) be smaller than $P(h)\delta$. Application of a union bound and reversion of the requirement on ε bounds $D(\hat{p}(Y,\bar{C})\|p(Y,\bar{C}))$ for the case of hard partitions by $\frac{n_y(\prod_i m_i)\ln(N+1) - \ln(P(h)\delta)}{N}$ for all h. Since $D(p\|q)$ is convex in the pair (p,q) (Cover & Thomas, 1991, Theorem 2.7.2), for soft partitions $D(\hat{p}(Y,\bar{C})\|p(Y,\bar{C}))$ is bounded from above by $\mathbb{E}_Q \frac{n_y(\prod_i m_i)\ln(N+1) - \ln(P(h)\delta)}{N}$. The calculation of $-\mathbb{E}_Q \ln P(h)$ done earlier completes the proof.

Applying the inequality relating the L_1 norm and the KL divergence $\|P_1 - P_2\|_1 \leq \sqrt{2D(P_1\|P_2)}$ (see (Cover & Thomas, 1991)) we obtain a bound on the variational distance.

Corollary 1. *Under the conditions of theorem 4:*

$$\|p(Y,\bar{C}) - \hat{p}(Y,\bar{C})\|_1 \leq \sqrt{\frac{2\left(\sum_i n_i H_U(C_i) + K_2\right)}{N}} \quad (18)$$

7. Generalization Bound for the Logarithmic Loss in Grid Clustering

The goal of this section is to provide a bound on the logarithmic loss $-\mathbb{E}\ln\hat{p}(Y|\bar{C}) = -\sum_{y,\bar{c}} p(y,\bar{c}) \ln \hat{p}(y|\bar{c})$. This loss corresponds to the prediction (and compression) power of the hypothesis. Since *ln* is an unbounded function and $\hat{p}(y|c)$ is not bounded from zero, we define a smoothed distribution:

$$p^*(y|\bar{c}) = \frac{\hat{p}(y|\bar{c}) + \gamma}{n_y\gamma + 1},$$

where $\gamma > 0$ is the smoothing parameter. To complete the definition: $p^*(\bar{c}) = \hat{p}(\bar{c})$ and $p^*(y,\bar{c}) = p^*(\bar{c})p^*(y|\bar{c})$. Instead of proving the bound for $\hat{p}$ it will be proved for p^*:

$$-\mathbb{E}\ln p^*(Y|\bar{C}) = -\sum_{y,\bar{c}} p(y,\bar{c}) \ln p^*(y|\bar{c})$$

$$= \sum_{y,\bar{c}} (\hat{p}(y,\bar{c}) - p(y,\bar{c})) \ln p^*(y|\bar{c}) - \sum_{y,\bar{c}} \hat{p}(y,\bar{c}) \ln p^*(y|\bar{c})$$

$$\leq \frac{1}{2}\|p(Y,\bar{C}) - \hat{p}(Y,\bar{C})\|_1 \ln \frac{n_y\gamma + 1}{\gamma} - \sum_{y,\bar{c}} \hat{p}(y,\bar{c}) \ln(\hat{p}(y|\bar{c}) + \gamma) + \ln(n_y\gamma + 1) \quad (19)$$

$$\leq \varepsilon \ln \frac{n_y\gamma + 1}{\gamma} - \sum_{y,\bar{c}} \hat{p}(y,\bar{c}) \ln \hat{p}(y|\bar{c}) + \ln(n_y\gamma + 1)$$

$$= \hat{H}(Y|\bar{C}) + \varepsilon \ln \frac{1}{\gamma} + (\varepsilon + 1)\ln(n_y\gamma + 1), \quad (20)$$

where inequality (19) is justified by (18) and ε is defined as half of its right hand side. $\hat{H}(Y|\bar{C})$ stays for the empirical estimation of the entropy of Y given $\bar{C}$. Equation (20) is minimized for $\gamma = \frac{\varepsilon}{n_y}$, when we get:

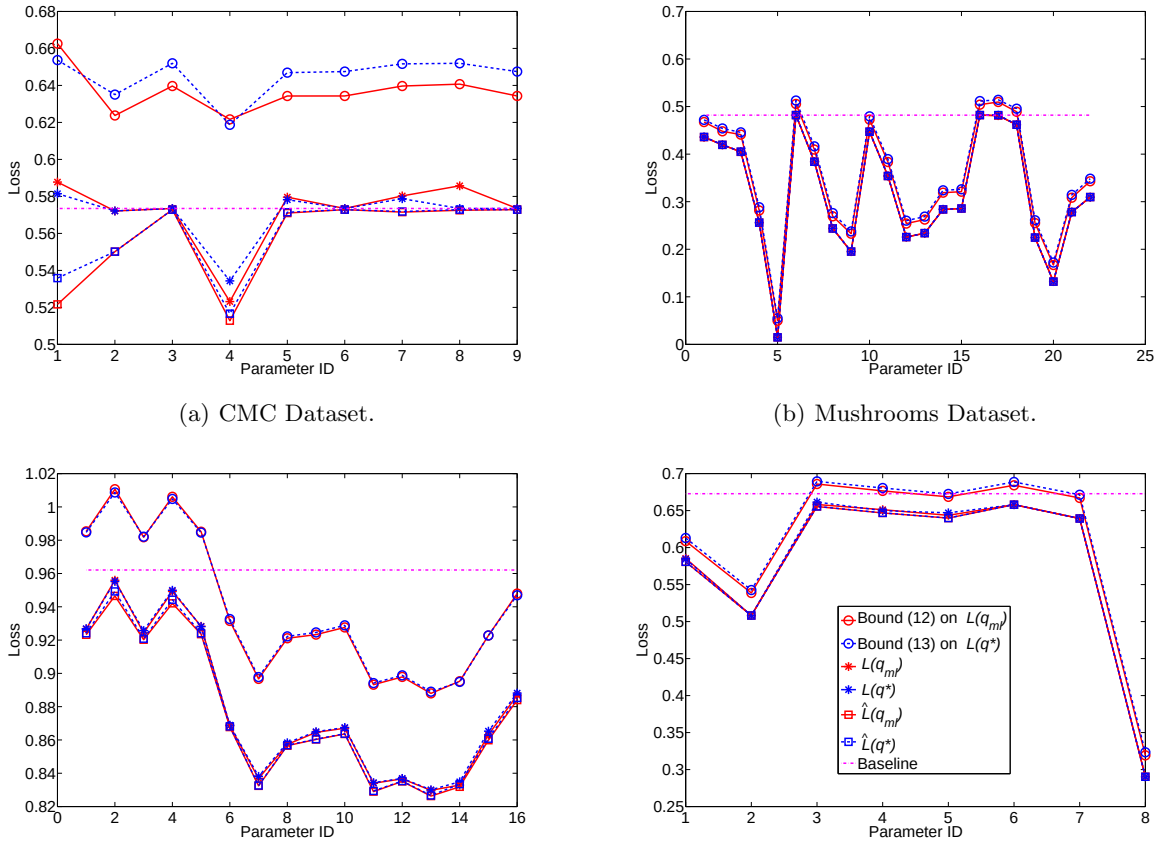
$$-\mathbb{E}\ln p^*(Y|\bar{C}) \leq \hat{H}(Y|\bar{C}) + \varepsilon \ln \frac{n_y}{\varepsilon} + (\varepsilon + 1)\ln(\varepsilon + 1). \quad (21)$$

One natural application of the bound (21) to be studied in future work is to the broadly used "bag-of-words" models, where a decision is made based on multiple observations with the conditional independence assumption on the observations given the label. For example, in the bag of words model for document classification by topic we assume that the words are independent given a topic (the label Y). There is a single parameter X coming from the space of all words, but the classification is based on multiple observations of this parameter - all words in the document. Since we have a single parameter we can resort to the direct mappings $q(Y|X)$, as in section 5. Usually, a topic that maximizes the log likelihood of all the words in a document is assigned. After simple algebraic manipulations this can be translated to maximization of a sum of $\ln[q(y|x)]$ over the document (up to correct normalization by $\ln[q(y)]$), which is directly related to the expectation bounded in (21).

A related work in this context (Shamir, Sabato & Tishby, 2008) uses some different techniques to derive a bound for $|H(Y|C) - \hat{H}(Y|C)|$. We note that $H(Y|C) = -\mathbb{E}\ln p(Y|C)$ is the minimal logarithmic loss that could be achieved if we knew the true joint distribution $p(Y,C)$. Thus, (Shamir et al., 2008) give a lower bound on the performance of any prediction model based on grid clustering, whereas (21) is an upper bound on the performance of the prediction strategy $p^*(Y|\bar{C})$.

8. Applications

In this section we provide a series of applications of the bounds (12) and (13) to prediction by a single feature



(a) CMC Dataset.

(b) Mushrooms Dataset.

(c) Letters Dataset.

(d) Nursery Dataset

Figure 1. **Application of bounds (12) and (13).** This figure displays an application of bounds (12) and (13) to the four datasets discussed in text. The legend in subfigure (d) corresponds to all the graphs. The graphs contain the training loss $\hat{L}(q_{ml})$, the test loss $L(q_{ml})$ and the value of the bound (12) for the maximum likelihood prediction rule $q_{ml}(x) = \arg\max_y \hat{p}(y|x)$. A second triplet on the graphs corresponds to $\hat{L}(q^*)$, $L(q^*)$, and the value of the bound (13) for the prediction rule $q^*(Y|X)$ that minimizes (13). Baseline corresponds to the performance level that can be achieved by predicting the test labels using a marginal distribution of Y on the train set. All the calculations are done per parameter. For better visibility of the points they have been connected with lines, but the lines have no meaning.

and feature ranking, as suggested in section 5. We use (12) to bound the generalization error of the maximum likelihood classification rule. For zero-one loss the maximum likelihood rule $q_{ml}(X)$ returns for each value of x the most frequent value of Y that appeared with that x in the sample: $q_{ml}(x) = \arg\max_y \hat{p}(y|x)$. We also use the iterations (14) to find a classification rule $q^*(Y|X)$ that minimizes (13).

The experiments were conducted on four datasets obtained at the UCI Machine Learning Repository: Contraceptive Method Choice (CMC), Mushrooms, Letters and Nursery. In all the experiments we use 5 random partitions of the data into 80% train and 20% test subsets. Table 1 provides a short summary of the main parameters of the datasets. See (Asuncion & Newman, 2007) for a full description.

Figure 1 shows the training loss and the test loss of the maximum likelihood classification rule $q_{ml}(Y|X)$ for the four datasets considered. We stress that the maximum likelihood rule is calculated per parameter; actually there are d maximum likelihood rules $q_{ml}(Y|X_i)$, one for each parameter i of a given problem. Along with the test loss we draw the value of the bound (12). Note that the bound is quite tight and follows the shape of the test loss remarkably well in all the cases. The gap between the bound and the test loss is less than 0.1.

The same figure includes an additional triplet of lines - training loss, test loss, and the bound (13) value - corresponding to the $q^*(Y|X)$ classification rule that minimizes (13). The performance of q^* is very close to the performance of q_{ml} and the value of (13) is very

Table 1. **Description of the datasets:** for every set we give the number of features, d, a list of cardinalities of the features, n_i, the number of labels, n_y, and a train set size, N, which is 80% of a dataset size.

DATA SET	d	n_i-S	n_y	N
CMC	9	34, 4, 4, 15, 2, 2, 4, 4, 2	3	1,178
MUSHROOMS	22	6, 4, 10, 2, 9, 2, 2, 2, 12, 2, 5, 4, 4, 9, 9, 1, 4, 3, 5, 9, 6, 7, 2	2	6,499
LETTERS	16	16 FOR ALL n_i-S	26	16,000
NURSERY	8	3, 5, 4, 4, 3, 2, 3, 3	5	10,368

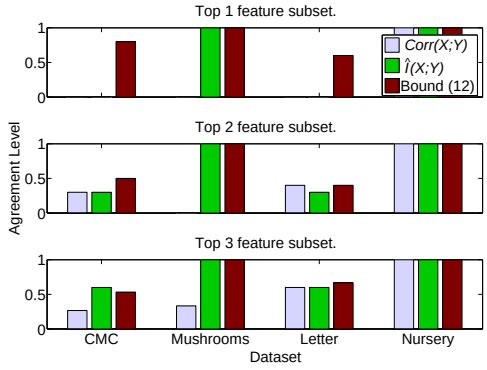


Figure 2. **Feature Ranking.** Agreement of $Corr(X;Y)$, $\hat{I}(X;Y)$, and the bound (12) with the test set on the top-1, top-2, and top-3 feature subsets.

close to the value of (12) with a small advantage to q_{ml} and (12) on average.

We conclude this section by comparing the bound (12) applied to feature ranking with the standard empirical mutual information $\hat{I}(X;Y) = \sum_{x,y} \hat{p}(x)\hat{p}(y|x) \ln \frac{\hat{p}(y|x)}{\hat{p}(y)}$ and the normalized correlation coefficient $Corr(X;Y) = \frac{Cov(X,Y)}{\sqrt{Var(X)Var(Y)}}$ indices. We compare agreement between the top-1, top-2, and top-3 parameter subsets suggested by the indices with the corresponding test-based sets - Figure 2. For the top-1 choice (the best single parameter) our bound is clearly superior - it provides a significant level of success in two cases where the other two indices completely fail. For the top-2 choice there is a slight advantage over the mutual information and a clear advantage over the normalized correlation. In top-3 the bound performs similarly to the mutual information and is still superior to the normalized correlation.

9. Discussion

This paper derives generalization bounds for multi-classification based on grid clustering. The bounds enable evaluation of clustering solutions based on generalization properties of a built-on classifier. We acknowledge that the $(\prod_i m_i) \ln n_y$ term in the bounds limits their applicability to relatively few dimensional problems. Nevertheless, this domain contains enough challenges such as feature ranking, where our bounds are especially tight, collaborative filtering and many more. An interesting direction for future work would be to extend the applicability of the approach to higher dimensions by utilizing dependencies between the parameters.

SVM Optimization: Inverse Dependence on Training Set Size

Abstract

We discuss how the runtime of SVM optimization should **decrease** as the size of the training data increases. We present theoretical and empirical results demonstrating how a simple subgradient descent approach indeed displays such behavior, at least for linear kernels.

1. Introduction

The traditional runtime analysis of training Support Vector Machines (SVMs), and indeed most runtime analysis of training learning methods, shows how the training runtime *increases* as the training set size increases. This is because the analysis views SVM training as an optimization problem, whose size increases as the training size increases, and asks "what is the runtime of finding a very accurate solution to the SVM training optimization problem?". However, this analysis ignores the underlying goal of SVM training, which is to find a classifier with low generalization error. When our goal is to obtain a good predictor, having more training data at our disposal should not increase the runtime required to get some desired generalization error: If we can get a predictor with a generalization error of 5% in an hour using a thousand examples, then given ten thousand examples we can always ignore nine thousand of them and do exactly what we did before, using the same runtime. But, can we use the extra nine thousand examples to get a predictor with a generalization error of 5% in *less* time?

In this paper we begin answering the above question. But first we analyze the runtime of various SVM optimization approaches in the data-laden regime, i.e. given unlimited amounts of data. This serves as a basis to our investigation and helps us compare different optimization approaches when working with very large data sets. A similar type of analysis for unregularized linear learning was recently presented by Bottou and Bousquet (2008)—here we handle the more practically relevant case of SVMs, although we focus on linear kernels.

We then return to the finite-data scenario and ask our original question: How does the runtime required in order to get some desired generalization error change with the amount of available data? In Section 5, we present both a theoretical analysis and a thorough empirical study demonstrating that, at least for linear kernels, the runtime of the subgradient descent optimizer PEGASOS (Shalev-Shwartz et al., 2007) does indeed decrease as more data is made available.

2. Background

We briefly introduce the SVM setting and the notation used in this paper, and survey the standard runtime analysis of several optimization approaches. The goal of SVM training is to find a linear predictor $\mathbf{w}$ that predicts the label $y \in \pm 1$ associated with a feature vector $\mathbf{x}$ as $\mathrm{sign}(\langle \mathbf{w}, \mathbf{x} \rangle)$. This is done by seeking a predictor with small empirical (hinge) loss relative to a large classification "margin". We assume that instance-label pairs come from some source distribution $P(\mathbf{X}, Y)$, and that we are given access to labeled examples $\{(\mathbf{x}_i, y_i)\}_{i=1}^m$ sampled i.i.d. from P. Training a SVM then amounts to minimizing, for some regularization parameter λ, the regularized empirical hinge loss:

$$\hat{f}_\lambda(\mathbf{w}) = \hat{\ell}(\mathbf{w}) + \frac{\lambda}{2} \|\mathbf{w}\|^2 \qquad (1)$$

where $\hat{\ell}(\mathbf{w}) = \frac{1}{m} \sum_i \ell(\mathbf{w}; (\mathbf{x}_i, y_i))$ and $\ell(\mathbf{w}; (\mathbf{x}, y)) = \max\{0, 1 - y \langle \mathbf{w}, \mathbf{x} \rangle\}$ is the hinge loss. For simplicity, we do not allow a bias term. We say that an optimization method finds an ϵ-accurate solution $\tilde{\mathbf{w}}$ if $\hat{f}_\lambda(\tilde{\mathbf{w}}) \leq \min_{\mathbf{w}} \hat{f}_\lambda(\mathbf{w}) + \epsilon$.

Instead of being provided with the feature vectors directly, we are often only provided with their inner products through a kernel function. Our focus here is on "linear kernels", i.e. we assume we are indeed provided with the feature vectors themselves. This scenario is natural in several applications, including document analysis where the bag-of-words vectors provide a sparse high dimensional representation that does not necessarily benefit from the kernel trick. We use d to denote the dimensionality of the feature

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

vectors. Or, if the feature vectors are sparse, we use d to denote the average number of non-zero elements in each feature vector (e.g. when input vectors are bag-of-words, d is the average number of words in a document).

The runtime of SVM training is usually analyzed as the required runtime to obtain an ϵ-accurate solution to the optimization problem $\min_{\mathbf{w}} \hat{f}_\lambda(\mathbf{w})$.

Traditional optimization approaches converge linearly, or even quadratically, to the optimal solution. That is, their runtime has a logarithmic, or double logarithmic, dependence on the optimization accuracy ϵ. However, they scale poorly with the size of the training set. For example, a naïve implementation of interior point search on the dual of the SVM problem would require a runtime of $\Omega(m^3)$ per iteration, with the number of iterations also theoretically increasing with m. To avoid a cubic dependence on m, many modern SVM solvers use "decomposition techniques": Only a subset of the dual variables is updated at each iteration (Platt, 1998; Joachims, 1998). It is possible to establish linear convergence for specific decomposition methods (e.g. Lin, 2002). However, a careful examination of this analysis reveals that the number of iterations before the linearly convergent stage can grow as m^2. In fact, Bottou and Lin (2007) argue that any method that solves the dual problem very accurately might in general require runtime $\Omega(dm^2)$, and also provide empirical evidence suggesting that modern dual-decomposition methods come close to a runtime of $\Omega(dm^2 \log(1/\epsilon))$. Therefore, for the purpose of comparison, we take the runtime of dual-decomposition methods as $O(dm^2 \log 1/\epsilon)$.

With the growing importance of handling very large data sets, optimization methods with a more moderate scaling on the data set size were presented. The flip side is that these approaches typically have much worse dependence on the optimization accuracy. A recent example is SVM-Perf (Joachims, 2006), an optimization method that uses a cutting planes approach for training linear SVMs. Smola et al. (2008) showed that SVM-Perf can find a solution with accuracy ϵ in time $O(md/(\lambda\epsilon))$.

Although SVM-Perf does have a much more favorable dependence on the data set size, and runs much faster on large data sets, its runtime still increases (linearly) with m. More recently, Shalev-Shwartz et al. (2007) presented PEGASOS, a simple stochastic subgradient optimizer for training linear SVMs, whose runtime does not at all increase with the sample size. PEGASOS is guaranteed to find, with high probability, an ϵ-accurate solution in time[1] $\tilde{O}(d/(\lambda\epsilon))$. Empirical comparisons show that PEGASOS is considerably faster than both SVM-Perf and dual decomposition methods on large data sets with sparse, linear, kernels (Shalev-Shwartz et al., 2007; Bottou, Web Page).

These runtime guarantees of SVM-Perf and PEGASOS are not comparable with those of traditional approaches: the runtimes scale better with m, but worse with ϵ, and also depend on λ. We will return to this issue in Section 4.

3. Error Decomposition

The goal of supervised learning, in the context we consider it, is to use the available training data in order to obtain a predictor with low generalization error (expected error over future predictions). However, since we cannot directly observe the generalization error of a predictor, the training error is used as a surrogate. But in order for the training error to be a good surrogate for the generalization error, we must restrict the space of allowed predictors. This can be done by restricting ourselves to a certain hypothesis class, or in the SVM formulation studied here, minimizing a combination of the training error and some regularization term.

In studying the generalization error of the predictor minimizing the training error on a limited hypothesis class, it is standard to decompose this error into:

- The **approximation error**— the minimum generalization error achievable by a predictor in the hypothesis class. The approximation error does not depend on the sample size, and is determined by the hypothesis class allowed.
- The **estimation error**—the difference between the approximation error and the error achieved by the predictor in the hypothesis class minimizing the training error. The estimation error of a predictor is a result of the training error being only an estimate of the generalization error, and so the predictor minimizing the training error being only an estimate of the predictor minimizing the generalization error. The quality of this estimation depends on the training set size and the size, or complexity, of the hypothesis class.

A similar decomposition is also possible for the somewhat more subtle case of regularized training error minimization, as in SVMs. We are now interested in the generalization error $\ell(\hat{\mathbf{w}}) = \mathbf{E}_{(\mathbf{X},Y)\sim P}\left[\ell(w;\mathbf{X},Y)\right]$ of the predictor $\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \hat{f}_\lambda(\mathbf{w})$ minimizing the training objective (1). Note that for the time being we are only concerned with the (hinge) loss, and not with the misclassification error, and even measure the generalization error in terms of the hinge loss. We will return to this issue in Section 5.2.

- The approximation error is now the generalization error $\ell(\mathbf{w}^*)$ achieved by the predictor $\mathbf{w}^* = \arg\min_{\mathbf{w}} f_\lambda(\mathbf{w})$ that minimizes the *regularized* gen-

[1] The $\tilde{O}(\cdot)$ notation hides logarithmic factors.

eralization error:

$$f_\lambda(\mathbf{w}) = \ell(\mathbf{w}) + \frac{\lambda}{2}\|\mathbf{w}\|^2 .$$

As before, the approximation error is independent of the training set or its size, and depends on the regularization parameter λ. This parameter plays a role similar to that of the complexity of the hypothesis class: Decreasing λ can decrease the approximation error.

- The estimation error is now the difference between the generalization error of $\mathbf{w}^*$ and the generalization error $\ell(\hat{\mathbf{w}})$ of the predictor minimizing the training objective $\hat{f}_\lambda(\mathbf{w})$. Again, this error is a result of the training error being only an estimate of the generalization error, and so the training objective $\hat{f}_\lambda(\mathbf{w})$ being only an estimate of the regularized loss $f_\lambda(\mathbf{w})$.

The error decompositions discussed so far are well understood, as is the trade-off between the approximation and estimation errors controlled by the complexity of the hypothesis class. In practice, however, we do not minimize the training objective exactly and so do not use the mathematically defined $\hat{\mathbf{w}}$. Rather, we use some optimization algorithm that runs for some finite time and yields a predictor $\tilde{\mathbf{w}}$ that only minimizes the training objective $\hat{f}_\lambda(\mathbf{w})$ to within some accuracy ϵ_{acc}. We should therefore consider the decomposition of the generalization error $\ell(\tilde{\mathbf{w}})$ of this predictor. In addition to the two error terms discussed above, a third error term now enters the picture:

- The **optimization error** is the difference in generalization error between the actual minimizer of the training objective and the output $\tilde{\mathbf{w}}$ of the optimization algorithm. The optimization *error* is controlled by the optimization *accuracy* ϵ_{acc}: The optimization accuracy is the difference in the training objective $\hat{f}_\lambda(\mathbf{w})$ while the optimization error is the resulting difference in generalization error $\ell(\tilde{\mathbf{w}}) - \ell(\hat{\mathbf{w}})$.

This more complete error decomposition, also depicted in Figure 1, was recently discussed by Bottou and Bousquet (2008). Since the end goal of optimizing the training error is to obtain a predictor $\tilde{\mathbf{w}}$ with low generalization error $\ell(\tilde{\mathbf{w}})$, it is useful to consider the entire error decomposition, and the interplay of its different components.

Before investigating the balance between the data set size and runtime required to obtain a desired generalization error, we first consider two extreme regimes: one in which only a limited training set is available, but computational resources are not a concern, and the other in which the training data available is virtually unlimited, but computational resources are bounded.

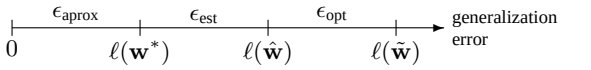

Figure 1. Decomposition of the generalization error of the output $\tilde{\mathbf{w}}$ of the optimization algorithm: $\ell(\tilde{\mathbf{w}}) = \epsilon_{\text{aprx}} + \epsilon_{\text{est}} + \epsilon_{\text{opt}}$.

empirical error	$\hat{\ell}(\mathbf{w}) = \frac{1}{m}\sum_{(\mathbf{x},y)\in S}\ell(\mathbf{w};(\mathbf{x},y))$
generalization error	$\ell(\mathbf{w}) = \mathbf{E}\left[\ell(\mathbf{w};\mathbf{X},Y)\right]$
SVM objective	$\hat{f}_\lambda(\mathbf{w}) = \hat{\ell}(\mathbf{w}) + \frac{\lambda}{2}\|\mathbf{w}\|^2$
Expected SVM obj.	$f_\lambda(\mathbf{w}) = \ell(\mathbf{w}) + \frac{\lambda}{2}\|\mathbf{w}\|^2$
Reference predictor	$\mathbf{w}_0$
Population optimum	$\mathbf{w}^* = \arg\min_{\mathbf{w}} f_\lambda(\mathbf{w})$
Empirical optimum	$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \hat{f}_\lambda(\mathbf{w})$
ϵ_{acc}-optimal predictor	$\tilde{\mathbf{w}}$ s.t. $\hat{f}_\lambda(\tilde{\mathbf{w}}) \le \hat{f}_\lambda(\hat{\mathbf{w}}) + \epsilon_{\text{acc}}$

3.1. The Data-Bounded Regime

The standard analysis of statistical learning theory can be viewed as an analysis of an extreme regime in which training data is scarce, and computational resources are plentiful. In this regime, the optimization error diminishes, as we can spend the time required to optimize the training objective very accurately. We need only consider the approximation and estimation errors. Such an analysis provides an understanding of the sample complexity as a function of the target error: how many samples are necessary to guarantee some desired error level.

For low-norm (large-margin) linear predictors, the estimation error can be bounded by $O\left(\frac{\|\mathbf{w}^*\|}{\sqrt{m}}\right)$ (Bartlett & Mendelson, 2003), yielding a sample complexity of $m = O\left(\frac{\|\mathbf{w}^*\|^2}{\epsilon^2}\right)$ to get a desired generalization error of $\ell(\mathbf{w}^*) + \epsilon$ (tighter bounds are possible under certain conditions, but for simplicity and more general applicability, here we stick with this simpler analysis).

3.2. The Data-Laden Regime

Another extreme regime is the regime in which we have virtually unlimited data (we can obtain samples on-demand), but computational resources are limited. This is captured by the PAC framework (Valiant, 1984), in which we are given unlimited, on-demand, access to samples, and consider computationally tractable methods for obtaining a predictor with low generalization error. Most work in the PAC framework focuses on the distinction between polynomial and super-polynomial computation. Here, we are interested in understating the details of this polynomial dependence—how does the runtime scale with the parameters of interest? Discussing runtime as a function of data set size is inappropriate here, since the data set size is unlimited. Rather, we are interested in understanding the runtime as a function of the target error: How much runtime is required to guarantee some desired error level.

As the data-laden regime does capture many large data set situations, in which data is virtually unlimited, such an analysis can be helpful in comparing different optimization approaches. We saw how traditional runtime guarantees of different approaches are sometimes seemingly incomparable: One guarantee might scale poorly with the sample size, while another scales poorly with the desired optimization accuracy. The analysis we perform here allows us to compare such guarantees and helps us understand which methods are appropriate for large data sets.

Recently, Bottou and Bousquet (2008) carried out such a "data-laden" analysis for unregularized learning of linear separators in low dimensions. Here, we perform a similar type of analysis for SVMs, i.e. regularized learning of a linear separator in high dimensions.

4. Data-Laden Analysis of SVM Solvers

To gain insight into SVM learning in the data-laden regime we perform the following "oracle" analysis: We assume there is some good low-norm predictor $\mathbf{w}_0$, which achieves a generalization error (expected hinge loss) of $\ell(\mathbf{w}_0)$ and has norm $\|\mathbf{w}_0\|$. We train a SVM by minimizing the training objective $\hat{f}_\lambda(\mathbf{w})$ to within optimization accuracy ϵ_{acc}. Since we have access to an unrestricted amount of data, we can choose what data set size to work with in order to achieve the lowest possible runtime.

We will decompose the generalization error of the output predictor $\tilde{\mathbf{w}}$ as follows:

$$\begin{aligned}\ell(\tilde{\mathbf{w}}) = \ell(\mathbf{w}_0) \\ + (f_\lambda(\tilde{\mathbf{w}}) - f_\lambda(\mathbf{w}^*)) \\ + (f_\lambda(\mathbf{w}^*) - f_\lambda(\mathbf{w}_0)) \\ + \frac{\lambda}{2}\|\mathbf{w}_0\|^2 - \frac{\lambda}{2}\|\tilde{\mathbf{w}}\|^2 \end{aligned} \quad (2)$$

The degradation in the regularized generalization error, $f_\lambda(\tilde{\mathbf{w}}) - f_\lambda(\mathbf{w}^*)$, which appears in the second term, can be bounded by the empirical degradation: For all $\mathbf{w}$ with $\|\mathbf{w}\|^2 \leq 2/\lambda$ (a larger norm would yield a worse SVM objective than $\mathbf{w}=0$, and so can be disqualified), with probability at least $1-\delta$ over the training set (Sridharan, 2008):

$$f_\lambda(\mathbf{w}) - f_\lambda(\mathbf{w}^*) \leq 2\left[\hat{f}_\lambda(\mathbf{w}) - \hat{f}_\lambda(\mathbf{w}^*)\right]_+ + O\left(\frac{\log\frac{1}{\delta}}{\lambda m}\right)$$

where $[z]_+ = max(z, 0)$. Recalling that $\tilde{\mathbf{w}}$ is an ϵ_{acc}-accurate minimizer of $\hat{f}_\lambda(\mathbf{w})$, we have:

$$f_\lambda(\tilde{\mathbf{w}}) - f_\lambda(\mathbf{w}^*) \leq 2\epsilon_{\text{acc}} + O\left(\frac{\log\frac{1}{\delta}}{\lambda m}\right) \quad (3)$$

Returning to the decomposition (2), the third term is non-positive due to the optimality of $\mathbf{w}^*$, and regarding δ as a constant we obtain that with arbitrary fixed probability:

$$\ell(\tilde{\mathbf{w}}) \leq \ell(\mathbf{w}_0) + 2\epsilon_{\text{acc}} + \frac{\lambda}{2}\|\mathbf{w}_0\|^2 + O\left(\frac{1}{\lambda m}\right) \quad (4)$$

In order to obtain an upper bound of $\ell(\mathbf{w}_0) + O(\epsilon)$ on the generalization error $\ell(\tilde{\mathbf{w}})$, each of the three remaining terms on the right hand side of (4) must be bounded from above by $O(\epsilon)$, yielding:

$$\epsilon_{\text{acc}} \leq O(\epsilon) \quad (5)$$

$$\lambda \leq O\left(\frac{\epsilon}{\|\mathbf{w}_0\|^2}\right) \quad (6)$$

$$m \geq \Omega\left(\frac{1}{\lambda\epsilon}\right) \geq \Omega\left(\frac{\|\mathbf{w}_0\|^2}{\epsilon^2}\right) \quad (7)$$

Using the above requirements on the optimization accuracy ϵ_{acc}, the regularization parameter λ and the working sample size m, we can revisit the runtime of the various SVM optimization approaches.

As discussed in Section 2, dual decomposition approaches require runtime $\Omega(m^2 d)$, with a very weak dependence on the optimization accuracy. Substituting in the sample size required for obtaining the target generalization error of $\ell(\mathbf{w}_0) + \epsilon$, we get a runtime of $\Omega\left(\frac{d\|\mathbf{w}_0\|^4}{\epsilon^4}\right)$.

We can perform a similar analysis for SVM-Perf by substituting the requirements on ϵ_{acc}, λ and m into its guaranteed runtime of $O\left(\frac{dm}{\lambda\epsilon_{\text{acc}}}\right)$. We obtain a runtime of $O\left(\frac{d\|\mathbf{w}_0\|^4}{\epsilon^4}\right)$, matching that in the analysis of dual decomposition methods above. It should be noted that SVM-Perf's runtime has been reported to have only a logarithmic dependence on $1/\epsilon_{\text{acc}}$ in practice (Smola et al., 2008). If that were the case, the runtime guarantee would drop to $\tilde{O}\left(\frac{d\|\mathbf{w}_0\|^4}{\epsilon^3}\right)$, perhaps explaining the faster runtime of SVM-Perf on large data sets in practice.

As for the stochastic gradient optimizer PEGASOS, substituting in the requirements on ϵ_{acc} and λ into its $\tilde{O}(d/(\lambda\epsilon_{\text{acc}}))$ runtime guarantee yields a data-laden runtime of $\tilde{O}\left(\frac{d\|\mathbf{w}_0\|^2}{\epsilon^2}\right)$. We see, then, that in the data-laden regime, where we can choose a data set of arbitrary size in order to obtain some target generalization error, the runtime guarantee of PEGASOS dominates those of other methods, including those with a much more favorable dependence on the optimization accuracy.

The traditional and data-laden runtimes, ignoring logarithmic factors, are summarized in the following table:

Method	ϵ_{acc}-accurate	$\ell(\tilde{\mathbf{w}}) \leq \ell(\mathbf{w}_0) + \epsilon$
Dual decompositoin	dm^2	$\frac{d\|\mathbf{w}_0\|^4}{\epsilon^4}$
SVM-Perf	$\frac{dm}{\lambda\epsilon_{\text{acc}}}$	$\frac{d\|\mathbf{w}_0\|^4}{\epsilon^4}$
PEGASOS	$\frac{d}{\lambda\epsilon_{\text{acc}}}$	$\frac{d\|\mathbf{w}_0\|^2}{\epsilon^2}$

5. The Intermediate Regime

We have so far considered two extreme regimes: one in which learning is bounded only by available data, but not by computational resources, and another where it is bounded only by computational resources, but unlimited data is available. These two analyzes tell us how many samples are needed in order to guarantee some target error rate (regardless of computational resources), and how much computation is needed to guarantee this target error rate (regardless of available data). However, if we have just enough samples to allow a certain error guarantee, the runtime needed in order to obtain such an error rate might be much higher than the runtime given unlimited samples. In terms of the error decomposition, the approximation and estimation errors together would already account for the target error rate, requiring the optimization error to be extremely small. Only when more and more samples are available might the required runtime decrease down to that obtained in the data-laden regime.

Accordingly, we study the runtime of a training method as a decreasing function of the available training set size. As argued earlier, studied this way, the required runtime should never increase as more data is available. We would like to understand how the excess data can be used to decrease the runtime.

In many optimization methods, including dual decomposition methods and SVM-Perf discussed earlier, the computational cost of each basic step increases, sometimes sharply, with the size of the data set considered. In such algorithms, increasing the working data set size in the hope of being able to optimize to within a lower optimization accuracy is a double-edged sword. Although we can reduce the required optimization accuracy, and doing so reduces the required runtime, we also increase the computational cost of each basic step, which sharply increases the runtime.

However, in the case of a stochastic gradient descent approach, the runtime to get some desired optimization accuracy does not increase as the sample size increases. In this case, increasing the sample size is a pure win: The desired optimization accuracy decreases, with no counter effect, yielding a net decrease in the runtime.

In the following sections, we present a detailed theoretical analysis based on performance guarantees, as well as an empirical investigation, demonstrating a decrease in PEGASOS runtime as more data is available.

5.1. Theoretical Analysis

Returning to the "oracle" analysis of Section 4 and substituting into equation (4) our bound on the optimization accuracy of PEGASOS after running for time T, we obtain:

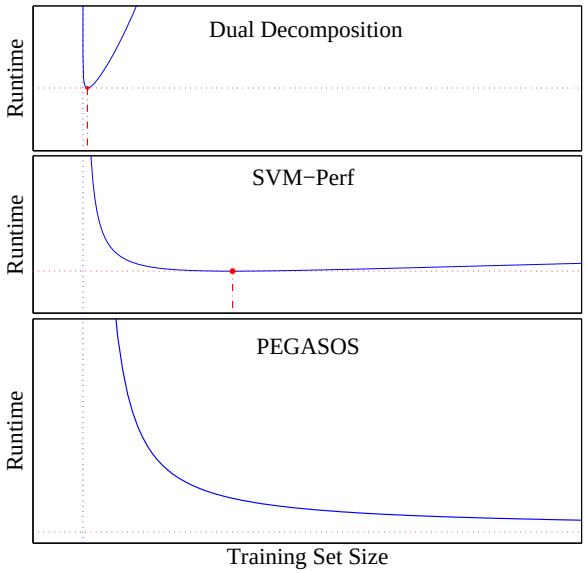

Figure 2. Descriptive behavior of the runtime needed to achieve some fixed error guarantee based on upper bounds for different optimization approaches (solid curves). The dotted lines are the sample-size requirement in the data-bounded regime (vertical) and the runtime requirement in the data-laden regime (horizontal). In the top two panels (dual decomposition and SVM-Perf), the minimum runtime is achieved for some finite training set size, indicated by a dash-dotted line.

$$\ell(\tilde{\mathbf{w}}) \leq \ell(\mathbf{w}_0) + \tilde{O}(\frac{d}{\lambda T}) + \frac{\lambda}{2}\left\|\mathbf{w}_0\right\|^2 + O(\frac{\left\|\mathbf{w}_0\right\|}{\sqrt{m}}) \quad (8)$$

The above bound is minimized when $\lambda = \tilde{\Theta}(\sqrt{\frac{d}{\|\mathbf{w}_0\|^2 T}})$, yielding $\ell(\tilde{\mathbf{w}}) \leq \ell(\mathbf{w}_0) + \epsilon(T, m)$ with

$$\epsilon(T, m) = \tilde{O}\left(\left\|\mathbf{w}_0\right\| \sqrt{\frac{d}{T}}\right) + O\left(\frac{\left\|\mathbf{w}_0\right\|}{\sqrt{m}}\right). \quad (9)$$

Inverting the above expression, we get the following bound on the runtime required to attain generalization error $\ell(\tilde{\mathbf{w}}) \leq \ell(\mathbf{w}_0) + \epsilon$ using a training set of size m:

$$T(m;\epsilon) = \tilde{O}\left(\frac{d}{\left(\frac{\epsilon}{\left\|\mathbf{w}_0\right\|} - O(\frac{1}{\sqrt{m}})\right)^2}\right). \quad (10)$$

This runtime analysis, which monotonically decreases with the available data set size, is depicted in the bottom panel of Figure 2. The data-bounded (statistical learning theory) analysis describes the vertical asymptote of $T(\cdot;\epsilon)$—at what sample size is it at all possible to achieve the desired error. The analysis of the data-laden regime of Section 4 described the minimal runtime using any amount of data, and thus specifies the horizontal asymptote $\inf T(m;\epsilon) =$

$\lim_{m\to\infty} T(m;\epsilon)$. The more detailed analysis carried out here bridges between these two extreme regimes.

Before moving on to empirically observing this behavior, let us contrast this behavior with that displayed by learning methods whose runtime required for obtaining a fixed optimization accuracy does increase with data set size. We can repeat the analysis above, replacing the first term on the right hand side of (8) with the guarantee on the optimization accuracy at runtime of T, for different algorithms.

For SVM-Perf, we have $\epsilon_{\text{acc}} \leq O\left(dm/(\lambda T)\right)$. The optimal choice of λ is then $\lambda = \Theta\left(\sqrt{\frac{dm}{T\|\mathbf{w}_0\|^2}}\right)$ and the runtime needed to guarantee generalization error $\ell(\mathbf{w}_0)+\epsilon$ when running SVM-Perf on m samples is $T(m;\epsilon) = O\left(dm \middle/ \left(\frac{\epsilon}{\|\mathbf{w}_0\|} - O(\frac{1}{\sqrt{m}})\right)^2\right)$. The behavior of this guarantee is depicted in the middle panel of Figure 2. As the sample size increases beyond the statistical limit $m_0 = \Theta(\|\mathbf{w}_0\|^2/\epsilon^2)$, the runtime indeed decreases sharply, until it reaches a minimum, corresponding to the data laden bound, precisely at $4m_0$, i.e. when the sample size is four times larger than the minimum required to be able to reach the desired target generalization error. Beyond this point, the other edge of the sword comes into play, and the runtime (according to the performance guarantees) increases as more samples are included.

The behavior of a dual decomposition method with runtime $\Theta(m^2 d \log\frac{1}{\epsilon_{\text{acc}}})$ is given by $T(m;\epsilon) = m^2 d \log(1/(\epsilon - \Theta\frac{\|\mathbf{w}_0\|}{\sqrt{m}}))$ and depicted in the top panel of Figure 2. Here, the optimal sample size is extremely close to the statistical limit, and increasing the sample size beyond the minimum increases the runtime quadratically.

5.2. Empirical Analysis

The above analysis is based on upper bounds, and is only descriptive, in that it ignores various constants and even certain logarithmic factors. We now show that this type of behavior can be observed empirically for the stochastic subgradient optimizer PEGASOS.

We trained PEGASOS[2] on training sets of increasing size taken from two large data sets, the Reuters CCAT and the CoverType datasets[3]. We measured the average hinge loss of the learned predictor on a (fixed) held-out test set. For each training set size, we found the median number of iterations (over multiple runs with multiple training sets) for achieving some target average hinge loss, which was very slightly above the best "test" hinge loss that could be reliably obtained by training on the entire available training set. For each training set size we used the optimal λ for achieving the desired target hinge loss[4]. The (median) required number of iterations is displayed in Figure 3. For easier interpretability and reproducibility, we report the number of iterations. Since each PEGASOS iteration takes constant time, the actual runtime is proportional to the number of iterations.

So far we have measured the generalization error only in terms of the average hinge loss $\ell(\tilde{\mathbf{w}})$. However, our true goal is usually to attain low misclassification error, $P(Y \neq \operatorname{sign}\langle\tilde{\mathbf{w}}, \mathbf{X}\rangle)$. The dashed lines in Figure 3 indicate the (median) number of iterations required to achieve a target misclassification error, which again is very slightly above the best that can be hoped for with the entire data set.

These empirical results demonstrate that the runtime of SVM training using PEGASOS indeed *decreases* as the size of the training set increases. It is important to note that PEGASOS is the fastest published method for these datasets (Shalev-Shwartz et al., 2007; Bottou, Web Page), and so we are indeed investigating the best possible runtimes. To gain an appreciation of this, as well as to observe the runtime dependence on the training set size for other methods, we repeated a limited version of the experiments using SVM-Perf and the dual decomposition method SVM-Light (Joachims, 1998). Figure 4 and its caption report the runtimes required by SVM-Perf and SVM-Light to achieve the same fixed misclassification error using varying data set sizes. We can indeed verify that PEGASOS's

[2] We used a variant of the method described by Shalev-Shwartz et al. (2007), with a single example used in each update: Following Bottou (Web Page), instead of sampling an example independently at each iteration, a random permutation over the training set is used. When the permutation is exhausted, a new, independent, random permutation is drawn. Although this variation does not match the theoretical analysis, it performs slightly better in practice. Additionally, the PEGASOS projection step is skipped, as it can be shown that even without it, $\|\mathbf{w}\|^2 \leq 4/\lambda$ is maintained.

[3] The binary text classification task CCAT from the Reuters RCV1 collection and Class 1 in the CoverType dataset of Blackard, Jock & Dean. CCAT consists of 804,414 examples with 47,236 features of which 0.16% are non-zero. CoverType has 581,012 examples with 54 features of which 22% are non-zero. We used 23,149 CCAT examples and 58,101 CoverType examples as test sets and sampled training sets from the remainder.

[4] Selecting λ based on results on the test set seems like cheating, and is indeed slightly cheating. However, the same λ was chosen for multiple random training sets of the same size, and represents the optimal λ for the *learning problem*, not for a specific training set (i.e. we are not gaining here from random fluctuations in learning). The setup in which the optimal λ is "known" is common in evaluation of SVM runtime. Choosing λ by proper validation involves many implementation choices that affect runtime, such as the size of the holdout and/or number of rounds of cross-validation, the range of λs considered, and the search strategy over λs. We therefore preferred a "known λ" setup, where we could obtain results that are cleaner, more interpretable, and less affected by implementation details. The behavior displayed by our results is still indicative of a realistic situation where λ must be selected.

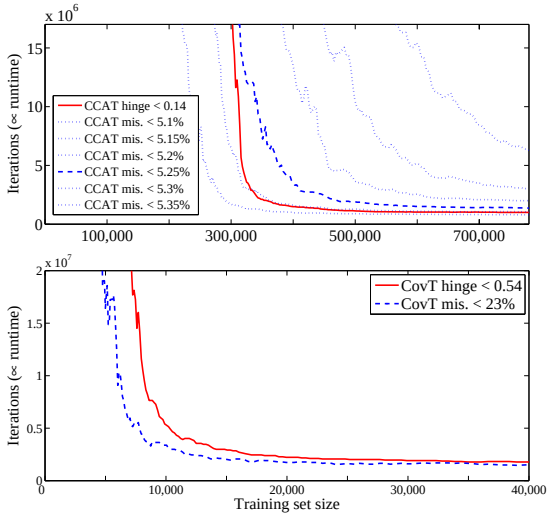

Figure 3. Number of PEGASOS iterations required to achieve the desired hinge loss (solid lines) or misclassification error (dashed and dotted lines) on the test set. Top: CCAT. The minimum achievable hinge loss and misclassification error are 0.132 and 5.05%. Bottom: CoverType. The minimum achievable hinge loss and misclassification error are 0.536 and 22.3%.

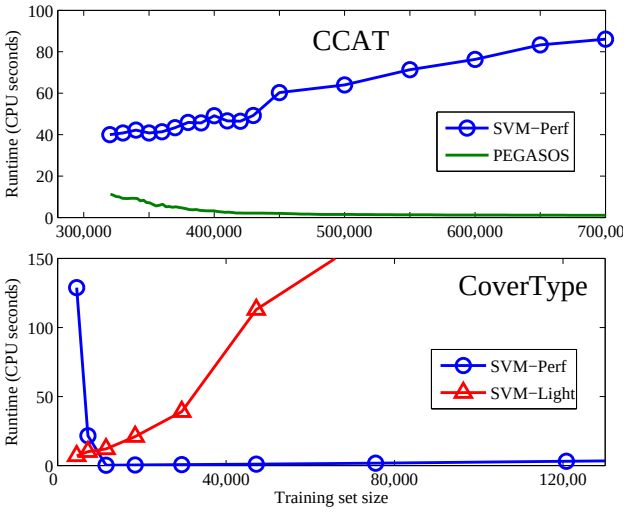

Figure 4. Runtime required to achieve average misclassification error of 5.25% on CCAT (top) and 23% on CoverType (bottom) on a 2.4 GHz Intel Core2, using optimal λ settings. SVM-Light runtimes for CCAT increased from 1371 seconds using 330k examples to 4.4 hours using 700k examples. SVM-Light runtimes for CoverType increased to 552 seconds using 120k examples.

runtime is significantly lower than the optimal SVM-Perf and SVM-Light runtimes on the CCAT dataset. On the CoverType data set, PEGASOS and SVM-Perf have similar optimal runtimes (both optimal runtimes were under a second, and depending on the machine used, each method was up to 50% faster or slower than the other), while SVM-Light's runtime is significantly higher (about 7 seconds). We also clearly see the increase in runtime for large training set sizes for both SVM-Light and SVM-Perf. On the CoverType dataset, we were able to experimentally observe the initial decrease in SVM-Perf runtime, when we are just past the statistical limit, and up to some optimal training set size. On CCAT, and on both data sets for SVM-Light, the optimal data set size is the minimal size statistically required and any increase in data set size increases runtime (since the theoretical analysis is just an upper bound, it is possible that there is no initial decrease, or that it is very narrow and hard to detect experimentally).

In order to gain a better understanding of the reduction in PEGASOS's runtime, we show in Figure 5 the average (over multiple training sets) generalization error achieved by PEGASOS over time, for various data set sizes. It should not be surprising that the generalization error decreases with the number of iterations, nor that it is lower for larger data sets. The important observation is that for smaller data sets the error decreases more slowly, even before the statistical limit for that data set is reached, as opposed to the hypothetical behavior depicted in the insert of Figure 5. This can also be seen in the dotted plots of Figure 3, which are essentially contour lines of the generalization error as a function of runtime and training set size—the error decreases when *either* runtime or training set size increase. And so, fixing the error, we can trade off between the runtime and data set size, decreasing one of them when the other is increased.

The hypothetical situation depicted in the insert occurs when runtime and dataset size each limit the attainable error independently. This corresponds to "L"-shaped contours: both a minimum runtime and a minimum dataset size are required to attain each error level, and once both requirements are met, the error is attainable. In such a situation, the runtime does *not* decrease as data set size increases, but rather, as in the "L"-shaped graph, remains constant once the statistical limit is passed. This happens, e.g., if the optimization can be carried out with a single pass over the data (or at least, if one pass is enough for getting very close to $\ell(\hat{\mathbf{w}})$). Although behavior such as this has been reported using *second-order* stochastic gradient de-

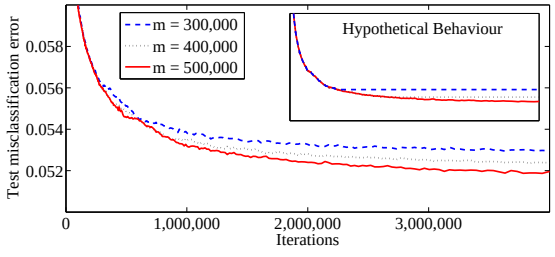

Figure 5. Average misclassification error achieved by PEGASOS on the CCAT test set as a function of runtime (#iterations), for various training set sizes. The insert is a cartoon depicting a hypothetical situation discussed in the text.

scent for *unregularized* linear learning (Bottou & LeCun, 2004), this is not the case here. Unfortunately we are not aware of an efficient one-pass optimizer for SVMs.

6. Discussion

We suggest here a new way of studying and understanding the runtime of training: Instead of viewing additional training data as a computational burden, we view it as an asset that can be used to our benefit. We already have a fairly good understanding, backed by substantial theory, on how additional training data can be used to lower the generalization error of a learned predictor. Here, we consider the situation in which we are satisfied with the error, and study how additional data can be used to decrease training runtime. To do so, we study runtime as an explicit function of the acceptable predictive performance.

Specifically, we show that a state-of-the-art stochastic gradient descent optimizer, PEGASOS, indeed requires training runtime that monotonically decreases as a function of the sample size. We show this both theoretically, by analyzing the behavior of upper bounds on the runtime, and empirically on two standard datasets where PEGASOS is the fastest known SVM optimizer. To the best of our knowledge, this is the first demonstration of a SVM optimizer that displays this natural behavior.

The reason PEGASOS's runtime decreases with increased data is that its runtime to get a fixed optimization accuracy does not depend on the training set size. This enables us to leverage a decreased estimation error, without paying a computational penalty for working with more data.

The theoretical analysis presented in Section 5.1, and we believe also the empirical reduction in PEGASOS's runtime, indeed relies on this decrease in estimation error. This decrease is significant close to the statistical limit on the sample size, as is evident in the results of Figure 3—a roughly 10–20% increase in sample size reduces the runtime by about a factor of five. However, the decrease diminishes for larger sample sizes. This can also be seen from the theoretical analysis—having a sample size which is greater than the statistical limit by a constant factor enables us to achieve a runtime which is greater than the theoretical (data-laden) limit by a constant factor (in fact, as the careful reader probably noticed, since our data-laden theoretical analysis ignores constant factors on ϵ and m, it seems that the training set size needed to be within the data-laden regime, as specified in equation (7), is the same as the minimum data set size required statistically). Such "constant factor" effects should not be discounted—having four times as much data (as is roughly the factor for CoverType) is often quite desirable, as is reducing the runtime by a factor of ten (as this four-fold increase achieves).

We are looking forward to seeing methods that more explicitly leverage large data sets in order to reduce runtime, achieving stronger decreases in practice, and being able to better leverage very large data sets. Although it seems that not much better can be done theoretically given only the simple oracle assumption of Section 4, a better theoretical analysis of such methods might be possible using richer assumptions. We would also like to see practical methods for non-linear (kernelized) SVMs that display similar behavior. Beyond SVMs, we believe that many other problems in machine learning, usually studied computationally as optimization problems, can and should be studied using the type of analysis presented here.

Abstract

In this paper we develop a spectral framework for estimating mixture distributions, specifically Gaussian mixture models. In physics, spectroscopy is often used for the identification of substances through their spectrum. Treating a kernel function $K(x, y)$ as "light" and the sampled data as "substance", the spectrum of their interaction (eigenvalues and eigenvectors of the kernel matrix K) unveils certain aspects of the underlying parametric distribution p, such as the parameters of a Gaussian mixture. Our approach extends the intuitions and analyses underlying the existing spectral techniques, such as spectral clustering and Kernel Principal Components Analysis (KPCA).

We construct algorithms to estimate parameters of Gaussian mixture models, including the number of mixture components, their means and covariance matrices, which are important in many practical applications. We provide a theoretical framework and show encouraging experimental results.

1. Introduction

Gaussian mixture models are a powerful tool for various tasks of data analysis, modeling and exploration. The basic problem is to estimate the parameters of a Gaussian mixture distribution $p(x) = \sum_{g=1}^{G} \pi^g p^g(x)$, from sampled data $x_1, \ldots, x_n \in \mathbb{R}^d$, where the mixture component $p^g = N(\mu^g, \Sigma^g)$ has the mean μ^g and the covariance matrix Σ^g, $g = 1, \ldots, G$. Gaussian mixture models are used in a broad range of scientific and engineering applications, including computer vision, speech recognition, and many other areas.

However, effectiveness of modeling hinges on choosing the right parameters for the mixture distribution. The problem of parameter selection for mixture models has a long history, going back to the work of (Pearson, 1894, [9]), who introduced the Method of Moments and applied it to the study of a population of Naples crabs, deducing the existence of two subspecies within the population.

The most commonly used method for parameter estimation is *Maximum Likelihood Estimation* (MLE), which suggests choosing the parameters in a way that maximizes the likelihood of the observed data, given a model. In modern practice this is most commonly done through the iterative optimization technique known as Expectation Maximization (EM) algorithm ([3]), which is typically initialized using k-means clustering. Recently significant progress on understanding theoretical issues surrounding learning mixture distributions and EM has been made in theoretical computer science, e.g., [2, 4].

Another set of methods for inferring mixture distribution is based on the Bayesian inference, which is done using a prior distribution on the parameters of the model. In recent literature ([7]) the Dirichlet process mixture models were used to produce posterior distribution for parameters of a mixture model. The inference procedure involves applying Markov Chain Monte-Carlo to draw samples from the posterior distribution.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

In this paper we propose a new method for estimating parameters of a mixture distribution, which is closely related to non-parametric spectral methods, such as spectral clustering (e.g., [8]) and Kernel Principal Components Analysis [11]. Those methods, as well as certain methods in manifold learning (e.g., [1]), construct a kernel matrix or a graph Laplacian matrix associated to a data set. The eigenvectors and eigenvalues of that matrix can then be used to study the structure of the data set. For example, in spectral clustering the presence of a small non-zero eigenvalue indicates the presence of clusters, while the corresponding eigenvector shows how the data set should be split. In particular, we note the work [12] where the authors analyze dependence of spectra on the input density distribution in the context of classification and argue that lower eigenfunctions can be truncated without sacrificing classification accuracy. We will develop the intuitions and analyses underlying these methods and take them a step further by offering a framework, which can be applied to analyzing parametric families, in particular a mixture of Gaussian distributions.

We would like to study mixture distributions by building explicit connections between their parameters and spectral properties of the corresponding kernel matrices. More specifically, we construct a family of probability-dependent operators and build estimators by matching eigenvalues and eigenfunctions of the operator associated to a probability distribution to those of the matrix associated to a data sample. Thus given a mixture distribution $p(x) = \sum_{g=1}^{G} \pi^g p^g(x)$, we use a Gaussian kernel $K(x,y) = e^{-\frac{\|x-y\|^2}{2\omega^2}}$ to construct the integral operator

$$\mathcal{G}_p^\omega f(y) = \int e^{-\frac{\|x-y\|^2}{2\omega^2}} f(x)\, p(x) dx$$

which will be the principal object of this paper. Our framework will rely on three key observations about the spectral properties of this operator and its connection to the sampled data.

Observation 1. (Single component) For the Gaussian distribution $p = N(\mu, \Sigma)$, we can analytically express eigenfunctions and eigenvalues of $\mathcal{G}_p^\omega$ in terms of the mean μ and the covariance Σ. This will allows us to reverse this dependence and explicitly express μ and Σ in terms of the spectral properties of $\mathcal{G}_p^\omega$.

Observation 2. (Mixture of components)

Let p be a mixture distribution $p(x) = \sum_{g=1}^{G} \pi^g p^g(x)$. Note that by linearity

$$\mathcal{G}_p^\omega f(y) = \sum_{g=1}^{G} \pi^g \int e^{-\frac{\|x-y\|^2}{2\omega^2}} f(x)\, p^g(x) dx$$

$$= \sum_{g=1}^{G} \pi^g \mathcal{G}_{p^g}^\omega f(y)$$

It can be seen (Theorem 1) that given enough separation between the mixture components, top eigenfunctions of the individual components $\mathcal{G}_{p^g}^\omega$ are approximated by top eigenfunctions of $\mathcal{G}_p^\omega$. That will allow us to connect eigenfunctions/eigenvalues of the mixture to eigenfunctions/eigenvalues of the individual components. A specific example of this is given in Fig. 2, which will be discussed in detail in Section 4.

Observation 3. (Estimation from data) The eigenfunctions and eigenvalues of $\mathcal{G}_p^\omega$ can be approximated given data sampled from $p(x)$ by eigenvectors and eigenvalues of empirical kernel matrices.

To highlight the effectiveness of our methodology consider the distribution in Fig. 1, where the density given by a mixture of two normal distributions $p = 0.9\, N(-3, 1^2) + 0.1\, N(0, 0.3^2)$ and a histogram obtained by sampling 1000 points are shown. From the Table 1, we see that the spectroscopic estimator has no difficulty providing reasonably accurate estimates for the mixing coefficients π^1, π^2, means μ^1, μ^2 and variances σ^1, σ^2 for each component, despite the fact that the mixture is unbalanced. We also see that these estimates can be further improved by using the spectroscopic estimate to initialize EM.

We note that, while EM is a computationally efficient and algorithmically attractive method, it is a local optimization procedure and the quality of the achieved maximum and accuracy of the resulting estimate are sensitive to initialization (see, e.g., [10]). If the initial value happens to be close to the global maximum, fast convergence can be guaranteed. However, finding such "lucky" regions of the parameter space may be nontrivial. To emphasize that point, consider the bottom two rows of Table 1, where the results of k-means clustering ($k = 2$) and EM initialized by k-means are shown. We see that k-means consistently provides a poor starting point as the energy minimizing configuration splits the large component, ignoring the small one. EM, initialized with k-means, stays at a local maximum and cannot provide an accurate estimate for the mixture. On the other hand, EM initialized with our method, converges to the correct solution.

We should note that our method requires sufficient separation between the components to provide accurate results. However there does not exist a computationally feasible method for estimating parameters of a mixture distribution in several dimensions without a separation assumption.

The rest of the paper is structured as follows: in Sec-

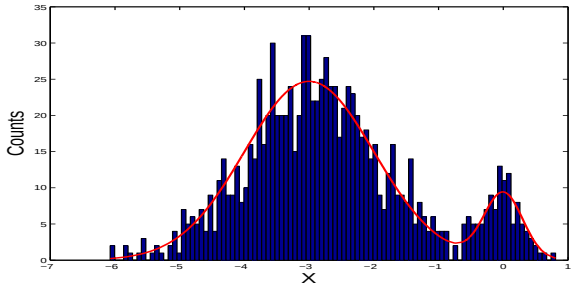

Figure 1. Histogram of 1000 data points sampled from $0.9N(-3, 1^2) + 0.1N(0, 0.3^2)$ and the distribution (red line).

tion 2, we describe our approach in the simplest setting of a one-dimensional component in $\mathbb{R}$. In Section 3, we analyze a single component in $\mathbb{R}^d$, in Section 4, we deal with a general case of a mixture distribution and state a basic theoretical result for the mixture. In section 5, we show some experimental results on a simulated mixture distribution with three components in $\mathbb{R}^5$ and show some experimental results on the USPS handwritten digit dataset. We conclude in Section 6.

2. Setting Up the Framework: Single Component in $\mathbb{R}$

We start the discussion by demonstrating the basis of our approach on the problem of estimating parameters of a single univariate Gaussian distribution $p(x) = N(\mu, \sigma^2)$. We first establish a connection between eigenfunctions and eigenvalues of the convolution operator $\mathcal{G}_p^\omega f(y) = \int_{\mathbb{R}} e^{-\frac{(x-y)^2}{2\omega^2}} f(x)\, p(x) dx$ and the parameters μ and σ^2. We show these parameters can be estimated from sampled data. We will need the following

Proposition 1 *(Refinement of a result in [13]) Let $\beta = 2\sigma^2/\omega^2$ and let $H_i(x)$ be the i-th order Hermite polynomial. Then eigenvalues and eigenfunctions of $\mathcal{G}_p^\omega$ for $i = 0, 1, \cdots$ are given by*

$$\lambda_i = \frac{\sqrt{2}}{(1+\beta+\sqrt{1+2\beta})^{1/2}} \left(\frac{\beta}{1+\beta+\sqrt{1+2\beta}}\right)^i \quad (1)$$

$$\phi_i(x) = \frac{(1+2\beta)^{1/8}}{\sqrt{2^i i!}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\frac{\sqrt{1+2\beta}-1}{2}\right) \times H_i\left(\left(\frac{1+2\beta}{4}\right)^{\frac{1}{4}} \frac{x-\mu}{\sigma}\right) \quad (2)$$

Since $H_0(x) = 1$, and putting $C = (1+2\beta)^{1/8}$

$$\phi_0(x) = C \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\frac{\sqrt{1+4\sigma^2/\omega^2}-1}{2}\right) \quad (3)$$

We observe that that the maximum value of $|\phi_0(x)|$ is taken at the mean of the distribution μ, hence $\mu = \text{argmax}_x |\phi_0(x)|$. We also observe that $\frac{\lambda_1}{\lambda_0} = \frac{2\sigma^2}{\omega^2}\left(1 + \frac{2\sigma^2}{\omega^2} + \sqrt{1+\frac{4\sigma^2}{\omega^2}}\right)^{-1}$. Taking $r = \lambda_1/\lambda_0$, we derive

$$\sigma^2 = \frac{r\omega^2}{(1-r)^2}. \quad (4)$$

Thus we have established an explicit connection between spectral properties of $\mathcal{G}_p^\omega$ and parameters of $p(x)$. We now present **Algorithm 1** for estimating μ and σ^2 from a sample $x_1, \ldots, x_n$ from $p(x)$.

- **Step 1.** Construct kernel matrix K_n, $(K_n)_{ij} = \frac{1}{n} e^{-\frac{(x_i - x_j)^2}{2\omega^2}}$. K_n serves as the empirical version of the operator $\mathcal{G}_p^\omega$. Compute the top eigenvector v_0 of K_n and the top two eigenvalues $\lambda_0(K_n), \lambda_1(K_n)$.

Actual value	$\mu = 0$	$\sigma = 1$
SE $(\hat{\mu}, \hat{\sigma})$	0.000 (0.014)	1.005 (0.012)
Std Est $(\bar{x}, s)$	0.002 (0.011)	1.001 (0.007)

Table 2. Average(standard deviation) of spectroscopic estimator SE$(\hat{\mu}, \hat{\sigma})$ and the standard estimator Std Est$(\bar{x}, s)$ of 100 simulation run. In each run, estimators are calculated from 1000 $i.i.d$ samples of $N(0, 1)$.

- **Step 2.** Construct estimators $\hat{\mu}$ and $\hat{\sigma}^2$ for mean and variance as follows:

$$\hat{\mu} = x_k, \qquad k = \operatorname*{argmax}_i |(v_0)_i|$$

$$\hat{\sigma}^2 = \frac{\omega^2 \hat{r}}{(1-\hat{r})^2},$$

where $\hat{r} = \frac{\lambda_0(K_n)}{\lambda_1(K_n)}$.

These estimators are constructed by substituting top eigenvector of K_n for the top eigenfunction of $\mathcal{G}_p^\omega$ and eigenvalues of K_n for the corresponding eigenvalues of $\mathcal{G}_p^\omega$.

It is well-known (e.g., [6]) that eigenvectors and eigenvalues of K_n approximate and converge to eigenfunctions and eigenvalues of $\mathcal{G}_p^\omega$ at the rate $\frac{1}{\sqrt{n}}$ as $n \to \infty$, which implies consistency of the estimators. The accuracy of $\hat{\mu}$ and $\hat{\sigma}^2$ depends on how well the empirical operator K_n approximates the underlying operator $\mathcal{G}_p$.

The Table 2 reports the average and the standard deviation of our spectroscopic estimators $(\hat{\mu}, \hat{\sigma}^2)$ compared the standard estimators $(\bar{x}, s^2)$ for one hundred repetitions of the simulation. We see that our spectroscopic estimators are comparable to the standard estimators for mean and variance of a single Gaussian.

3. Setting Up the Framework: Single Component in $\mathbb{R}^d$

In this section we extend our framework to estimating a single multivariate Gaussian $p = N(\mu, \Sigma)$ in $\mathbb{R}^d$. Let $\Sigma = \sum_{i=1}^d \sigma_i^2 u_i u_i^t$ be the spectral decomposition of the covariance matrix Σ. As before we put $\mathcal{G}_p^\omega f(x) = \int_{\mathbb{R}^d} e^{-\frac{\|x-y\|^2}{2\omega^2}} f(y)\, p(y) dy$. Since the kernel $e^{-\frac{\|x-y\|^2}{2\omega^2}}$ is invariant under rotations, it follows that the operator $\mathcal{G}_p^\omega$ can be decomposed as: $\mathcal{G}_p^\omega = \oplus_{i=1}^d \mathcal{G}_{p_i}^\omega$, where p_i is an 1-dimensional Gaussian with variance σ_i^2 and mean $\langle \mu, u_i \rangle$ along the direction of u_i.

It is easy to see that given two operators $\mathcal{F}$, $\mathcal{H}$, the spectrum of their direct sum $\mathcal{F} \oplus \mathcal{H}$ consists of pairwise products $\lambda\mu$, where λ and μ are their respective eigenvalues. The corresponding eigenfunction of the product is $e_{[\lambda,\mu]}(x, y) = e_\lambda(x)\, e_\mu(y)$.

Applying this result, we see that eigenvalues and eigenfunctions of of $\mathcal{G}_p^\omega$ can be written as products

$$\lambda_{[i_1,\ldots,i_d]}(\mathcal{G}_p^\omega) = \prod_{j=1}^d \lambda_{i_j}(\mathcal{G}_{p_j}^\omega)$$

$$\phi_{[i_1,\ldots,i_d]}(\mathcal{G}_p^\omega)(x) = \prod_{j=1}^d \phi_{i_j}(\mathcal{G}_{p_j}^\omega)(\langle x, u_j \rangle)$$

Where $[i_1, \ldots, i_d]$ is a multindex over all components. It can be seen that $\phi_{[0,\ldots,0]}$ is (up to a scaling factor) a Gaussian with the same mean μ as the original distribution $p(x)$. Thus μ can be estimated as the point with maximum value $\phi_{[0,\ldots,0]}$ in the same way as for 1-dimensional distributions.

Consider now ϕ_I, where $I = [\underbrace{0, \ldots, 0}_{i-1}, 1, 0, \ldots, 0]$. Since $H_2(x) = 2x$, Eq. 1 implies that $\frac{\phi_I(x)}{\phi_{[0,\ldots,0]}(x)}$ is a linear function in x with the gradient pointing in the direction of u_i. That allows us to estimate the principal directions. The resulting **Algorithm 2** for estimating μ and Σ is presented below:

Step 1. Construct kernel matrix K_n, $(K_n)_{st} = \frac{1}{n} e^{-\frac{\|x_s - x_t\|^2}{2\omega^2}}$. K_n serves as the empirical version of the operator $\mathcal{G}_p^\omega$. Compute eigenvalues $\lambda(K_n)$ and eigenvectors $v(K_n)$ of K_n. Denote the top eigenvector by v_0 and the corresponding eigenvalue by λ_0.

Step 2. Identify each eigenvector v_i, $v_i \neq v_0$, $i = 1, \ldots, d$ such that the values of $\frac{v_i}{v_0}$ are approximately linear in x, that is

$$\frac{v_i(x_s)}{v_0(x_s)} \approx a^T x_s + b, \qquad a, b \in \mathbb{R}^d$$

The corresponding principal direction u_i is estimated by $\hat{u}_i = \frac{a}{\|a\|}$. Let the corresponding eigenvalue be λ_i.

Step 3. Construct estimators $\hat{\mu}$ and $\hat{\Sigma}$ for mean and variance as follows:

$$\hat{\mu} = x_k, \qquad k = \operatorname*{argmax}_i |(v_0)_i|$$

$$\hat{\Sigma} = \sum_{i=1}^d \hat{\sigma}_i^2 \hat{u}_i \hat{u}_i^t,$$

where $\hat{\sigma}_i^2 = \frac{\omega^2 \hat{r}_i}{(1-\hat{r}_i)^2}$ and $\hat{r}_i = \frac{\lambda_0}{\lambda_i}$.

4. Spectroscopic Estimation for Mixtures of Gaussians

We now extend our framework to the case of a mixture of several multivariate Gaussian distributions with potentially different covariance matrices and mixture coefficients. To illustrate our approach we sample 1000 points from two different Gaussian distributions $N(2,1^2)$ and $N(-2,1^2)$ and from their mixture $0.5N(2,1^2)+0.5N(-2,1^2)$. The histogram of the mixture density is shown in the top left panel of Fig 2, and histograms of each mixture component are shown in the right top panels. Taking the bandwidth $\omega = 0.3$, we construct three kernel matrices K^1, K^2 and K for a sample from each of the components and the mixture distribution respectively. The middle and lower left panels show the top two eigenvectors of K, while the middle and lower right panels show the top eigenvector of K^1 and K^2 respectively.

The key observation is to notice the similarity between the left and right panels. That is, the top eigenvectors of the mixture are nearly identical to the top eigenvectors of each of the components. Thus knowing eigenvectors of the mixture allows us to approximate top eigenvectors (and the corresponding eigenvalues) for each of the components. Having access to these eigenvectors and using our Algorithms 1,2, allows us to estimate parameters of each of the mixture components.

This phenomenon is easily understood from the point of view of operator theory. The leading eigenfunctions of operators defined by each mixture component are approximately the eigenfunctions of the operators defined on the mixture distribution. To be explicit, let us consider the Gaussian convolution operator $\mathcal{G}_p^\omega$ defined by the mixture distribution $p(x) = \pi^1 p^1 + \pi^2 p^2$, with Gaussian components $p^1 = N(\mu^1, \Sigma^2)$ and $p^2 = N(\mu^2, \Sigma^2)$ and the Gaussian kernel $K(x,y)$ with bandwidth ω. The corresponding operators are $\mathcal{G}_{p^1}^\omega$ and $\mathcal{G}_{p^2}^\omega$ and $\mathcal{G}_p^\omega = \pi^1 \mathcal{G}_{p^1}^\omega + \pi^2 \mathcal{G}_{p^2}^\omega$ respectively. Consider an eigenfunction $\phi^1(x)$ of $\mathcal{G}_{p^1}^\omega$ with eigenvalue λ^1, $\mathcal{G}_{p^1}^\omega \phi^1 = \lambda^1 \phi^1$. We have

$$\mathcal{G}_p^\omega \phi^1(y) = \pi^1 \lambda^1 \phi^1(y) + \pi^2 \int K(x,y)\phi^1(x)p^2(x)dx.$$

It can be shown that eigenfunction $\phi^1(x)$ of $\mathcal{G}_{p^1}^\omega$ is centered at μ^1 and decays exponentially away from μ^1. Therefore, assuming the separation $\|\mu^1 - \mu^2\|$ is large enough, the second summand $\pi^2 \int K(x,y)\phi^1(x)p^2(x)dx \approx 0$ for all y uniformly, and hence $\mathcal{G}_p^\omega \phi^1 \approx \pi^1 \lambda^1 \phi^1$. When the approximation holds the top eigenfunctions of $\mathcal{G}_p^\omega$ are approximated by top eigenfunctions of either $\mathcal{G}_{p^1}^\omega$ or $\mathcal{G}_{p^2}^\omega$.

Theorem 1 *Given a d-dimensional mixture of two Gaussians* $p(\mathbf{x}) = \sum_{i=1}^2 \pi^i p^i(x)$ *where* π_i *is mixing weight and* p_i *is the density corresponding to* $N(\mu_i, \sigma^2 I)$. *Define* $\beta = 2\sigma^2/w^2$ *and* $\xi = \sqrt{2}\sigma/\sqrt{\sqrt{1+2\beta}-1}$, *then the first eigenfunction* (ϕ_0^1 *with an eigenvalue* λ_0^1) *of* $\mathcal{G}_{p_1}^w$ *is approximately an eigenfunction of* $\mathcal{G}_p^w$ *in the following sense: For any* $\epsilon > 0$ *we have that for all* y

$$\mathcal{G}_p^w \phi_0^1(y) = \pi_1 \lambda_0^1 (\phi_0^1(y) + T(y)) \quad \textit{and} \quad |T(y)| \le \epsilon$$

assuming that the separation satisfies

$$\frac{\|\mu_1 - \mu_2\|^2}{\xi^2 + \sigma^2} \ge 2\log\left(\frac{\pi_2}{\pi_1}\right) + 2\log\left(\frac{1}{\epsilon}\right) + \frac{d}{4}\log(1+2\beta)$$

We do not provide a proof of Theorem 1 for lack of space. A more general version of the theorem for several Gaussians with different covariance matrices can also be given along the same lines. Together with some perturbation analysis ([5]) it is possible to provide bounds on the resulting eigenvalues and eigenfunctions of the operator.

We now observe that for the operator $\mathcal{G}_{p^g}^\omega$, the top eigenfunction is the only eigenfunction with no sign change. Therefore, such eigenfunction of $\mathcal{G}_p^\omega$ corresponds to exactly one component of the mixture distribution. This immediately suggest a strategy for identifying components of the mixture: we look for eigenfunctions of $\mathcal{G}_p^\omega$ that have *no sign change*. Once these eigenfunctions of $\mathcal{G}_p^\omega$ are identified, each eigenfunction of $\mathcal{G}_p^\omega$ can be assigned to a group determined an eigenfunction with no sign change. As a result, the eigenvalues and eigenfunctions in each group only depend on one of the component p^g and mixing weight π^g. By reversing the relationship between parameters and eigenvalues/eigenfunctions, parameter estimations for each mixing component can be constructed based only on the eigenvalues/eigenvectors in the corresponding group.

4.1. Algorithm for Estimation of a Mixture of Gaussians

Following the discussion above, we now describe the resulting algorithm for estimating a multidimensional mixture of Gaussians $p(x) = \sum_{g=1}^G \pi^g N(\mu^g, \Sigma^g)$, from a sample $x_1, \ldots, x_n \in \mathbb{R}^d$, first giving the following

Definition 1 *For vectors* $d, e \in \mathbb{R}^n$*), we define*
1. ϵ**-support** *of* d *is the set of indices* $\{i\text{: } |d_i| \ge \epsilon,$ $i = 1, \cdots, n\}$.
2. d *has* **no sign changes up to precision** ϵ*, if* d *is*

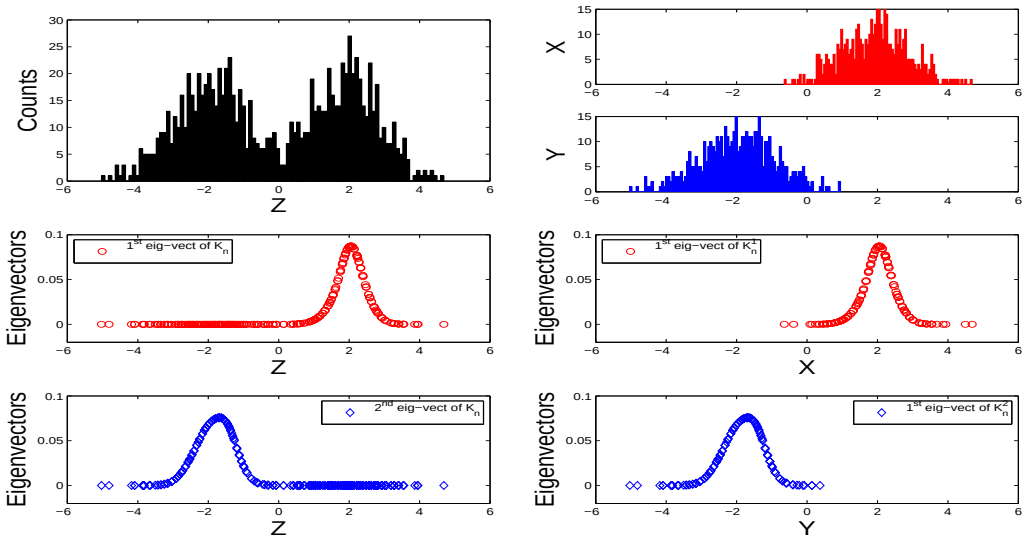

Figure 2. Eigenvectors of a Gaussian kernel matrix ($\omega = 0.3$) of 1000 data sampled from a Mixture Gaussian distribution $P = 0.5N(2, 12) + 0.5N(-2, 12)$. Top left panel: Histogram of the data. Middle left panel: First eigenvector of K_n. Bottom left panel: Second eigenvector of K_n. Top right panel: Histograms of data from each component. Middle right panel: First eigenvector of K_n^1. either positive or negative on the ϵ-support of e. $\{i : |e_i| \geq \epsilon\} \subset \{i : |d_i| \geq \epsilon\}$.

Algorithm 3. Spectroscopic estimation of a Gaussian mixture distribution.

Input: Data $x_1, \ldots, x_n \in \mathbb{R}^d$. **Parameters:** Kernel bandwidth $\omega > 0$, threshold $\epsilon > 0$.[1]
Output: Number of components $\hat{G}$. Estimated mean $\hat{\mu}^g \in \mathbb{R}^d$, mixing weight $\hat{\pi}^g$, $g = 1, \ldots, \hat{G}$ and covariance matrix Σ^g for each component.

- **Step 1.** Constructing K_n, the empirical approximation to $\mathcal{G}_p^\omega$:

  Put $(K_n)_{ij} = \frac{1}{n} \exp\left(-\frac{\|x_i - x_j\|^2}{2\omega^2}\right)$, $i, j = (1, \ldots, n)$. Compute the (leading) eigenvalues $\lambda_1, \lambda_2, \ldots$ and eigenvectors $v_1, v_2, \ldots$ of K_n.

- **Step 2.** Estimating the number of components G:

  Identify all eigenvectors of K_n, which have no sign changes up to precision ϵ. Estimate G by the number ($\hat{G}$) of such eigenvectors and denote those eigenvectors and the corresponding eigenvalues by $v_0^1, v_0^2, \ldots, v_0^{\hat{G}}$ and $\lambda_0^1, \lambda_0^2, \ldots, \lambda_0^{\hat{G}}$ respectively.

[1] In our implementation of the algorithm we choose $\epsilon = \max_j |(v_i)_j|/n$ for each eigenvector v_i. In the description of the algorithm we will use the same ϵ for simplicity.

- **Step 3.** Estimating the mean μ^g and the mixing weight π^g of each component:

  For the g'th component, $g = 1, \ldots, \hat{G}$, estimate the mean and the mixing weight as follows:

$$\hat{\mu}^g = x_k, \quad \text{where} \quad k = \underset{i}{\text{argmax}} \, |(v_0^g)_i|$$

$$\hat{\pi}^g = \frac{n^g}{\sum_{h=1}^{\hat{G}} n^h},$$

  where $n^h =$ cardinality of ϵ-support of v_0^h.

To estimate the covariance matrix Σ^g of each component p^g: we first all eigenvectors such that $\frac{v(x_s)}{v_0^g(x_s)}$ is approximately a linear function of x_s on the ϵ-support of v_0^g. Then we can apply the estimation methods described in **Algorithm 2**, **Step 3** on the ϵ-support of v_0^g.

5. Simulations and Experiments

Simulation: multivariate Gaussian mixture distribution.
A simulation on five dimensional data is carried out to test the proposed algorithm. The first two variables X_1 and X_2 are a mixture three Gaussian components $p(X) = \sum_{g=1}^3 \pi^g N(\mu^g, \Sigma^g)$ with mixing weights and group means shown in Table 3 and covariance matrices:

$$\Sigma^1 = \begin{pmatrix} 0.5 & -0.25 \\ -0.25 & 0.5 \end{pmatrix}, \quad \Sigma^2 = \begin{pmatrix} 0.5 & 0.25 \\ 0.25 & 0.5 \end{pmatrix},$$

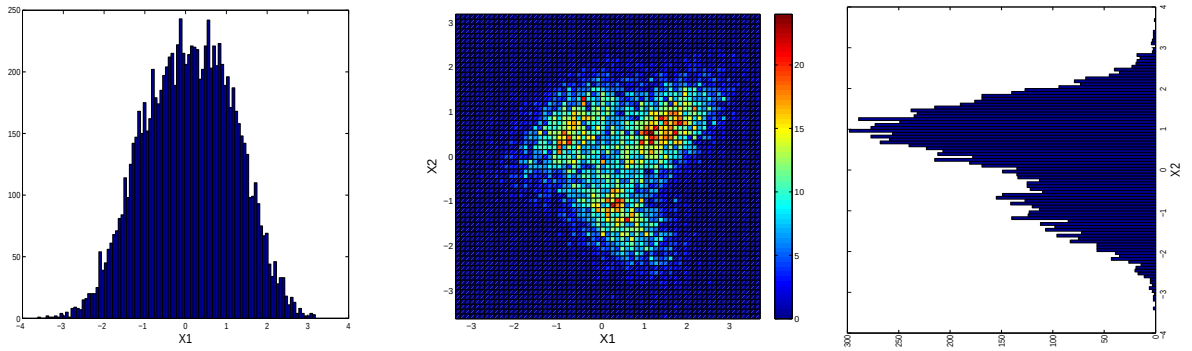

Figure 3. Left: Histogram of the first coordinate X_1; Middle: Two dimensional histogram of the first two coordinates (X_1, X_2). Right: Histogram of X_2.

$$\Sigma^3 = \begin{pmatrix} 0.5 & -0.25 \\ -0.25 & 0.5 \end{pmatrix}$$

The remaining three variables are Gaussian noise $N(0, 0.1I)$. In each simulation run, 3000 data points are sampled. The histogram of X_1, two-dimensional histogram of X_1 and X_2, and histogram of X_2 for one simulation run are shown in Figure 3. We see that it is impossible to identify the number of components by investigating the one-dimensional histograms. The Algorithm 3 with $\omega = 0.1$ was used to estimate the number of components G, mixing weights π^g. The simulation is run 50 times and the algorithm accurately estimated the number of groups in 46 of the 50 runs. Two times the number of groups was estimated as 2 and two times as 4. The average and standard deviation of the estimators of mixing weights and means for the 46 runs are reported in Table 3. We see that the estimates for mixing weights are close to the true values and the estimated group means are close to the estimates from labeled data. Covariance estimates, which we do not show due to space limitations, also show reasonable accuracy.

USPS ZIP code data.
To apply our method to some real-world data we choose a subset of the USPS handwritten digit dataset, consisting of 16x16 grayscale images. In this experiment, 658 "3"s, 652 "4"s, and 556 "5"s in the training data are pooled together as our sample (size 1866). The Spectroscopic estimation algorithm using a Gaussian kernel with bandwidth 2 is applied to the sample . Here we do not use the algorithm to estimate mean and variance of each component, since we do not expect the distribution of the 256 dimensional data to like a Gaussian distribution. Instead, we investigate the eigenvectors with no sign change over $\{x : |v(x)| > \epsilon\}$. We expect (1) the data corresponding to large absolute values of each of such eigenvectors present one mode

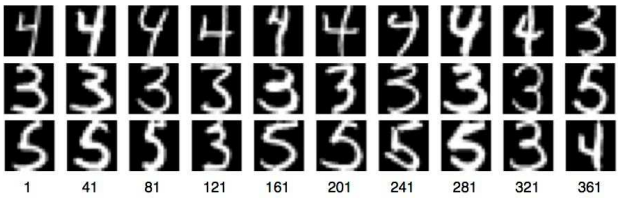

Figure 4. Images ordered by the three eigenvectors v_1, v_{16} and v_{49} identified by Algorithm 3. The images are the digits corresponding to the 1^{st}, 41^{st}, 81^{st}, $\cdots$, 361^{st} largest entries of $|v_1|$ (first row), $|v_{16}|$ (second row) and $|v_{49}|$ (third row).

	"3" (T)	"4" (T)	"5" (T)
"3" (P)	625	0	45
"4" (P)	17	640	32
"5" (P)	16	12	479

Table 4. Confusion matrix of clustering results for USPS handwritten digits. Each cell shows the number of data points belonging both in the **T**rue group (e.g. "3") and the **P**redicted group (e.g. "3")

(cluster) and (2) those data points are in the same digit group.

In the output of our algorithm, three eigenvectors v_1, v_{16} and v_{49} of K_n satisfy the condition of no sign change over $\{x : |v(x)| > \epsilon\}$ with $\epsilon = \max(v)/n$. We first rank the data by an decreasing order of $|v|$ and show the 1^{st}, 41^{st}, 81^{st}, $\cdots$, 361^{st} digits in Figure 4. All digits with larger value of $|v_1|$ belong to the group of "4"s, and other digits ("3" and "5") correspond to smaller values of $|v_1|$. Similarly, larger values of $|v_{16}|$ are in the group of "3"s and $|v_{49}|$ for "5"s.

By assigning digits to their component defined by one of the eigenvectors (v_1, v_{16}, v_{49}) we obtain the clustering results shown in the confusion Table 4. We see that

the overall accuracy of clustering is 93.46%. This clustering method can be thought of as an extension of the framework provided in this paper. While this method is closely related to spectral clustering, the procedures for choosing eigenvectors are different.

6. Conclusion

In this paper we have presented *Data Spectroscopy*, a new framework for inferring parameters of certain families of probability distributions from data. In particular we have analyzed the case of a mixture of Gaussian distributions and shown how to detect and estimate its components under the assumption of reasonable component separation. The framework is based on the spectral properties of data-dependent convolution operators and extends intuitions from spectral clustering and Kernel PCA. We have developed algorithms and have shown promising experimental results on simulated and real-world datasets.

We think that our approach provides new connections between spectral methods and inference of distributions from data, which may lead to development of algorithms for using labeled and unlabeled data in problems of machine learning.

Abstract

Haussler's convolution kernel provides a successful framework for engineering new positive semidefinite kernels, and has been applied to a wide range of data types and applications. In the framework, each data object represents a finite set of finer grained components. Then, Haussler's convolution kernel takes a pair of data objects as input, and returns the sum of the return values of the predetermined primitive positive semidefinite kernel calculated for all the possible pairs of the components of the input data objects. On the other hand, the *mapping kernel* that we introduce in this paper is a natural generalization of Haussler's convolution kernel, in that the input to the primitive kernel moves over a predetermined subset rather than the entire cross product. Although we have plural instances of the mapping kernel in the literature, their positive semidefiniteness was investigated in case-by-case manners, and worse yet, was sometimes incorrectly concluded. In fact, there exists a simple and easily checkable necessary and sufficient condition, which is generic in the sense that it enables us to investigate the positive semidefiniteness of an arbitrary instance of the mapping kernel. This is the first paper that presents and proves the validity of the condition. In addition, we introduce two important instances of the mapping kernel, which we refer to as the *size-of-index-structure-distribution* kernel and the *edit-cost-distribution* kernel. Both of them are naturally derived from well known (dis)similarity measurements in the literature (*e.g.* the maximum agreement tree, the edit distance), and are reasonably expected to improve the performance of the existing measures by evaluating their distributional features rather than their peak (maximum/minimum) features.

1. Introduction

Haussler's convolution kernel (Haussler, 1999) has been used as a general framework to tailor known primitive kernels to the context of specific applications. In this section, we first review a degenerated form of Haussler's convolution kernel, which proves in fact to be equivalent to the general form of Haussler's convolution kernel (see 2.2). Let each data point x in a space χ be associated with a finite subset χ'_x of a common space χ'. Furthermore, we assume that a kernel $k : \chi' \times \chi' \to \mathbb{R}$ is given. Then, Haussler's convolution kernel $K : \chi \times \chi \to \mathbb{R}$ is defined as follows (see 2.2).

$$K(x, y) = \sum_{(x',y') \in \chi'_x \times \chi'_y} k(x', y') \tag{1}$$

Haussler proved that, if $k(x', y')$ is positive semidefinite, then so is $K(x, y)$. Haussler's convolution kernel is known to have a wide range of application (Lodhi et al., 2001; Collins & Duffy, 2001; Suzuki et al., 2004).

On the other hand, the *mapping kernel* is a natural generalization of Haussler's convolution kernel, and is defined by Eq. (2) for $\{M_{x,y} \subseteqq \chi'_x \times \chi'_y \mid (x, y) \in \chi^2\}$. The problem that the present paper addresses is to determine whether the mapping kernel is positive semidefinite.

$$K(x, y) = \sum_{(x',y') \in M_{x,y}} k(x', y') \tag{2}$$

The main contribution of the present paper is to present a necessary and sufficient condition for the mapping kernel $K(x, y)$ defined by Eq. (2) to be positive semidefinite for all possible choices of positive semidefinite $k(x', y')$. More specifically, we prove that the condition is that the *mapping system* $\{M_{x,y} \mid (x, y) \in \chi^2\}$ is *transitive*, *i.e.*, $(x', y') \in M_{x,y} \wedge (y', z') \in M_{y,z} \Rightarrow (x', z') \in M_{x,z}$. Haussler's convolution kernel is indeed the special case of the mapping kernel for $\{M_{x,y} = \chi'_x \times \chi'_y\}$, which is apparently transitive.

We see plural instances of the mapping kernel in the literature, and some of them were mistreated in respective manners.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

- Although the *elastic tree kernel* (Kashima & Koyanagi, 2002) was treated as an instance of Haussler's convolution kernel, it is, in fact, an instance of the mapping kernel. Therefore, the positive semidefiniteness of the kernel should not have been determined based on Haussler's theorem.
- The *codon-improved kernel* (Zien et al., 2000) was claimed to be unconditionally positive semidefinite, since it was viewed as an instance of the polynomial kernel. The kernel, in fact, is an instance of the mapping kernel under certain settings of weights.

That is to say, the positive semidefiniteness of the aforementioned kernels were concluded on wrong grounds, and in fact, the conclusion regarding the codon-improved kernel is wrong — in reality, it is not necessarily positive semidefinite.

The kernels introduced in (Menchetti et al., 2005) and (Kuboyama et al., 2006) are also instances of the mapping kernel. In contrast to the elastic and codon-improved kernels, their positive semidefiniteness was properly investigated, albeit in specific manners.

This is the first paper that recognizes the mapping kernel as a generic class of kernels, and presents a necessary and sufficient condition that a mapping kernel becomes positive semidefinite. Furthermore, the condition is simple, intuitive and easy to check, and therefore, would make engineering of new instances of the mapping kernel easier, more efficient and more effective to a large extent.

As the second contribution of the present paper, we take advantage of the mapping kernel, and present a way to augment a couple of well-known frameworks to engineer similarity functions for discretely structured objects (*e.g.* strings, trees, general graphs).

It is known that the *maximum* sizes of shared substructures of the objects can be used as a good measure of similarities of the objects. The *maximum agreement subtree* is a good example. Also, the *edit distance* has been applied to various types of objects. An edit distance between two data objects is generally defined as the minimum cost of edit scripts that transform one object into the other.

These two frameworks are common in that they only focus on the maximum/minimum values of the similarity measures (*i.e.* the sizes of shared substructures and the costs of edit scripts), and therefore, only those substructures with the maximum sizes or those edit scripts with the minimum costs can contribute to the similarity functions. It is, however, reasonably presumable that distributional features of the measurements may carry useful information with regard to similarities of objects, and more accurate similarity functions can be engineered by evaluating the distributional features.

Based on the aforementioned consideration, we introduce two novel classes of kernels (similarity functions) each evaluating the distributional features of the sizes of shared substructures or the costs of edit scripts. Also, we show a general way to view them as mapping kernels. By virtue of our simple criteria for positive semidefinite mapping kernels, we can easily determine whether instances of the new kernel classes are positive semidefinite, and, if they are, we can take advantage of sophisticated classifiers such as support vector machines (SVM). In 3.1 and 3.2, we see that the examples of distribution-based similarity functions derived from maximum agreement subtrees and general tree edit distances are positive semidefinite, while those derived from *maximum refinement trees* (Hein et al., 1996) and *less-constrained tree edit distance* (Lu et al., 2001) are not.

2. The Mapping Kernel

In this section, as a preliminary, we quickly review the positive semidefinite kernel (2.1) and Haussler's convolution kernel (2.2). Then, we describe our main theorem with regard to the mapping kernel (2.3).

2.1. The Positive Semidefinite Kernel

A kernel $K : \chi \times \chi \longrightarrow \mathbb{R}$ is said to be positive semidefinite, if, and only if, for arbitrary $x_1, \ldots, x_n \in \chi$, the corresponding Gram matrix $G = [K(x_i, x_j)]_{i,j=1,\ldots,n}$ is a positive semidefinite matrix. Positive semidefiniteness of kernels is a critical condition for reproducing kernel Hilbert spaces to exist. In simpler cases where a data point space χ is finite, this condition is equivalent to the property that there exists a mapping $\Phi : \chi \longrightarrow \mathbb{R}^N$ such that $K(x, y) = \Phi(x)\Phi(y)^{\mathsf{T}}$.

In this paper, by a positive semidefinite matrix, we mean a real symmetric matrix (*i.e.* $A^{\mathsf{T}} = A$) that satisfies one of, hence, all of the mutually equivalent conditions stated below, where $\dim A = n$.

- $(c_1, \ldots, c_n)A(c_1, \ldots, c_n)^{\mathsf{T}} \geq 0$ for $\forall (c_1, \ldots, c_n) \in \mathbb{R}^n$.
- A has only non-negative real eigenvalues.
- There exists an n-dimensional orthogonal matrix P (*i.e.* $P^{\mathsf{T}}P = E_n$) such that $P^{\mathsf{T}}AP$ is a diagonal matrix with non-negative elements.
- $A = B^{\mathsf{T}}B$ for some $m \times n$ real matrix B.

2.2. Haussler's Convolution Kernel

Hausler's theorem (Haussler, 1999, Theorem 1) asserts the positive semidefiniteness of Haussler's R-convolution kernel, and Theorem 1 presents its special case for $D = 1$.

Theorem 1. *Let $k : \chi' \times \chi' \to \mathbb{R}$ be a positive semidefinite kernel. Given a relation $R \subseteq \chi' \times \chi$, $K : \chi \times \chi \to \mathbb{R}$ defined by Eq. (3) is also positive semidefinite.*

$$K(x, y) = \sum_{(x',x)\in R} \sum_{(y',y)\in R} k(x', y') \tag{3}$$

It is interesting to note that Haussler's theorem for $D > 1$ is obtained as a corollary to Theorem 1.

Corollary 1. (Haussler, 1999) *Let $k_d : \chi'_d \times \chi'_d \longrightarrow \mathbb{R}$ be positive semidefinite kernels for $d = 1, \ldots, D$. Given a relation $R \subset \chi'_1 \times \cdots \times \chi'_D \times \chi$, the kernel $K : \chi \times \chi \longrightarrow \mathbb{R}$ defined below is also positive semidefinite.*

$$K(x, y) = \sum_{(x'_1,\ldots,x'_D,x)\in R} \sum_{(y'_1,\ldots,y'_D,y)\in R} \prod_{d=1}^{D} k_d(x'_d, y'_d)$$

2.3. Definition and Main Theorem

Letting χ'_x denote $\{x' \in \chi' \mid (x', x) \in R\}$, Eq. (1) gives an equivalent form of Eq. (3). On the other hand, the *mapping kernel* is defined so that (x', y') moves over a subset $M_{x,y}$ of $\chi'_x \times \chi'_y$ rather than the entire cross product $\chi'_x \times \chi'_y$ (Eq. (2)).

The present paper shows that the mapping kernel is positive semidefinite for all possible choices of positive semidefinite underlying kernels k, if, and only if, $\{M_{x,y} \mid x, y \in \chi\}$ is *transitive* (Definition 2).

Therefore, for an arbitrary non-transitive $\{M_{x,y}\}$, a positive semidefinite underlying kernel $k(x', y')$ exists such that the resulting $K(x, y)$ is not positive semidefinite (4.1.2). On the other hand, $K(x, y)$ may be positive semidefinite even for a non-transitive $\{M_{x,y}\}$ and a positive semidefinite $k(x', y')$ (Example 1).

Example 1. The (k, m)-mismatch kernel $K_{(k,m)}(x, y)$ is positive semidefinite (Leslie et al., 2004). When χ'_x and χ'_y denote the sets of k-mers in x and y, $K_{(k,m)}(x, y)$ can be regarded as a mapping kernel for the non-transitive $\{M_{x,y}\}$ defined as follows.

$$M_{x,y} = \{(x', y') \mid K_{(k,m)}(x', y') \neq 0\} \subseteq \chi'_x \times \chi'_y$$

$$K_{(k,m)}(x, y) = \sum_{(x',y')\in M_{x,y}} K_{(k,m)}(x', y')$$

The result is formalized as follows.

Definition 1. A *mapping system* $\mathcal{M}$ is a triplet $(\chi, \{\chi'_x \mid x \in \chi\}, \{M_{x,y} \subseteq \chi'_x \times \chi'_y \mid (x, y) \in \chi^2\})$ such that $|M_{x,y}| < \infty$ and $(y', x') \in M_{y,x}$ if $(x', y') \in M_{x,y}$.

Definition 2. A mapping system $(\chi, \{\chi'_x\}, \{M_{x,y}\})$ is said to be *transitive*, if, and only if, $(x'_1, x'_2) \in M_{x_1,x_2} \wedge (x'_2, x'_3) \in M_{x_2,x_3} \Rightarrow (x'_1, x'_3) \in M_{x_1,x_3}$ holds for arbitrary $x_i \in \chi$ and $x'_i \in \chi'_{x_i}$ $(i = 1, 2, 3)$.

Definition 3. An *evaluating system* $\mathcal{E}$ for a mapping system $(\chi, \{\chi'_x\}, \{M_{x,y}\})$ is a triplet $(\chi', k, \{\gamma_x \mid x \in \chi\})$ with a positive semidefinite *underlying kernel* $k : \chi' \times \chi' \to \mathbb{R}$ and *projections* $\gamma_x : \chi'_x \to \chi'$.

Definition 4. For a mapping system $\mathcal{M} = (\chi, \{\chi'_x\}, \{M_{x,y}\})$ and an evaluating system $\mathcal{E} = (\chi', k, \{\gamma_x\})$ for $\mathcal{M}$, the *mapping kernel* with respect to $\mathcal{M}$ and $\mathcal{E}$ is defined by Eq. (4).

$$K(x, y) = \sum_{(x',y')\in M_{x,y}} k(\gamma_x(x'), \gamma_y(y')) \tag{4}$$

Now, our main theorem is described as follows, and its proof is given in Section 4.

Theorem 2. *For a mapping system $\mathcal{M}$, the following are equivalent to each other.*

1. *$\mathcal{M}$ is transitive.*
2. *For an arbitrary evaluating system $\mathcal{E}$ for $\mathcal{M}$, the mapping kernel with respect to $\mathcal{M}$ and $\mathcal{E}$ is positive semidefinite.*

It is possible to prove (1) $\Rightarrow$ (2) of Theorem 2 as a corollary to Theorem 1. Nevertheless, our direction in the present paper is opposite — we like to view Theorem 1 as a trivial corollary to Theorem 2. In fact, we will prove Theorem 2 without assuming Theorem 1 in Section 4.

3. Similarity Functions Based on Distributions

In this section, we introduce two new classes of the mapping kernel. The kernels are expected to improve the classification performance of known similarity measurements by evaluating their distributional features.

3.1. Size-of-index-structure-distribution Kernels

When some structures are commonly derived from two data objects, the structures may carry information with regard to similarities between the data objects. In this paper, we call such structures *index structures*.

The *agreement subtree* is a good example of the index structure, when data objects are represented as

trees. An agreement subtree between plural input trees is usually defined as a subtree *homeomorphically* included in all the input trees (Berry & Nicolas, 2004). In the present paper, we assume that the input trees are a pair of trees. Even when we fix the input tree pair, there may exist more than one agreement subtree, and the maximum size of the agreement subtrees can be naturally viewed as a measure of similarities between the input trees. The *maximum agreement subtrees* (MAST) problem is the problem to determine at least one agreement subtree with the *maximum size* among the possible agreement subtrees for the input trees. The MAST problem has been extensively studied from the application point of view (*e.g.* evolutionary trees (Hein et al., 1996; Berry & Nicolas, 2004), shape-axis trees (Pelillo, 2002)) as well as from the algorithm efficiency point of view.

When using the size of the maximum agreement subtrees as a similarity measurement between trees, we discard those agreement subtrees smaller in size than the maximum ones, and therefore, they do not contribute to the final evaluation at all. It is, however, reasonable to think that distributional features of the sizes of agreement subtrees may carry useful information with regard to similarities of the trees.

Based on the aforesaid consideration, we introduce the kernel of Eq. (5), which evaluates distributional features of the sizes of agreement subtrees. In Eq. (5), we let $\mathsf{AST}(x, y)$ denote the set of the agreement subtrees between x and y, and $f : \mathbb{N} \to \mathbb{R}_+ = \{y \geq 0 \mid y \in \mathbb{R}\}$ be an increasing function.

$$K(x, y) = \sum_{t \in \mathsf{AST}(x,y)} f(\mathsf{size\_of}(t)) \tag{5}$$

If x and y are rooted trees of bounded degree, and if $f(n) = \alpha^n$ or $f(n) = n$, for example, there exist polynomial-time efficient algorithms to calculate $K(x, y)$.

Beside the advantages due to the distributional features, the kernel could provide the advantage of using sophisticated classifiers such as SVM (Cristianini & Shawe-Taylor, 2000). In fact, our contribution asserts that $K(x, y)$ is positive semidefinite as follows. First, $K(x, y)$ can be viewed as a mapping kernel under the following notation.

- χ'_x is the set of the subtrees of x.
- $M_{x,y} = \{(x', y') \in \chi'_x \times \chi'_y \mid x' \cong y'\}$, where $x' \cong y'$ means that they are homeomorphic as trees.
- $k(x', y') = \begin{cases} f(\mathsf{size\_of}(x')) & \text{if } \mathsf{size\_of}(x') = \mathsf{size\_of}(y') \\ 0 & \text{otherwise.} \end{cases}$

It is easy to see that $\{M_{x,y}\}$ is transitive and $k(x', y')$ is positive semidefinite. Hence,

$$K(x, y) = \sum_{t \in \mathsf{AST}(x,y)} f(\mathsf{size\_of}(t)) = \sum_{(x',y') \in M_{x,y}} k(x', y')$$

is positive semidefinite by Theorem 2.

Besides the maximum agreement subtree, the *maximum refinement subtree* (Hein et al., 1996; Berry & Nicolas, 2004), *maximum subtree isomorphism* (Pelillo, 2002; Aoki et al., 2003) and *maximum agreement supertree* (Jansson et al., 2005) are also used as index structures for trees. As for general graphs, the *maximal common clique* included in an input pair of graphs is also studied in association with MAST in (Pelillo, 2002).

For each of those index structures, we can define kernels in the same way as for MAST. We have only to replace $\mathsf{AST}(x, y)$ in Eq. (5) with the set of the respective index structures. Moreover, except for the maximum refinement subtree, through the same discussion as for MAST, the kernels prove to be positive semidefinite.

Interestingly, Theorem 2 also implies that the kernels defined based on the minimum refinement subtree are not necessarily positive semidefinite. The minimum refinement subtree for $x' \subseteqq x$ and $y' \subseteqq y$ is defined as the minimum tree t such that both x' and y' can be derived from t through a sequence of *edge contractions*, and the maximum refinement subtree problem (*a.k.a.* the maximum compatible tree problem) is the problem to find a minimum refinement subtree with the largest size. Different from the agreement subtree, the relation of having a refinement is not an equivalence relation — even if x' and y', and y' and z', have refinement subtrees, x' and z' do not necessarily have a refinement subtree. This implies that the corresponding $M_{x,y}$ is not necessarily transitive. Therefore, Theorem 2 asserts that the corresponding $K(x, y)$ is not necessarily positive semidefinite.

3.2. Edit-cost-distribution Kernels

The *Edit distance* is also used as an effective measure of similarities between discrete data structures (*e.g.* (Wagner & Fischer, 1974) for strings, (Barnard et al., 1995) for trees, (Bunke, 1997) for general graphs).

Let x be an object consisting of one or more components. For example, a string consists of one or more characters which are laid out on a line. For another example, a graph consists of one or more vertices and edges, and each edge connects a vertex to another. We first give a general definition of *edit operations*, *edit*

scripts, *edit costs* and *edit distances* for such objects.

An edit operation is an operation on a component of x, and is one of (i) substituting a component b for a component a of x (denoted by $\langle a \to b\rangle$), (ii) deleting a component a of x (denoted by $\langle a \to \bullet\rangle$), and (iii) inserting a component a into x (denoted by $\langle \bullet \to a\rangle$). An edit script is a sequence of zero or more edit operations which transforms an object into another. When a cost $\gamma\langle a \to b\rangle \in \mathbb{R}$ is given for each edit operation $\langle a \to b\rangle$[1], the cost $\gamma(\sigma)$ of an edit script σ is the sum of the costs of the edit operations that comprise σ. Finally, an edit distance $d(x, y)$ between objects x and y is defined by:

$$d(x, y) = \min\{\gamma(\sigma) \mid \sigma \text{ transforms } x \text{ into } y\}.$$

Therefore, those edit scripts with larger costs than the minimum cost do not contribute to the final edit distance. In contrast, by introducing kernels by Eq. (6) with a decreasing function $f : \mathbb{R}_+ \to \mathbb{R}_+$, we try to take advantage of the information that those discarded edit scripts potentially carry.

$$K(x, y) = \sum_{\sigma \text{ transforms } x \text{ into } y} f(\gamma(\sigma)) \qquad (6)$$

It is important to note that there exists a natural interpretation of Eq. (6). In a natural setting where the cost $\gamma\langle a \to b\rangle$ is defined as the negative logarithm of the probability that the substitution of b for a (a or b could be $\bullet$) would occur (*e.g.* (Li & Jiang, 2005; Salzberg, 1997)), we let $f(x) = e^{-x}$. For an edit script $\sigma = \langle x'_1 \to y'_1\rangle \cdots \langle x'_n \to y'_n\rangle$ transforming x into y, $f(\gamma(\sigma))$ is evaluated as follows.

$$\begin{aligned} f(\gamma(\sigma)) &= e^{-\gamma(\sigma)} = e^{-\sum_{i=1}^{n} \gamma\langle x'_i \to y'_i\rangle} \\ &= e^{-\sum_{i=1}^{n} -\log \Pr(x'_i \to y'_i)} = \prod_{i=1}^{n} \Pr(x'_i \to y'_i) \end{aligned}$$

Hence, $K(x, y)$ by Eq. (6) equals the total probability that x would be transformed into y.

Usage of sophisticated classifiers such as SVM is another potential advantage of the kernels of the form of Eq. (6). In fact, as shown below, the kernels can be viewed as mapping kernels, if we can pose the following four assumptions.

[1]Usually, components are labeled with elements of an alphabet, and costs of edit operations are defined on the labels rather than on the components. However, for simplicity, we assume that the cost function is defined over the space of objects in the present paper. In addition, to make the resulting edit distance be a distance metric, the costs are often assumed to be a distance metric.

1. The cost function is symmetric (*i.e.* $\gamma\langle a \to b\rangle = \gamma\langle b \to a\rangle$).
2. We let $f(x) = e^{-cx}$ for some positive constant c.
3. In order to avoid calculating infinite sums, we take only *irreducible* edit scripts into consideration in calculating Eq. (6) — Assume that $\sigma = \langle x'_1 \to y'_1\rangle \ldots \langle x'_n \to y'_n\rangle$ transforms x into y. σ is irreducible, if, and only if, (1) x'_i (resp. y'_i) is either a component of x (resp. y) or $\bullet$ and (2) exactly one edit operation $\langle x'_i \to y'_i\rangle$ is applied to each component of x and y.
4. If two irreducible edit scripts differ from each other only in the order of the included edit operations, they are identified in calculating Eq. (6), that is, they are evaluated only once.

For $\sigma = \langle x'_1 \to y'_1\rangle \ldots \langle x'_n \to y'_n\rangle$, we assume that x'_i and y'_i are respectively components of x and y, if, and only if, $i \in \{1, \ldots, m(\sigma)\}$, and call $\langle x'_1 \to y'_1\rangle \cdots \langle x'_{m(\sigma)} \to y'_{m(\sigma)}\rangle$ the *core* of σ. Then, $\gamma(\sigma)$ and $K(x, y)$ are evaluated as follows.

$$\begin{aligned} \gamma(\sigma) &= \sum_{i=1}^{m(\sigma)} (\gamma\langle x'_i \to y'_i\rangle - \gamma\langle x'_i \to \bullet\rangle - \gamma\langle \bullet \to y'_i\rangle) \\ &\quad + \sum_{x' \in x} \gamma\langle x' \to \bullet\rangle + \sum_{y' \in y} \gamma\langle \bullet \to y'\rangle \end{aligned}$$

$$\begin{aligned} K(x, y) = &\prod_{\xi \in x} f(\gamma\langle \xi \to \bullet\rangle) \cdot \prod_{\eta \in y} f(\gamma\langle \bullet \to \eta\rangle) \cdot \\ &\left[\sum_{\sigma} \left(\prod_{i=1}^{m(\sigma)} \frac{f(\gamma\langle x'_i \to y'_i\rangle)}{f(\gamma\langle x'_i \to \bullet\rangle) f(\gamma\langle \bullet \to y'_i\rangle)} \right)\right] \end{aligned} \qquad (7)$$

In Eq. (7), the first two factors of the right-hand side are functions of x and y, and therefore, we denote them by $g(x)$ and $g(y)$, respectively. On the other hand, the last factor is a function of $x' = (x'_1, \ldots, x'_{m(\sigma)})$ and $y' = (y'_1, \ldots, y'_{m(\sigma)})$, and is denoted by $k(x', y')$. We define $M_{x,y}$ as follows.

$$\begin{aligned} M_{x,y} = \{&((x'_1, \ldots, x'_m), (y'_1, \ldots, y'_m)) \mid \\ &\exists\sigma[\langle x'_1 \to y'_1\rangle \cdots \langle x'_m \to y'_m\rangle \text{ is the core of } \sigma]\} \end{aligned}$$

Then, the following holds

$$\begin{aligned} K(x, y) &= g(x) \cdot g(y) \cdot \left(\sum_{(x', y') \in M_{x,y}} k(x', y') \right) \\ &= g(x) \cdot g(y) \cdot \bar{K}(x, y) \end{aligned}$$

In particular, $\bar{K}(x, y)$ is a mapping kernel, and $K(x, y)$ is positive semidefinite, if, and only if, so is $\bar{K}(x, y)$,

since $g(x)$ cannot take the value 0. The kernel $\bar{K}(x,y)$, however, is not necessarily positive semidefinite, even if $k(x',y')$ is positive semidefinite, since $\{M_{x,y}\}$ is not necessarily transitive. We will investigate this problem taking the *tree edit distance* as an example.

For the tree edit distance, the edit operations act on vertices of trees. For a pair (x',y') to be the core of some irreducible tree edit script, it is necessary and sufficient that φ defined by $\varphi(x'_i) = y'_i$ preserves the ancestor-descendent relation and the sibling (left-to-right) relation (Tai, 1979). Therefore, $M_{x,y}$ for the general tree edit distance is defined as follows, where $x'_i < x'_j$ means x'_j is an ancestor of x'_i and $x'_i \prec x'_j$ means x'_j is located on the right side of x'_i.

$$M_{x,y} = \{((x'_1,\ldots,x'_m),(y'_1,\ldots,y'_m)) \mid [x'_i < x'_j \Leftrightarrow y'_i < y'_j] \wedge [x'_i \prec x'_j \Leftrightarrow y'_i \prec y'_j]\} \quad (8)$$

It is straightforward to verify that $\{M_{x,y}\}$ is transitive. Therefore, Theorem 2 asserts that, if $k(x',y')$ is positive semidefinite, so is $\bar{K}(x,y)$ for this $\{M_{x,y}\}$.

On the other hand, two subclasses of the general tree edit distance have been proposed. They are *constrained* (*a.k.a.* structure-preserving) tree edit distance (Zhang, 1995) and *less-constrained* (*a.k.a.* alignable) tree edit distance (Lu et al., 2001).

Those subclasses of the general tree edit distance determine respective $M_{x,y}$, which are generally proper subsets of those define by (8). Since $\{M_{x,y}\}$ for the constrained tree edit distance is easily verified to be transitive, the resulting $\bar{K}(x,y)$ turns out positive semidefinite by virtue of Theorem 2. In contrast to the constrained edit distance, $\{M_{x,y}\}$ for the less-constrained tree edit distance is not transitive. Therefore, Theorem 2 implies that $\bar{K}(x,y)$ is not necessarily positive semidefinite.

4. Proof of Theorem 2

4.1. Key Lemma

Let X^{ij} be m-dimensional square matrices parameterized by $(i,j) = \{1,\ldots,n\}^2$, and let X denote the derived mn-dimensional square matrix $[X^{ij}]_{i,j=1,\ldots,n}$ — the $(m(i-1)+k, m(j-1)+l)$-element of X, denoted by X^{ij}_{kl}, is defined to be the (k,l)-element of X^{ij}.

Furthermore, for an m-dimensional square matrix A, $\mathrm{smry}_A(X)$ denotes the n-dimensional square matrix $[\mathrm{tr}(A^\mathsf{T} X^{ij})]_{i,j=1,\ldots,n}$. Note that the (i,j)-element of $\mathrm{smry}_A(X)$ is given by Eq. (9).

$$\mathrm{tr}(A^\mathsf{T} X^{ij}) = \sum_{k=1}^{m}\sum_{l=1}^{m} A_{kl} X^{ij}_{kl} \quad (9)$$

Proposition 1. *For an m-dimensional square matrix A, the following are equivalent to each other.*

1. *A is positive semidefinite.*
2. *$\mathrm{smry}_A(X)$ is positive semidefinite for an arbitrary mn-dimensional positive semidefinite matrix X.*

Proof. First, we prove the assertion assuming that A is diagonal, whose I-th diagonal element is α_I.

The condition 2 implies 1, since we see $\alpha_I \geq 0$ for any I by letting X be the sparse matrix such that X_{kl} is 1, if $k = l = I$, and 0, otherwise.

On the other hand, the converse follows from Eq. (10), since $\mathrm{smry}_A(X) = Z^\mathsf{T} Z$ holds for the $m^2 n \times n$ matrix Z such that $Z_{mn(I-1)+m(k-1)+i,j} = \sqrt{\alpha_I} Y^{kj}_{iI}$, where Y is an mn-dimensional matrix such that $X = Y^\mathsf{T} Y$.

$$\begin{aligned} \mathrm{tr} A^\mathsf{T} X^{ij} &= \sum_{I=1}^{m} \alpha_I \left(\sum_{k=1}^{n}\sum_{l=1}^{m} Y^{ki}_{lI} Y^{kj}_{lI} \right) \quad (10) \\ &= \sum_{I=1}^{m}\sum_{k=1}^{n}\sum_{l=1}^{m} (\sqrt{\alpha_I} Y^{ki}_{lI})(\sqrt{\alpha_I} Y^{kj}_{lI}) \end{aligned}$$

The general cases for non-diagonal A reduces to the diagonal case, since, for P such that $P^\mathsf{T} A P$ is diagonal, $\mathrm{smry}_A(X) = \mathrm{smry}_{P^\mathsf{T} A P}(\tilde{X})$ holds for $\tilde{X} = [P^\mathsf{T} X^{ij} P]_{i,j=1,\ldots,n}$. □

4.2. (1) Implies (2)

Investigating whether K is positive semidefinite is equivalent to investigating whether the Gram matrices for finite subsets of χ are positive semidefinite. Therefore, without any loss of generality, we may assume that χ is a finite set $\{x_1,\ldots,x_n\}$. Since M_{x_i,x_j} are finite, we may also assume χ'_{x_i} are finite.

We slightly extend the definition of $(\chi', k, \{\gamma_x\})$ by adding a new element $\bullet \in \chi'$ such that $k(\bullet,\bullet) = k(\bullet,x') = k(x',\bullet) = 0$ hold for an arbitrary $x' \in \chi'$. Even after the extension, $(\chi', k, \{\gamma_x\})$ still remains an evaluating system for $\mathcal{M}$.

Next, we define $\bar{\chi}', \bar{M}$ and $\{\bar{\gamma}_x\}$ as follows: $\bar{\chi}'$ is the disjoint union $\bigsqcup_{i=1}^{n} \chi'_{x_i}$; $\bar{x}'$ denotes the image of $x' \in \chi'_x$ in $\bar{\chi}'$; $\bar{M} = \{(\bar{x}',\bar{y}') \mid (x',y') \in M_{x,y} \wedge x,y \in \chi\}$; $\bar{\gamma}_x : \bar{\chi}' \longrightarrow \chi'$ satisfies that $\bar{\gamma}_x(\bar{x}') = \gamma_x(x')$, if $x' \in \chi'_x$, and $\bar{\gamma}_x(\bar{x}') = \bullet$, otherwise. Then, the mapping kernel K with respect to $\mathcal{M}$ and $\mathcal{E}$ is rewritten as follows.

$$K(x,y) = \sum_{(\bar{x}',\bar{y}') \in \bar{M}} k(\bar{\gamma}_x(\bar{x}'), \bar{\gamma}_y(\bar{y}'))$$

Furthermore, $K(x_i,x_j) = \mathrm{tr}(A^\mathsf{T} X^{ij})$ holds, when we define m-dimensional matrices A and X^{ij} for $\bar{\chi}' =$

$\{\bar{x}'_1, \ldots, \bar{x}'_m\}$. $A_{kl} = 1$ if $(\bar{x}'_k, \bar{x}'_l) \in \bar{M}$, and $A_{kl} = 0$ otherwise; $X^{ij}_{kl} = k(\bar{\gamma}_{x_i}(\bar{x}'_k), \bar{\gamma}_{x_j}(\bar{x}'_l))$.

To show the assertion, it suffices to prove A is positive semidefinite by Proposition 1 ($X = [X^{ij}]_{i,j=1,\ldots,n}$ is positive semidefinite by definition). A is symmetric, since $(x', y') \in M_{x,y} \Leftrightarrow (y', x') \in M_{y,x}$ holds. The hypothesis that $\{M_{x,y}\}$ is transitive implies that $\{1, \ldots, m\}$ is decomposed into $U_1 \sqcup \cdots \sqcup U_M$ such that: $U_a \cap U_b = \emptyset$, if $a \neq b$; $(\bar{x}'_k, \bar{x}'_l) \in \bar{M}$, if, and only if, $k, l \in U_a$ for some $a \in \{1, \ldots, M\}$. Therefore, $A = \bigoplus_{a=1}^{M} A[U_a]$ holds, and therefore, A is positive semidefinite, since so are $A[U_a]$.

4.3. (2) Implies (1)

We prove the cotraposition of the assertion. If $\mathcal{M}$ is not transitive, A includes at least one of the following sub-matrices (without any loss of generality, we may assume $k < l < b$), where $A[i_1, \ldots, i_n]$ denote the n-dimensional matrix whose (α, β)-element is A_{i_α, i_β}.

$$A[k, l] = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \tag{11}$$

$$A[k, l] = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix} \tag{12}$$

$$A[k, l, b] = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 1 \end{bmatrix} \tag{13}$$

Note that any of them has a negative eigenvalue, since $\det A < 0$ holds.

We will see that there exists an instance of $\mathcal{E} = (\chi', k, \{\gamma_x\})$ such that $\mathrm{smry}_A(X)$, which is the Gram matrix for χ, is not positive semidefinite, if any of the above three cases occurs. In the remaining of this section, we will give a proof only for the case where Eq. (13) holds. The assertion for the simpler cases, that is, where either Eq. (11) or (12) holds, can be proved in almost the same way.

Let i, j and a denote the indices such that $x'_k \in \chi'_{x_i}$, $x'_l \in \chi'_{x_j}$ and $x'_b \in \chi'_{x_a}$ (be reminded that $\bar{\chi}'$ is defined as the disjoint union of χ'_x for $x \in \chi$). The indices are not necessarily different from each other. Further, let column vectors $\vec{e}_1$, $\vec{e}_2$ and $\vec{e}_3$ be an orthogonal basis of $\mathbb{R}^3$ such that the following holds.

$$[\vec{e}_1, \vec{e}_2, \vec{e}_3]^\mathsf{T} A[k, l, b][\vec{e}_1, \vec{e}_2, \vec{e}_3] = \begin{bmatrix} \alpha_1 & 0 & 0 \\ 0 & \alpha_2 & 0 \\ 0 & 0 & \alpha_3 \end{bmatrix}$$

We assume $\alpha_1 < 0$ without any loss of generality, and define positive semidefinite K as follows.

$$K = [\vec{e}_1, \vec{e}_2, \vec{e}_3] \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} [\vec{e}_1, \vec{e}_2, \vec{e}_3]^\mathsf{T}$$

$$\begin{aligned} &\therefore \ \mathrm{tr}(A[k, l, b]^\mathsf{T} K) \\ &= \ \mathrm{tr}\left(\begin{bmatrix} \alpha_1 & 0 & 0 \\ 0 & \alpha_2 & 0 \\ 0 & 0 & \alpha_3 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \right) = \alpha_1 < 0 \end{aligned}$$

Now, we define $\mathcal{E} = (\chi', k, \{\gamma_x\})$ as follows.

- $\chi' = \{\bullet, \xi, \eta, \zeta\}$
- $\begin{bmatrix} k(\xi,\xi) & k(\xi,\eta) & k(\xi,\zeta) \\ k(\eta,\xi) & k(\eta,\eta) & k(\eta,\zeta) \\ k(\zeta,\xi) & k(\zeta,\eta) & k(\zeta,\zeta) \end{bmatrix} = K$
- $\gamma_x(x') = \begin{cases} \xi, & \text{if } x = x_i \text{ and } x' = x'_k, \\ \eta, & \text{if } x = x_j \text{ and } x' = x'_l, \\ \zeta, & \text{if } x = x_a \text{ and } x' = x'_b, \\ \bullet, & \text{otherwise.} \end{cases}$

Below, we investigate three cases: the indices take the same value, that is, $i = j = a$; two of the indices coincide with each other, where we can assume $i = j \neq a$ without loss of generality: the indices are different from one another, that is, $i \neq j \neq a \neq i$. For each case, we see that some diagonally located submatrix of $\mathrm{smry}_A(X)$ is not positive semidefinite. This implies that $\mathrm{smry}_A(X)$ itself is not positive semidefinite.

Case $i = j = a$**:** The submatrix $\mathrm{smry}_A(X)[i]$ is not positive semidefinite.

$$\mathrm{smry}_A(X)[i] = \mathrm{tr}(A[k, l, b]^\mathsf{T} K) < 0$$

Case $i = j \neq a$**:** We will show that $\mathrm{smry}_A(X)[i, k]$ is not positive semidefinite.

$$\begin{aligned} \mathrm{tr}(A^\mathsf{T} X^{ii}) &= \mathrm{tr}(A[k, l, b]^\mathsf{T}[1, 2] K[1, 2]) \\ \mathrm{tr}(A^\mathsf{T} X^{ia}) &= A[k, l, b]^\mathsf{T}{}_{1,3} K_{1,3} + A[k, l, b]^\mathsf{T}{}_{2,3} K_{2,3} \\ \mathrm{tr}(A^\mathsf{T} X^{ai}) &= A[k, l, b]^\mathsf{T}{}_{3,1} K_{3,1} + A[k, l, b]^\mathsf{T}{}_{3,2} K_{3,2} \\ \mathrm{tr}(A^\mathsf{T} X^{aa}) &= A[k, l, b]^\mathsf{T}{}_{3,3} K_{3,3} \end{aligned}$$

$$\therefore \mathrm{tr}\left(\mathrm{smry}_A(X)[i, a] \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \right) = \mathrm{tr}(A[k, l, b]^\mathsf{T} K) < 0$$

By Proposition 1 $\mathrm{smry}_A(X)[i, a]$ turns out not to be positive semidefinite.

Case $i \neq j \neq a \neq i$**:** For $\alpha, \beta = 1, 2, 3$, the (α, β)-element of $\mathrm{smry}_A(X)[i, j, a]$ coincides with

$A[k,l,b]^{\mathsf{T}}{}_{\alpha,\beta} K_{\alpha,\beta}$.

$$\begin{aligned} & \mathrm{tr}\left(\mathrm{smry}_A(X)[i,j,a]\begin{bmatrix}1&1&1\\1&1&1\\1&1&1\end{bmatrix}\right) \\ = \;& \mathrm{tr}(A[k,l,b]^{\mathsf{T}} K) < 0 \end{aligned}$$

By Proposition 1, $\mathrm{smry}_A(X)[i,j,a]$ turns out not to be positive semidefinite.

mStruct: A New Admixture Model for Inference of Population Structure in Light of Both Genetic Admixing and Allele Mutations

Suyash Shringarpure SUYASH@CS.CMU.EDU

School of Computer Science, Carnegie Mellon University, Pittsburgh, PA 15213 USA

Abstract

Traditional methods for analyzing population structure, such as the *Structure* program, ignore the influence of mutational effects. We propose *mStruct*, an admixture of population-specific mixtures of inheritance models, that addresses the task of structure inference and mutation estimation jointly through a hierarchical Bayesian framework, and a variational algorithm for inference. We validated our method on synthetic data, and used it to analyze the HGDP-CEPH cell line panel of microsatellites used in (Rosenberg et al., 2002) and the HGDP SNP data used in (Conrad et al., 2006). A comparison of the structural maps of world populations estimated by *mStruct* and *Structure* is presented, and we also report potentially interesting mutation patterns in world populations estimated by *mStruct*, which is not possible by *Structure*.

1. Introduction

The deluge of genomic polymorphism data, such as the genome-wide multilocus genotype profiles of variable number of tandem repeats (i.e., microsatellites) and single nucleotide polymorphisms (i.e., SNPs), has fueled the long-standing interest in analyzing patterns of genetic variations.to reconstruct the ancestral structures of modern human populations, because such genetic ancestral information can shed light on the evolutionary history of modern populations and provide guidelines for more accurate association studies and other population genetics problems.

One of the state-of-the-art methods for population structure analysis based on multilocus genotype data is the program *Structure*, whose basic form is based on a statistical formalism known as the admixture model (Pritchard et al., 2000). Admixtures are instances of a more general class of hierarchical Bayesian models known as *mixed membership models* (Erosheva et al., 2004), which postulate that genetic markers of each individual are *iid* (Pritchard et al., 2000) or spatially coupled (Falush et al., 2003) samples from multiple population-specific fixed-dimensional multinomial distributions (which we will call *allele frequency profiles* (Falush et al., 2003), or AP) of marker alleles. Under this assumption, the *admixture* model identifies each ancestral population by a specific AP (that defines a unique allele frequency distribution for each ancestral population for each marker) and displays the fraction of contributions from each AP in a modern individual chromosome as a *structural map*. Figure 1 shows an example of a structural map of four modern populations inferred from a portion of the HapMap multi-population dataset by *Structure*. In this *population structural map*, each individual is represented as a thin vertical line which shows the fraction of the individual's chromosome which originated from each ancestral population, as given by a unique AP. This method has been successfully applied to human genetic data in (Rosenberg et al., 2002) and has unraveled impressive patterns in the genetic structures of world population.

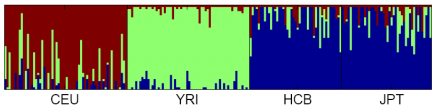

Figure 1. Population structural map inferred by *Structure* on HapMap data consisting of 4 populations. The colors represent different populations

However, since an AP merely represents the *frequency* of alleles in an ancestral population, rather than the actual allelic content or haplotypes of the alleles themselves, the admixture models developed so far based on AP do not model genetic changes due to mutations from the ancestral alleles. Indeed, a serious pitfall of the model underlying *Structure*, as pointed out in (Excoffier & Hamilton, 2003), is that there is no

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

mutation model for modern individual alleles with respect to hypothetical common prototypes in the ancestral populations, i.e, every unique allele in the modern population is assumed to have a distinct ancestral frequency, rather than allowing the possibility of it just being a descendent of some common ancestral allele. Thus, while *Structure* aims to provide ancestry information for each individual and each locus, there is no explicit representation of "ancestors" as a physical set of "founding alleles". Therefore, the inferred population structural map emphasizes revealing the contributions of *abstract* population-specific allele frequency profiles, which does not directly reflect individual diversity or the extent of genetic changes with respect to the founders. Therefore, *Structure* does not enable inference of the founding genetic patterns, the age of the founding alleles, or the population divergence time (Excoffier & Hamilton, 2003).

Another important issue in determining population structure is to look for the presence of admixture, a basic assumption of the *Structure* model. However, as we shall see later, on the HGDP data, it produces results that cluster individuals cleanly into one allele frequency profile or the other, thus leading us to conclude that there was little or no admixture between the human populations. While such a partitioning of individuals would be desirable for clustering them into groups, it does not offer us any biological insight into the intermixing of the populations.

In this paper, we present *mStruct* (for *structure under mutations*), based on an admixture of population-specific mixtures of inheritance model (AdMim). AdMim is an *admixture of mixtures* model, which represents each ancestral population as a mixture of ancestral alleles each with its own inheritance process, and each modern individual as an "ancestry proportion vector" (ancestry vector or *map vector*) that indicates membership proportions among the ancestral populations. By a simple but important extension to the LDA-like (Blei et al., 2003) admixture model used by *Structure*, *mStruct* facilitates estimation of both the *structural map* of populations (incorporating mutations) and the mutation rates of either SNP or microsatellite alleles. A new variational inference algorithm was developed for inference and learning. We compare our method with *Structure* on both synthetic genotype data, and on the microsatellite and SNP genotype data of world populations (Rosenberg et al., 2002; Conrad et al., 2006). Our results show the presence of significant levels of admixture among the founding populations. We also report interesting genetic divergence in world populations revealed by the mutation patterns we estimated.

2. The Statistical Model

2.1. Representation of Populations

To reveal the genetic composition of each modern individual in terms of contributions from hypothetical ancestral populations via statistical inference on multilocus genotype data, one must first choose an appropriate representation of ancestral populations. Below, we begin with a brief description of a commonly used method, followed by a new method that we propose.

2.1.1. Population-Specific *Allele Frequency* Profiles

Due to the polymorphic nature of genetic markers, an intuitive statistic to characterize a population is the frequencies of all observed alleles at all loci. For example, we can represent an ancestral population k by a unique set of population-specific *multinomial* distributions, $\boldsymbol{\beta}^k \equiv \{\vec{\beta}_i^k \ ; \ i = 1 : I\}$, where $\vec{\beta}_i^k = [\beta_{i,1}^k, \ldots, \beta_{i,L_i'}^k]$ is the vector of multinomial parameters, also known as the *allele frequency profile* (Falush et al., 2003), or AP, of the allele distribution at locus i in ancestral population k; L_i' denotes the total number of observed marker alleles at locus i, and I denotes the total number of marker loci. This representation, known as *population-specific ancestry proportion profile*, is used by the program *Structure*.

2.1.2. Population-Specific *Mixtures of Ancestral Alleles*

A problem with the population-specific AP profile representation is that it ignores the possibility of mutations underlying the alleles observed in modern populations with respect to their ancestral alleles. To capture this, we propose to represent a population by a genetically more realistic statistical model known as the *population-specific mixtures of ancestral alleles (MAA)*. For each locus i, an MAA for ancestral population k is a triple $\{\mu_i^k, \delta_i^k, \vec{\beta}_i^k\}$ consisting of a set of *ancestral* (or founder) alleles $\mu_i^k = (\mu_{i,1}^k, \ldots, \mu_{i,L_i}^k)$, which can differ from their descendent alleles in the modern population; a mutation rate δ_i^k associated with the locus, which can be further generalized to be allele-specific if necessary; and an AP $\vec{\beta}_i^k$ which now represents the frequencies of the *ancestral* alleles. Here L_i denotes the total number of ancestral alleles at loci i.

An MAA is strictly more expressive than an AP, because the incorporation of a mutation model helps to capture details about the population structure which an AP cannot; and the MAA reduces to the AP when the mutation rates become zero and the founders are identical to their descendents. As we show shortly, with an MAA, one can examine the mutation parameters corresponding to each ancestral population via

Bayesian inference from genotype data; this might enable us to infer the age of alleles, and also estimate population divergence times.

Let $i \in \{1, \ldots, I\}$ index the position of a locus in the study genome, $n \in \{1, \ldots, N\}$ index an individual in the study population, and $e \in \{0, 1\}$ index the two possible parental origin of an allele (in this study we do not require strict phase information of the two alleles, so the index e is merely used to indicate diploid data). Under an MAA specific to an ancestral population k, the correspondence between a marker allele X_{i,n_e} and a founder $\mu^k_{i,l} \in \mu^k_i$ is not directly observable. For each allele founder $\mu^k_{i,l}$, we associate with it an inheritance model $p(\cdot|\mu^k_{i,l}, \delta^k_{i,l})$ from which descendants can be sampled. Then, given specifications of the ancestral population from which X_{i,n_e} is derived (denoted by hidden indicator variable Z_{i,n_e}), the conditional distribution of X_{i,n_e} under MAA follows a mixture of population-specific inheritance model: $p(x_{i,n_e} = l' \mid Z_{i,n_e} = k) = \sum_{l=1}^{L} \beta^k_{i,l} p(x_{i,n_e}|\mu^k_{i,l}, \delta^k_{i,l})$. Comparing to the counterpart of this function under AP: $p(x_{i,n_e} = l' \mid Z_{i,n_e} = k) = \beta^k_{i,l'}$, we can see that the latter cannot explicitly model allele diversities in terms of molecular evolution from the founders.

2.2. A New Admixture Model for Population Structure

The concept of admixture arises when modeling objects (e.g., human beings) each comprising multiple instances of some attributes (e.g., marker alleles), each of which comes from a (possibly different) source distribution $P_k(\cdot|\Theta_k)$, according to an individual-specific *admixing coefficient vector* (a.k.a. *map vector*) $\vec{\theta}$. The *map vector* represents the normalized contribution from each of the source distributions $\{P_k \; ; \; k = 1 : K\}$ to the study object. For example, for every individual, the alleles at all marker loci may be inherited from founders in different ancestral populations, each represented by a unique distribution of founding alleles and the way they can be inherited. Formally, this scenario can be captured in the following generative process:

1. For each individual n, draw the admixing vector: $\vec{\theta_n} \sim P(\cdot|\alpha)$, where $P(\cdot|\alpha)$ is a pre-chosen map prior.
2. For each marker allele $x_{i,n_e} \in \mathbf{x}_n$
   - 2.1: draw the latent *ancestral-population-origin* indicator $z_{i,n_e} \sim \text{Multinomial}(\cdot|\vec{\theta_n})$;
   - 2.2: draw the allele $x_{i,n_e}|z_{i,n_e} = k \sim P_k(\cdot|\Theta_k)$.

As discussed in the previous section, an ancestral population can be either represented as an AP or as an MAA. These two different representations lead to two different probability distributions for $P_k(\cdot|\Theta_k)$ in the last sampling step above, and thereby two different admixtures of very different characteristics.

2.2.1. The Existing Model

In *Structure*, the ancestral populations are represented by a set of population-specific APs. Thus the distribution $P_k(\cdot|\Theta_k)$ from which an observed allele can be sampled is a multinomial distribution defined by the rates of all observed alleles in the ancestral population, i.e., $x_{i,n_e}|z_{i,n_e} = k \sim \text{Multinomial}(\cdot|\vec{\beta}^k_i)$. Using this probability distribution in the general admixture scheme outlined above, we can see that *Structure* essentially implements an *admixture of population-specific allele rates* model. But a serious pitfall of using such a model, as pointed out in (Excoffier & Hamilton, 2003), is that there is no error model for individual alleles with respect to the common prototypes, i.e, every unique measurement at a particular allele is assumed to be a new allele, rather than allowing the possibility of it just being the mutation of some common ancestral allele at that marker.

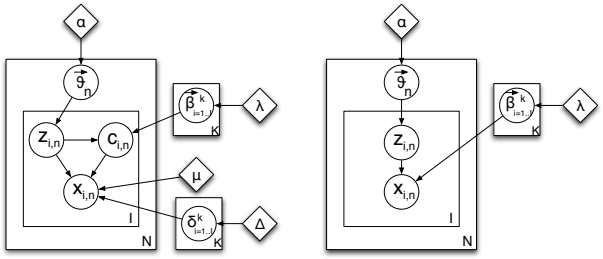
2.2.2. The Proposed Model

We propose to represent each ancestral population by a set of population-specific MAAs. Under this representation, now the distribution $P_k(\cdot|\Theta_k)$ from which an observed allele can be sampled becomes a mixture of inheritance models, each defined on a specific founder. The ensuing sampling module to be plugged into the general admixture scheme outlined above (to replace step 2.2) becomes a two-step generative process:

- 2.2a: draw the latent founder indicator $c_{i,n_e}|z_{i,n_e} = k \sim \text{Multinomial}(\cdot|\vec{\beta}^k_i)$;
- 2.2b: draw the allele $x_{i,n_e}|c_{i,n_e} = l, z_{i,n_e} = k \sim P_m(\cdot|\mu^k_{i,l}, \delta^k_{i,l})$,

where $P_m()$ is a mutation model that can be flexibly defined based on whether the genetic markers are microsatellites or single nucleotide polymorphisms. We call this model an *admixture of population-specific inheritance models* (AdMim), while the previous model is technically only an admixture of population specific allele frequency profiles. Figure 2(a) shows a graphical model the overall generative scheme for AdMim, in comparison with the admixture of population-specific allele rates discussed earlier. From the figure, we can clearly see that *Structure* is virtually identical to an LDA model, while *mStruct* is an extended LDA model which allows noisy observations.

For simplicity of presentation, in the model described above we assume that for a particular individual, the genetic markers at each locus are conditionally *iid* samples from a set of population-specific fixed-dimensional mixture of inheritance models, and that the set of founder alleles at a particular locus is the same for all ancestral populations($\mu^k_i = \mu_i$). Also our model assumes Hardy-Weinberg equilibrium within populations. The simplifying assumptions of



(a) *mStruct* (b) *Structure 2.1*

Figure 2. Graphical Models: the circles represent random variables and diamonds represent hyperparameters.

unlinked loci, no linkage disequilibrium between loci within populations can be easily removed by incorporating Markovian dependencies over ancestral indicators Z_{i,n_e} and Z_{i+1,n_e} of adjacent loci, and over other parameters such as the allele frequencies $\vec{\beta}_i^k$ in exactly the same way as in *Structure*. We can also introduce Markovian dependencies over mutation rates at adjacent loci, which might be desirable to better reflect the dynamics of molecular evolution in the genome. We defer such extensions to a later paper.

2.3. Mutation Model

As described above, our model is applicable to almost all kinds of genetic markers by plugging in an appropriate allele mutation model (i.e., inheritance model) $P_m()$. We now discuss two mutation models, for microsatellites and SNPs, respectively.

2.3.1. Microsatellite Mutation Model

Microsatellites are the repeats of a small sequences in DNA about 1-4 base pairs in length which are usually represented as integer counts. The choice of a suitable microsatellite mutation model is important, for both computational and interpretation purposes. Below we discuss the mutation model that we use and the biological interpretation of the parameters of the mutation model. We begin with a stepwise mutation model for microsatellites widely used in forensic analysis (Valdes et al., 1993; Lin et al., 2006).

This model defines a conditional distribution of a progeny allele b given its progenitor allele a, both of which take continuous values:

$$p(b|a) = \frac{1}{2}\xi(1-\delta)\delta^{|b-a|-1}, \qquad (1)$$

where ξ is the mutation rate (probability of any mutation), and δ is the factor by which mutation decreases as distance between the two alleles increases. Although this mutation distribution is not stationary (i.e. it does not ensure allele frequencies to be constant over the generations), it is simple and commonly used in forensic inference. To some degree δ can be regarded as a parameter that controls the probability of unit-distance mutation, as can be seen from the following identity: $p(b+1|a)/p(b|a) = \delta$.

In practice, the two-parameter stepwise continuous mutation model described above complicates the inference process. We propose a discrete microsatellite mutation model that is a simplification of Eq. 1, but captures its main idea. We posit that: $P(b|a) \propto \delta^{|b-a|}$. It is not hard to show that normalizing this probability mass function gives us the mutation model as:

$$P(b|a) = \frac{1-\delta}{1-\delta^a+\delta}\delta^{|b-a|}. \qquad (2)$$

We can interpret δ as a variance parameter, the factor by which probability drops as a fuction of the distance between the mutated version b of the allele a.

Determination of founder set at each locus: According to our model assumptions, there can be a different number of founder alleles at each locus. This number is typically smaller than the number of alleles observed at each marker since the founder alleles are "ancestral". To estimate the appropriate number and allele states of founders, we fit finite mixtures of microsatellite mutation models, and use the Bayesian Information Criterion (BIC) to determine the cardinality of the mixture.

Choice of mutation prior: In our model, the δ parameter, as explained above, is a population-specific parameter that controls the probability of stepwise mutations. Being a parameter that controls the variance of the mutation distribution, there is a possibility that inference on the model will encourage higher values of δ to improve the log-likelihood, in the absence of any prior distribution on δ. To avoid this situation, and to allow more meaningful and realistic results to emerge from the inference process, we impose on δ a beta prior that will be biased towards smaller values of δ. The beta prior will be a fixed one and will not be among the parameters we estimate.

2.3.2. SNP Mutation Model

SNPs, or single nucleotide polymorphisms, represent the largest class of individual differences in DNA. In general, there is a well-defined correlation between the age of the mutation producing a SNP allele and the frequency of the allele. For SNPs, we use a simple pointwise mutation model, rather than more complex block models. Thus, the observations in SNP data are only binary in nature (0/1). So, given the observed allele b, we say that the probability of it being derived from the founder allele a is given by:

$$P(b|a) = \delta^{\mathcal{I}[b=a]} \times (1-\delta)^{\mathcal{I}[b\neq a]}; \quad a,b \in \{0,1\}. \qquad (3)$$

In this case, the mutation parameter δ is the probability that the observed allele is not identical to the

founder allele, but derived from it due to a mutation.

2.4. Inference and Parameter Estimation

2.4.1. Probability Distribution on the Model

For notational convenience, we will ignore the diploid nature of observations in the analysis that follows. With the understanding that the analysis is carried out for the n^{th} individual, we will drop the subscript n. Also, we overload the indicator variables z_i and c_i to be both, arrays with only one element equal to 1 , as well as scalars with a value equal to the index at which the array forms have 1s. In other words: $z_i \in 1,\ldots,K, c_i \in 1,\ldots,L, z_{i,k} = \mathcal{I}[z_i = k]$, and $c_{i,l} = \mathcal{I}[c_i = l]$.

The joint probability distribution of the the data and the relevant variables under the AdMim model can then be written as:

$$p\left(\mathbf{x},\mathbf{z},\mathbf{c},\vec{\theta}|\alpha,\boldsymbol{\beta},\mu,\delta\right) = p\left(\vec{\theta}|\alpha\right)\prod_{i=1}^{I} p\left(z_i|\vec{\theta}\right) p\left(c_i|z_i,\vec{\beta}_i^{k=1\cdot K}\right).$$

The marginal likelihood of the data can be computed by summing/integrating out the latent variables. However, a closed-form solution to this summation/integration is not possible, and indeed exact inference on hidden variables such as the map vector $\vec{\theta}$, and estimation of model parameters such as the mutation rates δ under AdMim is intractable.(Pritchard et al., 2000) developed an MCMC algorithms for approximate inference for their admixture model underlying *Structure*. We choose to apply a computationally more efficient approximate inference method known as variational inference (Jordan et al., 1999).

2.5. Variational Inference

We use a mean-field approximation for performing inference on the model. This approximation method approximates an intractable joint posterior $p()$ of the all hidden variables in the model by a product of marginal distributions $q() = \prod q_i()$, each over only a single hidden variable. The optimal parameterization of $q_i()$ for each variable is obtained by minimizing the Kullback-Leibler divergence between the variational approximation q and the true joint posterior p. Using results from the the Generalised Mean Field theory (Xing et al., 2003), we can write the variational distributions of the latent variables as follows:

$$q(\vec{\theta}) \propto \prod_{k=1}^{K} \theta_k^{\alpha_k - 1 + \sum_{i=1}^{I}\langle z_{i,k}\rangle}$$

$$q(c_i) \propto \prod_{l=1}^{L}\left(\prod_{k=1}^{K}\left(\beta_{i,l}^k f(x_i|\mu_{i,l},\delta_i^k)\right)^{\langle z_{i,k}\rangle}\right)^{c_{i,l}}$$

$$q(z_i) \propto \prod_{k=1}^{K}\left(e^{\langle log(\theta_k)\rangle}\left(\prod_{l=1}^{L}\beta_{i,l}^k f(x_i|\mu_{i,l},\delta_i^k)^{\langle c_{i,l}\rangle}\right)\right)^{z_{i,k}}.$$

In the distributions above, the '$\langle\rangle$' are used to indicate the expected values of the enclosed random variables. A close inspection of the above formulae reveals that these variational distributions have the form $q(\vec{\theta}) \sim \text{Dirichlet}(\gamma_1,\ldots,\gamma_K)$, $q(z_i) \sim \text{Multinomial}(\rho_{i,1},\ldots,\rho_{i,K})$, and $q(c_i) \sim \text{Multinomial}(\xi_{i,1},\ldots,\xi_{i,L})$, respectively, where the parameters $\gamma_k, \rho_{i,k}$ and $\xi_{i,l}$ are given by the following equations:

$$\gamma_k = \alpha_k + \sum_{i=1}^{I}\langle z_{i,k}\rangle$$

$$\rho_{i,k} = \frac{e^{\langle log(\theta_k)\rangle}\left(\prod_{l=1}^{L}\beta_{i,l}^k f(x_i|\mu_{i,l},\delta_i^k)^{\langle c_{i,l}\rangle}\right)}{\sum_{k=1}^{K}\left(e^{\langle log(\theta_k)\rangle}\left(\prod_{l=1}^{L}\beta_{i,l}^k f(x_i|\mu_{i,l},\delta_i^k)^{\langle c_{i,l}\rangle}\right)\right)}$$

$$\xi_{i,k} = \frac{\prod_{k=1}^{K}\left(\beta_{i,l}^k f(x_i|\mu_{i,l},\delta_i^k)\right)^{\langle z_{i,k}\rangle}}{\sum_{k=1}^{K}\left(\prod_{k=1}^{K}\left(\beta_{i,l}^k f(x_i|\mu_{i,l},\delta_i^k)\right)^{\langle z_{i,k}\rangle}\right)}$$

and they have the properties: $\langle log(\theta_k)\rangle = \gamma_k$, $\langle z_{i,k}\rangle = \rho_{i,k}$ and $\langle c_{i,l}\rangle = \xi_{i,l}$, which suggest that they can be computed via fixed point iterations. It can be shown that this iteration will converge to a local optimum, similar to what happens in an EM algorithm. Empirically, a near global optimal can be obtained by multiple random restarts of the fixed point iteration. Typically, such a mean-field variational inference converges much faster then sampling (Xing et al., 2003).

3. Hyperparameter Estimation

The parameters of our model, i.e., $\{\mu,\delta,\boldsymbol{\beta}\}$, and the Dirichlet hyperparameter α, can be estimated by maximizing the lower bound on the log-likelihood as a function of the current values of the hyperparameters, via a variational EM algorithm. Due to space limits, details of this empirical Bayes estimation scheme are available in the extended version.

4. Experiments and Results

We validated our model on a synthetic microsatellite dataset where the simulated values of the hidden map vector θ_n of each individual and the population parameters $\{\mu^k,\delta^k,\vec{\beta}^k\}$ of each ancestral population are known as ground truth. The goal is to assess the performance of *mStruct* in terms of accuracy and consistency of the estimated map vectors and population parameters, and test of the correctness of the inference and estimation algorithms we developed. We also conduct empirical analysis using *mStruct* of two real datasets: the HGDP-CEPH cell line panel of microsatellite loci and the HGDP SNP data, in comparison with the *Structure* program (version 2.1).

4.1. Validations on Synthetic Data

We simulated 20 microsatellite genotype datasets using the AdMim generative process described in section 2.2, with 100 diploid individuals from 2 ances-

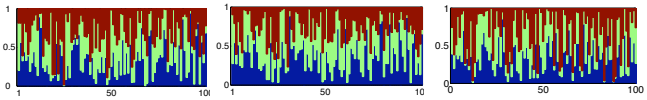


Figure 3. Ancestry spectra for a 3-population simulated dataset. First panel shows the true ancestry proportion vectors. Middle panel shows the estimate by *mStruct*. Right panel shows the estimate from *Structure* .

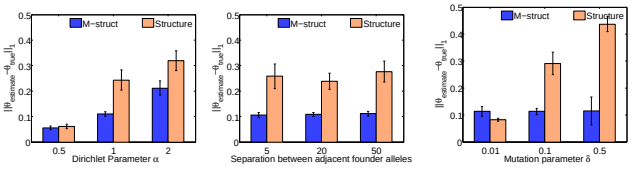
tral populations, at 50 genotype loci. Each locus has 4 founding alleles, separated by adjustable distances; the mutation parameter at each locus for both populations had default value 0.1, but can be varied to simulate different degrees of divergence. The founding allele frequencies, $\vec{\beta}_i^k$, were drawn from a flat Dirichlet prior with parameter 1. The map vectors θ_n were sampled from a symmetric beta distribution with parameter α, allowing different levels of admixing. We examine the accuracies of several estimates of interest under a number of different simulation conditions, and for each condition we report the statistics of the accuracies across 20 iid synthetic datasets. Due to space limitations, we only report two experiments below; the additional results on accuracy of ancestral alleles recovery and the ancestral-allele frequency estimation are available in the full paper.

4.1.1. Accuracy of Population Map Estimate

The map vector θ_n reflects the proportions of contributions from different ancestral population to the maker-alleles of each individual. The display of the map vectors of all individuals in a study population gives a *Map* of population structure (see, e.g., Fig. 1 in the introduction), which has been the main output of the *Structure* program . We compare the accuracy of the estimated θ_n w.r.t. the ground truth recorded during the simulation in terms of their L1 distances.

Figure 3 shows an example of this comparison, and we can see that *mStruct* is visually more accurate than *Structure*. Figure 4 shows the accuracy of the Map estimate by *mStruct* on synthetic datasets simulated with different properties, in comparison with that of *Structure*. Fig. 4(a) shows that, under different degrees of biases of population admixing induced by the Beta prior of θ_n, *mStruct* consistently outperforms *Structure*. Specifically, as the value of the Beta prior hyperparameter α increases, fewer individuals tend to belong completely to only one population, and more and more individuals become highly admixed. As the figure shows, the performance of both methods degrades as we progress toward this end; however, the severity of degradation of *mStruct* is much less than that of *Structure*. *mStruct* remains robust and performs better than *Structure* as the separations between founding alleles decreases (Fig.4(b)), which tends to increasingly confound the ancestral origins of modern alleles. Finally, Fig. 4(c) shows how the presence of mutations affects the performance of both methods. At very low values of the mutation parameters, the performances of both models are comparable; but as the mutation parameter increases in magnitude, the performance of *Structure* degrades significantly. On the other hand, the decrease in accuracy for *mStruct* is hardly noticeable. This shows that our model is resistant to the confounding effect of large mutations.



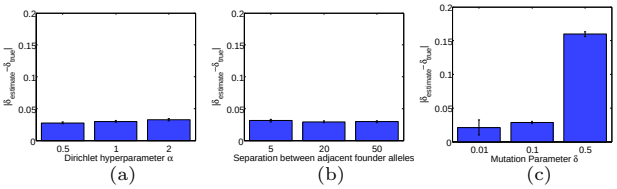
(a) (b) (c)

Figure 4. Accuracy of θ est. under different conditions.

4.1.2. Accuracy of Parameter Estimation.

An important aspect of guarantee and utility we desire for our model and inference algorithm is that it should offer consistent estimates of the population parameters $\{\mu^k, \delta^k, \vec{\beta}^k\}$ underlying the composition of the ancestral population and their inheritance processes. These estimates offer important insight of the evolutionary history and dynamics of modern population genotype data. We have extensively investigated the robustness and accuracy of all these estimates. Due to space limitations, here we only report highlights of mutation rate estimation.

Mutation parameter estimation: We evaluate the performance at recovery of δ^k's by a simple distance measure, (L1 distance measure), between the true and inferred values. We expect that using the beta prior described earlier improves the recovery of the population-specific mutation parameters. As shown in Figure 5, the estimates of δ^k's are robust and remain low-bias under different degree of admixing (due to changing α) and different ancestor dispersion (due to changing distances among the μ^k's). The accuracy decreases as the value of the mutation parameter itself increases, but remains respectable, as shown in Figure. 5(c).



(a) (b) (c)

Figure 5. Accuracy of microsatellite mutation para. est.

4.2. Empirical Analysis of Real Datasets

The HGDP-CEPH cell line panel (Cann et al., 2002; Cavalli-Sforza, 2005) used in (Rosenberg et al., 2002)contains genotype information from 1056 indvid-

uals from 52 populations at 377 autosomal microsatellite loci, along with geographical and population labels. The HGDP SNP data (Conrad et al., 2006) contains the SNPs genotypes at 2834 loci of 927 unrelated individuals that overlap with the HGDP-CEPH data. To make results for both types of data comparable, we chose the set of only those individuals present in both datasets. As in (Rosenberg et al., 2002), the choice of the total number of ancestral populations is left to the user, and here we only show results of $K = 4$ due to space limitations.

4.2.1. Structural Maps from HGDP Data

We compare the structural maps inferred from both the microsatellite and the SNP data using *mStruct* and *Structure* (top panels in Figure 6). The structural maps produced by both programs are quite similar in the case of SNPs, but are very different for microsatellites. The most obvious difference between the maps produced by both programs is the degree of admixing that the individuals in the program are assigned. *Structure* assigns each geographical population to a distinct profile. Thus, it seems to predict very little admixing effect in modern human populations. While useful for clustering, this might result in loss of potentially useful information about actual evolutionary history of populations. In contrast, the structure map produced by *mStruct* for microsatellites suggests that all populations share a common ancestral population with a unique extra component that characterizes their particular genotypes. It is interesting to note that clustering individuals by the ancestry proportion vectors due to *mStruct* will produce exactly the same clustering partitions as that due to *Structure*. The structural maps produced in the case of SNP data are quite similar for both softwares, with results from *mStruct* again predicting more admixture than *Structure*. It is also interesting to see that the ancestry proportions for European and Middle Eastern regions are more distinct from each other in *mStruct* than in *Structure*, allowing for better separation of the two geographical regions. A possible cause for the inconsistency between the results produced by *mStruct* for SNP data and microsatellite data could be the large difference between their mutation rates, or due to the choice of a simplistic SNP mutation model.This issue will be explored in more detail in the full version of the paper.

4.2.2. Analysis of the Mutation Spectrums

Now we report a preliminary analysis of the evolutionary dynamics reflected by the estimated mutation spectrums of different ancestral populations (denoted "am-spectrum"), and of different modern geographical populations (denoted "gm-spectrum"), which is not possible by *Structure*. For the am-spectrum, we compute the mean mutation rates over all loci and founding alleles for each ancestral population as estimated by *mStruct*. We estimate the gm-spectrum as follows: for every individual, a mutation rate is computed as the per-locus number of observed alleles that are attributed to mutations, weighted by the mutation rate corresponding to the ancestral allele chosen for that locus. This can be computed by observing the population-indicator (Z) and the allele-indicator (C) for each individual. We then compute the population mutation rates by averaging mutation rates of all individuals having the same geographical label.

As shown in the gm-spectrums in Figure 6 (lower subpanels on the right), the mutation rates for African populations are indeed higher than those of other modern populations. This indicates that they diverged earlier, a common hypothesis of human migration. Other trends in the gm-spectrums also reveal interesting insights, which we do not have space to discuss. The am-spectrums of SNP data in Figure 6 suggest that the founder ancestral population that dominates modern African populations has a higher mutation rate than the other ancestral population, indicating that is the older of the two ancestral populations. The mutation estimates are largely consistent for both microsatellites and SNPs in comparative order, but vastly different in numerical values.

4.3. Model Selection

As with all probabilistic models, we face a tradeoff between model complexity and the log-likelihood value that the model achieves. In our case, complexity is controlled by the number of ancestral populations we pick, K.

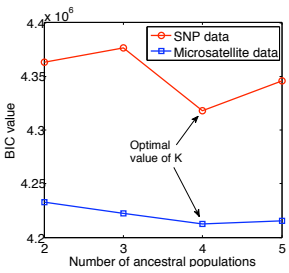


Figure 7. BIC scores for K=2 to 5.

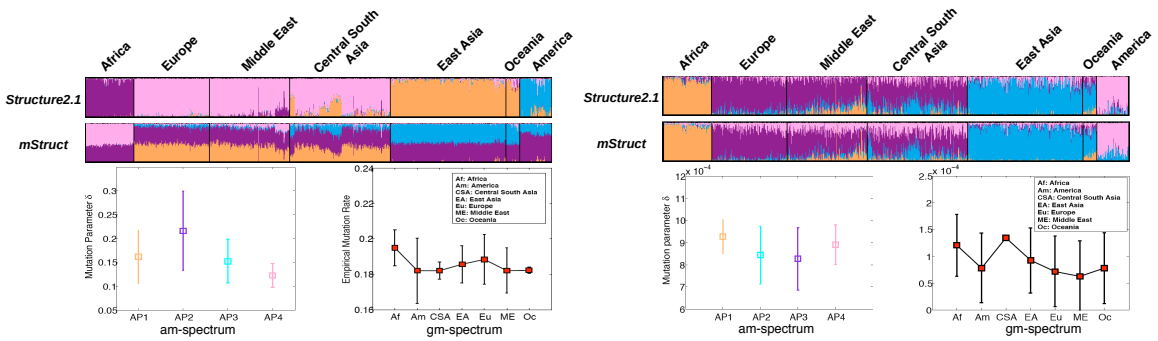
Unlike non-parametric or infinite dimensional models (e.g., Dirichlet processes etc.), for models of fixed dimension, it is not clear in general as to what value of K gives us the best balance between model complexity and log-likelihood. In such cases, different information criteria are often used to determine the optimal model complexity. To determine what number of ancestral populations fit the HGDP SNP and microsatellite data best, we computed BIC scores for K=2 to K=5 for both kinds of data separately. The results are shown in Figure 7. The BIC curves for both SNPs and microsatellites suggest K=4 as the best fit for the data.



(a) from Microsatellite data (b) from SNP data

Figure 6. Structural maps, mutation spectrums, from the HGDP data via *mStruct* and *Structure*.

5. Discussions

We have developed *mStruct*, which allows estimation of genetic contributions of ancestral populations in each modern individual in light of both population admixture and allele mutation. The variational inference algorithm that we developed allows tractable approximate inference on the model. The ancestral proportions of each individual enable representing population structure in a way that is both visually easy to interpret, as well as amenable to further computational analysis. In conjunction with geographical location, the inferred ancestry proportions could be used to detect migrations,sub-populations etc quite easily. Moreover, the ability to estimate population and locus specific mutation rates also allows us to substantiate evolutionary dynamics claims based on high/low mutation rates in certain geographical population, or on high/low mutation rates at certain loci in the genome. While the estimates of mutation rates that *mStruct* provides are not on an absolute scale, the comparison of their relative magnitudes is certainly informative. As of now, there remain a number of possible extensions to the methodology we presented so far. It would be instructive to see the impact of allowing linked loci as in (Falush et al., 2003). We have not yet addressed the issue of the most suitable choice of mutation process, but instead have chosen one that is reasonable and computationally tractable. It would be interesting to combine *mStruct* with the nonparametric Bayesian models based on the Dirichlet processes such as (Sohn & Xing, 2007). Our model might be described as a noisy-channel version of the LDA model, where the observations are modified instances of the original alleles. It is not hard to imagine applications of this model to other tasks such as image modeling or IR tasks involving noisy data, with minor changes in the distributions from which the observations are sampled.

Expectation-Maximization for Sparse and Non-Negative PCA

Christian D. Sigg CHRSIGG@INF.ETHZ.CH
Joachim M. Buhmann JBUHMANN@INF.ETHZ.CH
Institute of Computational Science, ETH Zurich, 8092 Zurich, Switzerland

Abstract

We study the problem of finding the dominant eigenvector of the sample covariance matrix, under additional constraints on the vector: a cardinality constraint limits the number of non-zero elements, and non-negativity forces the elements to have equal sign. This problem is known as sparse and non-negative principal component analysis (PCA), and has many applications including dimensionality reduction and feature selection. Based on expectation-maximization for probabilistic PCA, we present an algorithm for any combination of these constraints. Its complexity is at most quadratic in the number of dimensions of the data. We demonstrate significant improvements in performance and computational efficiency compared to other constrained PCA algorithms, on large data sets from biology and computer vision. Finally, we show the usefulness of non-negative sparse PCA for unsupervised feature selection in a gene clustering task.

1. Introduction

Principal component analysis (PCA) provides a lower dimensional approximation of high dimensional data, where the reconstruction error (measured by Euclidean distance) is minimal. The first principal component (PC) is the solution to

$$\arg\max_{\mathbf{w}} \mathbf{w}^\top \mathbf{C}\mathbf{w}, \text{ subject to } \|\mathbf{w}\|_2 = 1, \qquad (1)$$

where $\mathbf{C} \in \mathbb{R}^{D\times D}$ is the positive semi-definite covariance matrix of the data. It is straightforward to show that the first PC is the dominant eigenvector of $\mathbf{C}$, i.e. the eigenvector corresponding to the largest eigenvalue. The first PC maximizes the variance of the projected data, while the second PC again maximizes the variance, under the constraint that it is orthogonal to the first, and so on.

Constrained PCA and its Applications. We consider problem (1) under two additional constraints on $\mathbf{w}$: Sparsity $\|\mathbf{w}\|_0 \leq K$[1] and non-negativity $\mathbf{w} \succeq \mathbf{0}$. Constraining PCA permits a trade-off between maximizing *statistical fidelity* on the one hand, and facilitating *interpretability* and *applicability* on the other (d'Aspremont et al., 2007). Although it is often the case that PCA provides a good approximation with few PCs, each component is usually a linear combination of all original features. Enforcing *sparsity* facilitates identification of the relevant influence factors and is therefore an unsupervised feature selection method. In applications where a fixed penalty is associated with each included dimension (e.g. transaction costs in finance), a small loss in variance for a large reduction in cardinality can lead to an overall better solution. Enforcing *non-negativity* renders PCA applicable to domains where only positive influence of features is deemed appropriate (e.g. due to the underlying physical process). Moreover, the total variance is explained *additively* by each component, instead of the mixed sign structure of unconstrained PCA. Often non-negative solutions already show some degree of sparsity, but a combination of both constraints enables precise control of the cardinality. Sparse PCA has been successfully applied to gene ranking (d'Aspremont et al., 2007), and non-negative sparse PCA has been compared favorably to non-negative matrix factorization for image parts extraction (Zass & Shashua, 2006).

Related Work. Problem (1) is a *concave programming* problem, and is NP-hard if either sparsity or non-negativity is enforced (Horst et al., 2000). Although an efficient global optimizer is therefore unlikely, local optimizers often find good or even optimal solutions in practice, and global optimality can be tested

[1] See final paragraph of this section for a definition of our notation.

in $O(D^3)$ (d'Aspremont et al., 2007), where D is the dimensionality of the data. As is evident from writing the objective function of (1) as

$$\mathbf{w}^\top \mathbf{C}\mathbf{w} = \sum_{i=1}^{D}\sum_{j=1}^{D} C_{ij} w_i w_j, \tag{2}$$

setting w_k to zero excludes the k-th column and row of $\mathbf{C}$ from the summation. For a *given* sparsity pattern $\mathcal{S} = \{i|w_i \neq 0\}$, the optimal solution is the dominant eigenvector of the corresponding submatrix of $\mathbf{C}$. For sparse PCA, the computationally hard part is therefore to identify the optimal sparsity pattern, and any solution can potentially be improved by keeping $\mathcal{S}$ only and recomputing the weights, a process called *variational renormalization* by Moghaddam et al. (2006).

Sparse PCA methods can be characterized by the following two paradigms:

1. Relaxation of the hard cardinality constraint $\|\mathbf{w}\|_0 \leq K$ into a convex constraint $\|\mathbf{w}\|_1 \leq B$, thus approximating the combinatorial problem by continuous optimization of (1) on a convex feasible region.

2. Direct combinatorial optimization of $\mathcal{S}$. Due to the potentially exponential runtime of exact methods, heuristics such as greedy search have to be employed for large values of D.

Cadima and Jolliffe (1995) proposed thresholding the $(D-K)$ smallest elements of the dominant eigenvector to zero, which has complexity $O(D^2)$. Better results have been achieved by the SPCA algorithm of Zou et al. (2004), which is based on iterative elastic net regression. Combinatorial optimization was introduced by Moghaddam et al. (2006), who derived an exact branch-and-bound method and a greedy algorithm, that computes the full sparsity path $1 \leq K \leq D$ in $O(D^4)$. Based on a semi-definite relaxation of the sparse PCA problem, d'Aspremont et al. (2007) proposed PathSPCA, which reduces the complexity of each greedy step to $O(D^2)$, and renders computation of the full regularization path possible in $O(D^3)$. Finally, Sriperumbudur et al. (2007) formulate sparse PCA as a d.c. program (Horst et al., 2000) and provide an iterative algorithm called DC-PCA, where each iteration consists of solving a quadratically constrained QP with complexity $O(D^3)$.

Non-negative (sparse) PCA was proposed by Zass and Shashua (2006). In contrast to the methods discussed so far, their algorithm (called NSPCA) optimizes the cumulative variance of L components jointly, versus a sequential approach that computes one component after another. Orthonormality of the components is enforced by a penalty in the objective function (see section 4 for a discussion about orthogonality for non-negative components), and the desired sparsity is again expressed in terms of the whole set of L components.

Our Contribution. To our knowledge, there is no algorithm either for sparse or non-negative sparse PCA that achieves competitive results in less than $O(D^3)$. In this paper, we propose an $O(D^2)$ algorithm that enforces sparsity, or non-negativity or both constraints simultaneously in the same framework, which is rooted in expectation-maximization for a probabilistic generative model of PCA (see next section). As for the combinatorial algorithms, the desired cardinality can be expressed directly as $K = |\mathcal{S}|$, instead of a bound B on the l_1 norm of $\mathbf{w}$ (which requires searching for the appropriate value). Although computing the full regularization path is also of order $O(D^3)$, our method *directly* computes a solution for any K in $O(D^2)$, in contrast to forward greedy search which needs to build up a solution incrementally. As is the case with SPCA, our method works on the data matrix $\mathbf{X} \in \mathbb{R}^{N\times D}$ (N is the number of samples), instead of the covariance matrix $\mathbf{C}$. To summarize, the low complexity combined with an efficient treatment of the $D \gg N$ case enables an application of our method to large data sets of high dimensionality.

Notation. Vectors are indexed as $\mathbf{w}_{(t)}$, and elements of vectors as w_i. $\|\mathbf{w}\|_1 = \sum_i |w_i|$ and $\|\mathbf{w}\|_0 = |\mathcal{S}|$, where $\mathcal{S} = \{i|w_i \neq 0\}$. $\|\mathbf{w}\|_0$ is also called the *cardinality* of $\mathbf{w}$. $\mathbf{I}$ is the identity matrix, $\mathbf{0}$ a vector of zero elements, and $\mathbf{w} \succeq \mathbf{0} \Leftrightarrow \forall i : w_i \geq 0$. $\mathbf{x} \circ \mathbf{y}$ denotes element-wise multiplication of $\mathbf{x}$ and $\mathbf{y}$, and $\mathrm{tr}(\mathbf{X}) = \sum_i X_{ii}$ is the trace of matrix $\mathbf{X}$. $\mathbb{E}[.]$ is the expectation operator, and $\mathcal{N}$ denotes a Gaussian distribution.

2. EM for Probabilistic PCA

Tipping and Bishop (1999) and independently Roweis (1998) proposed a generative model for PCA, where the full covariance matrix $\mathbf{\Sigma} \in \mathbb{R}^{D\times D}$ of the Gaussian distribution is approximated by its first L eigenvectors (in terms of magnitude of the respective eigenvalues). The latent variable $\mathbf{y} \in \mathbb{R}^L$ (in the principal component subspace) is distributed according to a zero mean, unit covariance Gaussian

$$p(\mathbf{y}) = \mathcal{N}(\mathbf{0}, \mathbf{I}). \tag{3}$$

The observation $\mathbf{x} \in \mathbb{R}^D$, conditioned on the value of the latent variable $\mathbf{y}$, is linear-Gaussian distributed

according to

$$p(\mathbf{x}|\mathbf{y}) = \mathcal{N}(\mathbf{W}\mathbf{y} + \boldsymbol{\mu}, \sigma^2\mathbf{I}), \tag{4}$$

where the matrix $\mathbf{W} \in \mathbb{R}^{D\times L}$ spans the principal subspace, and $\boldsymbol{\mu} \in \mathbb{R}^D$ is the mean of the data. To simplify the presentation, we will assume centered data from now on.

The EM equations for probabilistic PCA have the following form. The E-step keeps track of

$$\mathbb{E}[\mathbf{y}_{(n)}] = \mathbf{M}_{(t)}^{-1}\mathbf{W}_{(t)}^\top\mathbf{x}_{(n)} \tag{5}$$

$$\mathbb{E}[\mathbf{y}_{(n)}\mathbf{y}_{(n)}^\top] = \sigma_t^2\mathbf{M}_{(t)}^{-1} + \mathbb{E}[\mathbf{y}_{(n)}]\mathbb{E}[\mathbf{y}_{(n)}]^\top, \tag{6}$$

where $\mathbf{M} \in \mathbb{R}^{L\times L}$ is defined as

$$\mathbf{M} = \mathbf{W}^\top\mathbf{W} + \sigma^2\mathbf{I}. \tag{7}$$

The M-step equations are

$$\mathbf{W}_{(t+1)} = \left[\sum_{n=1}^N \mathbf{x}_{(n)}\mathbb{E}[\mathbf{y}_{(n)}]^\top\right]\left[\sum_{n=1}^N \mathbb{E}[\mathbf{y}_{(n)}\mathbf{y}_{(n)}^\top]\right]^{-1} \tag{8}$$

$$\sigma_{t+1}^2 = \frac{1}{ND}\sum_{n=1}^N \Big[\|\mathbf{x}_{(n)}\|_2^2 - 2\mathbb{E}[\mathbf{y}_{(n)}]^\top\mathbf{W}_{(t+1)}^\top\mathbf{x}_{(n)} + \operatorname{tr}\Big(\mathbb{E}[\mathbf{y}_{(n)}\mathbf{y}_{(n)}^\top]\mathbf{W}_{(t+1)}^\top\mathbf{W}_{(t+1)}\Big)\Big]. \tag{9}$$

In order to efficiently incorporate constraints into the EM algorithm (see next section), we make three simplifications: take the limit $\sigma^2 \to 0$, consider a one-dimensional subspace and normalize $\|\mathbf{w}_{(t)}\|_2$ to unity. The first simplification reduces probabilistic PCA to standard PCA. Computing several components will be treated in section 4, and the unity constraint on $\|\mathbf{w}_{(t)}\|_2$ is easily restored after each EM iteration. The E-step now amounts to

$$\mathbb{E}[y_n] = \mathbf{w}_{(t)}^\top\mathbf{x}_{(n)}, \tag{10}$$

and the M-step is

$$\mathbf{w}_{(t+1)} = \frac{\sum_{n=1}^N \mathbf{x}_{(n)}\mathbb{E}[y_n]}{\sum_{n=1}^N \mathbb{E}[y_n]^2}. \tag{11}$$

These two equations have the following interpretation (Roweis, 1998): The E-step orthogonally projects the data onto the current estimate of the subspace, while the M-step re-estimates the projection to minimize squared reconstruction error for fixed subspace coordinates. We summarize this result in algorithm 1, which iteratively computes the solution to eq. (1). Due to the fact that so far only $\|\mathbf{w}\|_2 = 1$ is enforced, convergence to the global optimum doesn't depend on the initial estimate $\mathbf{w}_{(1)}$. This will no longer be the case for additional constraints.

Algorithm 1 Iterative Computation of First PC

Input: Data $\mathbf{X} \in \mathbb{R}^{N\times D}$, initial estimate $\mathbf{w}_{(1)}$, ε
Algorithm:
$t \leftarrow 1$
repeat
  $\mathbf{y} = \mathbf{X}\mathbf{w}_{(t)}$
  $\mathbf{w}_{(t+1)} = \arg\min_{\mathbf{w}} \sum_{n=1}^N \|\mathbf{x}_{(n)} - y_n\mathbf{w}\|_2^2$
  $\mathbf{w}_{(t+1)} \leftarrow \mathbf{w}_{(t+1)}/\|\mathbf{w}_{(t+1)}\|_2$
  $t \leftarrow t + 1$
until $|\mathbf{w}_{(t+1)}^\top\mathbf{w}_{(t)}| > 1 - \varepsilon$
Output: $\mathbf{w}$

3. Constrained PCA

Consider the minimization step in algorithm 1, which can be written as

$$\mathbf{w}^* = \arg\min_{\mathbf{w}} J(\mathbf{w}) := h\mathbf{w}^\top\mathbf{w} - 2\mathbf{f}^\top\mathbf{w}, \tag{12}$$

with $h = \sum_{n=1}^N y_n^2$ and $\mathbf{f} = \sum_{n=1}^N y_n\mathbf{x}_{(n)}$. Eq. (12) is a quadratic program (QP), and is convex due to the non-negativity of h. Furthermore, because the Hessian is a scaled identity matrix, the problem is also isotropic. The unique global optimum is found by analytical differentiation of the objective function

$$\nabla J \stackrel{!}{=} 0 \Rightarrow \mathbf{w}^* = \frac{\mathbf{f}}{h}, \tag{13}$$

which of course is identical to eq. (11).

3.1. Sparsity

It is well known (Tibshirani, 1996) that solving a QP under an additional constraint on $\|\mathbf{w}\|_1$ favors a sparse solution. This constraint corresponds to restricting the feasible region to an l_1 diamond:

$$\mathbf{w}^\circ = \arg\min_{\mathbf{w}} \left(h\mathbf{w}^\top\mathbf{w} - 2\mathbf{f}^\top\mathbf{w}\right) \quad \text{s.t.} \quad \|\mathbf{w}\|_1 \le B, \tag{14}$$

where the upper bound B is chosen such that $\mathbf{w}^\circ$ has the desired cardinality. The l_1 constrained QP is again convex, and because the objective function is isotropic, it implies that $\mathbf{w}^\circ$ is the feasible point minimizing l_2 distance to the unconstrained optimum $\mathbf{w}^*$.

We derive an efficient and optimal algorithm for eq. (14), where the desired cardinality can be specified directly by the number K of non-zero dimensions. Observe that $\mathbf{w}^\circ$ must have the same sign structure as $\mathbf{f}$, therefore we can transform the problem such that both $\mathbf{w}^*$ and $\mathbf{w}^\circ$ come to lie in the non-negative orthant. The algorithm (illustrated in fig. 1) approaches $\mathbf{w}^\circ$

with axis-aligned steps in the direction of the largest element of the negative gradient

$$-\nabla J(\mathbf{w}) \propto \mathbf{w}^* - \mathbf{w}, \tag{15}$$

until the boundary of the feasible region is hit or the gradient vanishes. Because the elements of $\mathbf{w}$ become positive one after another, and their magnitude increases monotonically, B is set implicitly by terminating the gradient descent once the cardinality of the solution vector is K. Finally, the solution is transformed back into the original orthant of $\mathbf{w}^*$.

Proposition 3.1 *Axis-aligned gradient descent with infinitesimal stepsize terminates at the optimal feasible point* $\mathbf{w}^\circ$.

Proof. Optimality is trivial if $\mathbf{w}^*$ lies within the feasible region, so we consider the case where the l_1 constraint is active. The objective function in eq. (14) is equivalent to

$$\|\mathbf{w}^* - \mathbf{w}\|_2^2 = \sum_{d=1}^{D} \left(w_d^* - w_d\right)^2. \tag{16}$$

The gradient descent procedure invests all available coefficient weight B into decreasing the largest term(s) of this sum, which follows from eq. (15). We show equivalence of $\mathbf{w}^\circ$ to the gradient descent solution $\mathbf{v}$ by contradiction. Suppose the computation of $\mathbf{w}^\circ$ follows a different strategy, so at least one summation term $(w_l^* - w_l^\circ)^2$ is larger than $\max_d (w_d^* - v_d)^2$. However, subtracting a small amount from w_s° $(s \neq l)$ and adding it to w_l° doesn't change $\|\mathbf{w}^\circ\|_1$ but decreases the objective, which is a contradiction. □

Implementation of axis-aligned gradient descent amounts to sorting the elements of $-\nabla J(\mathbf{w})$ in descending order (an $O(D \log D)$ operation), and iterating over its first K elements. At each iteration $k \in \{1, \ldots, K\}$, the first k elements of $\mathbf{w}$ are manipulated, resulting in complexity $O(K^2)$ for the whole loop. Algorithm 2 provides a full specification of the method. Because EM is a local optimizer, the initial direction $\mathbf{w}_{(1)}$ must be chosen carefully to achieve good results. For sparse PCA, initialization with the unconstrained first principal component gave best results (see section 5). Initialization is therefore the most expensive operation of the algorithm with its $O(D^2)$ complexity. For the $D \gg N$ case, it can be reduced to $O(N^2)$ by working with $\mathbf{X}\mathbf{X}^\top$ instead of $\mathbf{X}^\top\mathbf{X}$. As initialization is independent of K, $\mathbf{w}_{(1)}$ can be cached and re-used when varying the sparsity parameter. The number of EM iterations t until convergence also depends on D and K, but our experiments (see section 5) suggest that dependence is weak and sub-linear. On average, $t < 10$ iterations were sufficient to achieve convergence.

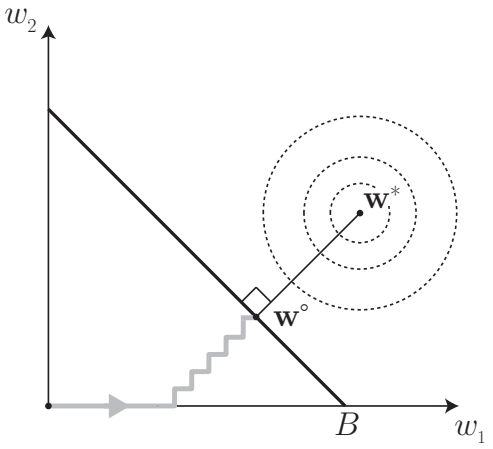

Figure 1. Starting at the origin, $\mathbf{w}^\circ$ is approached by axis-aligned steps in the direction of the largest element of the negative gradient. As dimensions enter the solution vector one after another, and the corresponding weights w_i increase monotonically, the bound B is set implicitly by terminating once $\|\mathbf{w}\|_0 = K$.

3.2. Non-Negativity

Enforcing non-negativity is achieved in the same way as sparsity. Here, the the feasible region is constrained to the non-negative orthant, which is again a convex domain:

$$\begin{aligned} \mathbf{w}^\circ \quad &= \quad \arg\min_{\mathbf{w}} \left(h\mathbf{w}^\top\mathbf{w} - 2\mathbf{f}^\top\mathbf{w}\right) \\ &\text{s.t.} \quad \mathbf{w} \succeq \mathbf{0}. \end{aligned} \tag{17}$$

Eq. (17) implies that choosing $w_i = 0$ for $f_i < 0$ is optimal. The non-negativity constraint can then be dropped, and optimization for the other elements of $\mathbf{w}$ proceeds as before.

The first PC is invariant to a change of sign. However, this symmetry is broken if the non-negativity constraint is enforced. As an extreme example, non-negative EM fails if the initial projection $\mathbf{w}_{(1)}$ is a dominant eigenvector that only consists of non-positive elements - the minimum of eq. (17) is the zero vector. But changing the sign of $\mathbf{w}_{(1)}$ implies that the non-negativity constraint becomes inactive, and the algorithm terminates immediately with the optimal solution. We choose to initialize EM for non-negative PCA with a random unit vector in the non-negative orthant, which exploits the benefit of random restarts.

For non-negative sparse PCA, the feasible region is defined as the intersection of the non-negative orthant

Algorithm 2 EM for Sparse PCA

Input: $\mathbf{X} \in \mathbb{R}^{N \times D}$, $K \in \{1, \ldots, D\}$, ε
Algorithm:
$t \leftarrow 1$
$\mathbf{w}_{(t)} \leftarrow$ first principal component of $\mathbf{X}$
repeat
  $\mathbf{y} \leftarrow \mathbf{X}\mathbf{w}_{(t)}$
  $\mathbf{w}^* \leftarrow \sum_{n=1}^{N} y_n \mathbf{x}_{(n)} / \sum_{n=1}^{N} y_n^2$
  $\mathbf{s} \leftarrow$ elements $|w_i^*|$ sorted in descending order
  $\boldsymbol{\pi} \leftarrow$ indices of sorting order
  $\mathbf{w}_{(t+1)} \leftarrow \mathbf{0}$
  for $k = 1$ **to** K **do**
    Add $(s_k - s_{k+1})$ to elements $1, \ldots, k$ of $\mathbf{w}_{(t+1)}$
  end for
  Permute elements of $\mathbf{w}_{(t+1)}$ according to $\boldsymbol{\pi}^{-1}$
  $\mathbf{w}_{(t+1)} \leftarrow \mathbf{w}_{(t+1)} \circ \operatorname{sign}(\mathbf{w}^*) / \|\mathbf{w}_{(t+1)}\|_2$
  $t \leftarrow t + 1$
until $|\mathbf{w}_{(t+1)}^\top \mathbf{w}_{(t)}| > 1 - \varepsilon$
Output: $\mathbf{w}$

and the l_1 diamond. As the intersection of two convex sets is again convex, the combined constraints can be treated in the same framework. We establish convergence of our method in the following proposition:

Proposition 3.2 *EM for sparse and non-negative PCA converges to a local minimum of the l_2 reconstruction error.*

Proof. Given a feasible $\mathbf{w}_{(t)}$ (either by proper initialization or after one EM iteration), both the E-step and the M-step never increase l_2 reconstruction error. Orthogonal projection $\mathbf{y} = \mathbf{X}\mathbf{w}$ in the E-step is the l_2 optimal choice of subspace coordinates for given $\mathbf{w}$. Error minimization w.r.t. $\mathbf{w}$ in the M-step either recovers $\mathbf{w}_{(t)}$ as it is feasible, or provides an improved $\mathbf{w}_{(t+1)}$. □

4. Several Components

A full eigen decomposition of the covariance matrix $\mathbf{C}$ provides all r PCs, where r is the rank of $\mathbf{C}$. Sorted in descending order of eigenvalue magnitude, each eigenvector maximizes the variance of the projected data, under the constraint that it is orthogonal to all other components considered so far. For sparse PCA, we compute more than one component by means of iterative deflation: having identified the first component $\mathbf{w}_{(1)}$, project the data to its orthogonal subspace using

$$\mathbf{P} = \mathbf{I} - \mathbf{w}_{(1)}\mathbf{w}_{(1)}^\top, \tag{18}$$

re-run EM to identify $\mathbf{w}_{(2)}$, and so on. Although deflation suffers from numerical errors that accumulate over each iteration, this inaccuracy is not a serious problem as long as the desired number of components L is small compared to r (which is true in many applications of PCA).

Desiring non-negativity and orthogonality implies that each feature can be part of at most one component:

$$w_i^{(l)} > 0 \Rightarrow w_i^{(m)} = 0 \tag{19}$$

for $m \neq l$, i.e. the sparsity patterns have to be disjoint: $\mathcal{S}_l \bigcap \mathcal{S}_m = \emptyset$, for $l \neq m$ and $\mathcal{S}_l = \{i | w_i^{(l)} > 0\}$. This constraint might be too strong for some applications, where it can be relaxed to require a minimum angle between components. This *quasi*-orthogonality is enforced by adding a quadratic penalty term

$$\alpha \mathbf{w}^\top \mathbf{V}\mathbf{V}^\top \mathbf{w}, \tag{20}$$

to eq. (17), where $\mathbf{V} = \left[\mathbf{w}_{(1)}\mathbf{w}_{(2)} \cdots \mathbf{w}_{(l-1)}\right]$ contains previously identified components as columns, and α is a tuning parameter. Because $\mathbf{V}\mathbf{V}^\top$ is also positive semi-definite, the QP remains convex, but the Hessian is no longer isotropic. We have used the standard Matlab QP solver, but there exist special algorithms for this case in the literature (Sha et al., 2007).

5. Experimental Results

We report performance and efficiency of our method in comparison to three algorithms: SPCA[2] and PathSPCA[3] for cardinality constrained PCA, and NSPCA[4] for non-negative sparse PCA. SPCA was chosen because it has conceptual similarities to our algorithm: both are iterative methods that solve an l_1 constrained convex program, and both use the data matrix instead of the covariance matrix. PathSPCA was chosen because it is (to our knowledge) the most efficient combinatorial algorithm. We are not aware of any other non-negative PCA algorithm besides NSPCA.

The data sets considered in the evaluation are the following:

1. CBCL face images (Sung, 1996): 2429 gray scale images of size 19×19 pixels, which have been used in the evaluation of (Zass & Shashua, 2006).
2. Leukemia data (Armstrong et al., 2002): Expression profiles of 12582 genes from 72 patients. Sim-

[2]We use the Matlab implementation of SPCA by Karl Sjöstrand, available at `http://www2.imm.dtu.dk/~kas/software/spca/index.html`.

ilar data sets have been used in the evaluation of (Zou et al., 2004) and (d'Aspremont et al., 2007).

The two data sets cover the $N > D$ and $D \gg N$ case and are large enough such that differences in computational complexity can be established with confidence. Both were standardized such that each dimension has zero mean and unit variance.

5.1. Sparse PCA

Figure 2 (left) plots explained variance versus cardinality for SPCA, PathSPCA and our algorithm (called emPCA) on the face image data set. Variational renormalization is necessary for SPCA and emPCA to close the performance gap to PathSPCA, which computes optimal weights for a specific sparsity pattern by construction. Figure 2 (middle) shows analogous results for the gene expression data. As a reference, we have also plotted results for simple thresholding (after renormalization).

To complement theoretical analysis of computational complexity, we have also measured running times of reference Matlab implementations, provided by their respective authors (SPCA is a re-implementation of the author's R code in Matlab). CPU time was measured using Matlab's `tic` and `toc` timer constructs, running on an Intel Core 2 Duo processor at 2.2GHz with 3GB of RAM. Our focus is not to report absolute numbers, but rather demonstrate the dependency on the choice of K. Figure 2 (right) plots the running times versus cardinality on the gene expression data. The PathSPCA curve is well explained by the incremental forward greedy search. SPCA is harder to analyze, due to its active set optimization scheme: at each iteration of the algorithm, active features are reexamined and possibly excluded, but might be added again later on. emPCA is only marginally affected by the choice of K, but shows an increased number of EM iterations for $10 \leq K \leq 25$, which was observed on other data sets as well.

5.2. Non-Negative PCA

The impact of the non-negativity constraint on the explained variance depends on the sign structure of $\mathbf{w}^*$. Because the first principal component for the face image data happens to lie in the non-negative orthant, we projected the data onto its orthogonal subspace such that the constraint becomes active. Figure 3 (left) shows the variance versus cardinality trade-off curves for non-negative sparse PCA. For NSPCA, the sparsity penalty β was determined for each K using bisection search, which was aborted when the relative length of the parameter search interval was below a threshold of 10^{-5}. Both the variance achieved and the number of cardinalities for which a solution was found strongly depend on the value of α, which corresponds to a unit norm penalty (for the case of a single component). For smaller values of α the performance of NSPCA is comparable to emPCA, but only solutions close to the full cardinality are found. Increasing the magnitude of α makes it possible to sweep the whole cardinality path, but the performance degrades.

Because both algorithms are initialized randomly, we chose the best result after ten restarts. Running times for both methods showed no strong dependency on K. Average times for $K \in \{1, \ldots, 100\}$ were $0.4s$ for emPCA ($0.15s$ standard deviation) and $24s$ for NSPCA ($14.7s$ standard deviation).

We already motivated in section 4 that requiring orthogonality between several non-negative components can be restrictive. If the first PC happens to lie in the

non-negative orthant, the constraints have to be modified such that more than one component can satisfy them. We have explored the following two strategies:

1. Enforcing orthogonality, but constraining the cardinality of each component.

2. Relaxing the orthogonality constraint, by enforcing a minimum angle between components instead.

There is a methodological difficulty in comparing the performance of NSPCA and emPCA. The former maximizes cumulative variance of all components jointly, while our algorithm computes them sequentially, maximizing the variance under the constraint that subsequent components are orthogonal to previous ones (see section 4). We therefore expect emPCA to capture more variance in the first components, while NSPCA is expected to capture larger cumulative variance. Figure 3 (middle) shows the results of applying the first strategy to the face image data. The NSPCA sparsity penalty β was tuned to achieve a joint cardinality of 200 for all components. For emPCA we distributed the active features evenly among components by setting $K = 20$ for all of them. As in figure 3 (left), emPCA captures significantly more of the variance, suggesting that the way NSPCA incorporates sparsity seriously degrades performance. This observation was confirmed for various values of K and L.

Finally, figure 3 (right) reports results for the second strategy, where a minimum angle of 85 degrees was enforced between components. Here, the complementary objectives of NSPCA and emPCA match with our prior expectations. Again, various values for L and minimum angle lead to essentially the same behavior.

5.3. Unsupervised Gene Selection

We apply emPCA to select a subset of genes of the leukemia data, and measure subset relevance by following the evaluation methodology of Varshavsky et al. (2006). For each gene subset, we cluster the data using k-means ($k = 3$), and compare the cluster assignments to the true labeling of the data, which differentiates between three types of leukemia (ALL, AML and MLL). Agreement is measured using Jaccard scores (Varshavsky et al., 2006), where a value of one signifies perfect correspondence between cluster assignment and label. We compare emPCA to simple ranking of the CE criterion as proposed by the authors, which has shown competitive performance to other popular gene selection methods. Figure 4 shows that selecting 70 genes according to the first non-negative sparse PC

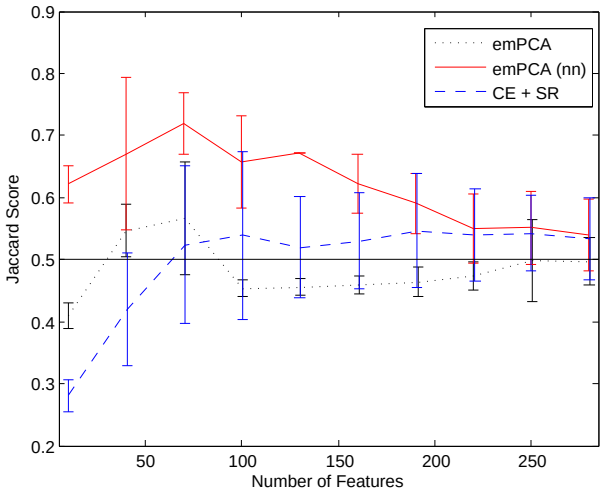

Figure 4. Mean and standard deviation for Jaccard scores after subset selection and k-means clustering ($k = 3$), averaged over 100 random initializations of the centroids (see text). A small amount of jitter has been added to better distinguish error bars.

results in a significantly better Jaccard score than a clustering of the full data set.

6. Conclusions

We have presented a novel algorithm for constrained principal component analysis, based on expectation-maximization for probabilistic PCA. Our method is applicable to a broad range of problems: it includes sparsity, non-negativity or both kinds of constraints, it has an efficient formulation for $N > D$ and $D \gg N$ type of data, and it enforces either strict or quasi-orthogonality between successive components. Desired sparsity is directly specified in the number of non-zero elements, instead of a bound on the l_1 norm of the vector. We have demonstrated on popular data sets from biology and computer vision that our method achieves competitive results for sparse problems, and that it shows significant improvements for non-negative sparse problems. Its unmatched computational efficiency enables a constrained principal component analysis of substantially larger data sets and lower requirements on available computation time.

Although our algorithm is rooted in expectation-maximization for a generative model of PCA, constraints are added at the optimization stage. In the future, we will study how to include them in the model itself, which would enable a Bayesian analysis and data-driven determination of the proper sparsity and number of components. Secondly, we intend to examine whether our algorithm can be extended to the related

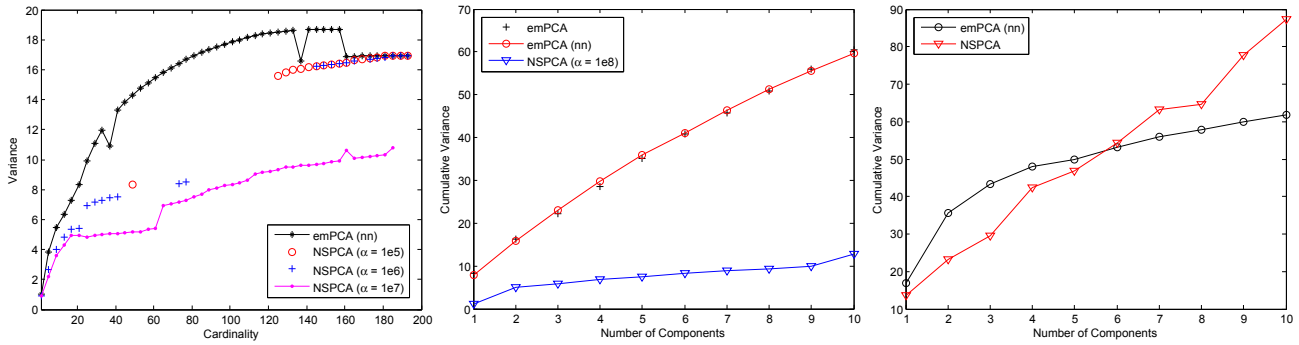

Figure 3. Left: Variance versus cardinality trade-off curves for non-negative sparse PCA methods on face image data. For NSPCA, the sparsity penalty β was determined using bisection search (see text). Values indicate better result after ten random restarts. *Middle:* Cumulative variance versus number of orthogonal components. For NSPCA, β was tuned to achieve a joint cardinality of 200 for all components. For emPCA, we set $K = 20$ for every component. emPCA (without non-negativity constraints) is plotted for reference. *Right:* Cumulative variance versus number of quasi-orthogonal components. A minimum angle of 85 degrees was enforced between components.

problem of constrained linear discriminant analysis.

A Matlab implementation of emPCA is available at `http://www.inf.ethz.ch/personal/chrsigg/icml2008`.

Abstract

We present a reinforcement learning architecture, Dyna-2, that encompasses both sample-based learning and sample-based search, and that generalises across states during both learning and search. We apply Dyna-2 to high performance Computer Go. In this domain the most successful planning methods are based on sample-based search algorithms, such as UCT, in which states are treated individually, and the most successful learning methods are based on temporal-difference learning algorithms, such as Sarsa, in which linear function approximation is used. In both cases, an estimate of the value function is formed, but in the first case it is transient, computed and then discarded after each move, whereas in the second case it is more permanent, slowly accumulating over many moves and games. The idea of Dyna-2 is for the transient planning memory and the permanent learning memory to remain separate, but for both to be based on linear function approximation and both to be updated by Sarsa. To apply Dyna-2 to 9×9 Computer Go, we use a million binary features in the function approximator, based on templates matching small fragments of the board. Using only the transient memory, Dyna-2 performed at least as well as UCT. Using both memories combined, it significantly outperformed UCT. Our program based on Dyna-2 achieved a higher rating on the Computer Go Online Server than any handcrafted or traditional search based program.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

1. Introduction

Reinforcement learning can be subdivided into two fundamental problems: *learning* and *planning*. Informally, the goal of learning is for an agent to improve its policy from its interactions with the environment. The goal of planning is for an agent to improve its policy without further interaction with its environment. The agent can deliberate, reason, ponder, think or search, so as to find the best behaviour in the available computation time. Sample-based methods can be applied to both problems. During learning, the agent samples experience from the real world: it executes an action at each time-step and observes its consequences. During planning, the agent samples experience from a *model* of the world: it *simulates* an action at each computational step and observes its consequences. We propose that an agent can both learn and plan effectively using sample-based reinforcement learning algorithms. We use the game of 9×9 Go as an example of a large-scale, high-performance application in which learning and planning both play significant roles.

In the domain of Computer Go, the most successful learning methods have used sample-based reinforcement learning to extract domain knowledge from games of self-play (Schraudolph et al., 1994; Dahl, 1999; Enzenberger, 2003; Silver et al., 2007). The value of a position is approximated by a multi-layer perceptron, or a linear combination of binary features, that form a compact representation of the state space. Temporal difference learning is used to update the value function, slowly accumulating knowledge from the complete history of experience.

The most successful planning methods use sample-based search to identify the best move in the current position. 9×9 Go programs based on the UCT algorithm (Kocsis & Szepesvari, 2006) have now achieved master level (Gelly & Silver, 2007; Coulom, 2007). The UCT algorithm begins each new move with no domain

knowledge, but rapidly learns the values of positions in a temporary search tree. Each state in the tree is explicitly represented, and the value of each state is learned by Monte-Carlo simulation, from games of self-play that start from the current position.

In this paper we develop an architecture, Dyna-2, that combines these two approaches. Like the Dyna architecture (Sutton, 1990), the agent updates a value function both from real experience, and from simulated experience that is sampled using a model of the world. The new idea is to maintain two separate memories: a permanent learning memory that is updated from real experience; and a transient planning memory that is updated from simulated experience. Both memories use linear function approximation to form a compact representation of the state space, and both memories are updated by temporal-difference learning.

2. Reinforcement Learning

We consider sequential decision-making processes, in which at each time-step t the agent receives a state s_t, executes an action a_t according to its current policy $\pi_t(s, a)$, and then receives a scalar reward r_{t+1}.

2.1. Sample-Based Learning

Most efficient reinforcement learning methods use a *value function* as an intermediate step for computing a policy. In episodic tasks the action-value function $Q^\pi(s, a)$ is the expected total reward from state s after taking action a and then following policy π.

In large domains, it is not possible or practical to learn a value for each individual state. In this case, it is necessary to approximate the value function using features $\phi(s, a)$ and parameters θ. A simple and successful approach (Sutton, 1996) is to use a linear function approximation $Q(s, a) = \phi(s, a)^T\theta$. We note that table lookup is a special case of linear function approximation, using binary features $\phi(s, a) = e(s, a)$, where $e(s, a)$ is a unit vector with a one in the single component corresponding to (s, a) and zeros elsewhere.

The TD(λ) algorithm (Sutton, 1988) estimates the value of the current state from the value of subsequent states. The λ parameter determines the temporal span over which values are updated. At one extreme, TD(0) bootstraps the value of a state from its immediate successor. At the other extreme, TD(1) updates the value of a state from the final return; it is equivalent to Monte-Carlo evaluation (Sutton & Barto, 1998). TD(λ) can be incrementally computed by maintaining a vector of *eligibility traces* z_t.

The Sarsa algorithm (Rummery & Niranjan, 1994) combines temporal difference evaluation with policy improvement. An action-value function is estimated by the TD(λ) algorithm, and the policy is improved by selecting actions according to an ϵ-greedy policy. The action-value function is updated from each tuple (s, a, r, s', a') of experience, using the TD(λ) update rule,

$$\delta_t = r_{t+1} + Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t) \quad (1)$$

$$z_t = \lambda z_{t-1} + \phi(s_t, a_t) \quad (2)$$

$$\theta_t = \theta_{t-1} + \alpha\delta_t z_t(s) \quad (3)$$

2.2. Sample-Based Search

Sample-based planning applies sample-based reinforcement learning methods to simulated experience. This requires a sample model of the world: a state transition generator $A_t(s, a) \in \mathcal{S} \times \mathcal{A} \mapsto \mathcal{S}$ and reward generator $B_t(s, a) \in \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$. The effectiveness of sample-based planning depends on the accuracy of the model (Paduraru, 2007). In *sample-based search*, experience is simulated from the real state s, so as to identify the best action from this state.

Monte-Carlo simulation is a simple but effective method for sample-based search. Multiple episodes are simulated, starting from the real state s, and following a random policy. The action-values $Q(s, a)$ are estimated by the empirical average of the returns of all episodes in which action a was taken from the real state s. After simulation is complete, the agent selects the greedy action $\text{argmax}_a\, Q(s, a)$, and proceeds to the next real state.

Monte-Carlo tree search constructs a search tree containing all state–action pairs that have been visited by the agent. Each simulation consists of two distinct phases: greedy action selection while within the tree, and then random action selection until termination. If a simulated state s is fully represented in the search tree, i.e. all actions from s have already been tried, then the agent selects the greedy action $\text{argmax}_a\, Q(s, a)$. Otherwise, the agent selects actions at random. After each simulation, the action-values $Q(s, a)$ of all states and actions experienced in the episode are updated to the empirical average return following each state–action pair. In practice, only one new state–action pair is added per episode, resulting in a tree-like expansion.

The UCT algorithm (Kocsis & Szepesvari, 2006) improves the greedy action selection in Monte-Carlo tree search. Each state of the search tree is treated as a multi-armed bandit, and actions are chosen using the UCB algorithm for balancing exploration and exploita-

tion (Auer et al., 2002).

2.3. Dyna

The Dyna architecture (Sutton, 1990) combines sample-based learning with sample-based planning. The agent learns a model of the world from real experience, and updates its action-value function from both real and simulated experience. Before each real action is selected, the agent performs some sample-based planning. For example, the Dyna-Q algorithm remembers all previous states, actions and transitions. During planning, experience is simulated by sampling states, actions and transitions from the empirical distribution. A Q-learning update is applied to update the action-value function after each sampled transition, and after each real transition.

2.4. Tracking

Traditional learning methods focus on finding a single best solution to the learning problem. In reinforcement learning one may seek an algorithm that converges on the optimal value function (or optimal policy). However, in large domains the agent may not have sufficient resources to perfectly represent the optimal value function. In this case we can actually achieve better performance by *tracking* the current situation rather than *converging* on the best overall parameters. The agent can specialise its value function to its current region of the state space, and update its representation as it moves through the state space. The potential for specialisation means that tracking methods may outperform converging methods, even in stationary domains (Sutton et al., 2007).

3. Permanent and Transient Memories

We define a *memory* to be the set of features and corresponding parameters used by an agent to estimate the value function. In our architecture, the agent maintains two distinct memories: a *permanent memory* (ϕ, θ) updated during sample-based learning, and a *transient memory* $(\bar{\phi}, \bar{\theta})$ updated during sample-based search. The value function is a linear combination of the transient and permanent memories, such that the transient memory tracks a local correction to the permanent memory,

$$Q(s,a) = \phi(s,a)^T\theta \quad (4)$$

$$\bar{Q}(s,a) = \phi(s,a)^T\theta + \bar{\phi}(s,a)^T\bar{\theta} \quad (5)$$

where $Q(s,a)$ is a permanent value function, and $\bar{Q}(s,a)$ is a combined value function.

We refer to the distribution of states and actions encountered during real experience as the *learning distribution*, and the distribution encountered during simulated experience as the *search distribution*. The permanent memory is updated from the learning distribution and converges on the best overall representation of the value function, based on the agent's past experience. The transient memory is updated from the search distribution and tracks the local nuances of the value function, based on the agent's expected future experience.

    end while
  end while
end procedure

The Dyna-2 architecture can be summarised as Dyna with Sarsa updates, permanent and transient memories, and linear function approximation (see Algorithm 1). The agent updates its permanent memory from real experience. Before selecting a real action, the agent executes a sample-based search from the current state. The search procedure simulates complete episodes from the current state, sampled from the model, until no more computation time is available. The transient memory is updated during these simulations to learn a local correction to the permanent memory; it is cleared at the beginning of each real episode.

A particular instance of Dyna-2 must specify learning parameters: a policy π to select real actions; a set of features ϕ for the permanent memory; a temporal difference parameter λ; and a learning rate $\alpha(s, a)$. Similarly, it must specify the equivalent search parameters: a policy $\bar{\pi}$ to select actions during simulation; a set of features $\bar{\phi}$ for the transient memory; a temporal difference parameter $\bar{\lambda}$; and a learning rate $\bar{\alpha}(s, a)$.

The Dyna-2 architecture subsumes a large family of learning and search algorithms. If there is no transient memory, $\bar{\phi} = \emptyset$, then the search procedure has no effect and may be skipped. This results in the linear Sarsa algorithm.

If there is no permanent memory, $\phi = \emptyset$, then Dyna-2 reduces to a sample-based search algorithm. For example, Monte-Carlo tree search is achieved by choosing table lookup $\bar{\phi}(s, a) = e(s, a)$[1]; using a simulation policy that is greedy within the tree, and then uniform random until termination; and selecting learning parameters $\bar{\lambda} = 1$ and $\bar{\alpha}(s, a) = 1/n(s, a)$, where $n(s, a)$ counts the number of times that action a has been selected in state s. The UCT algorithm replaces the greedy phase of the simulation policy with the UCB rule for action selection.

Finally, we note that real experience may be accumulated offline prior to execution. Dyna-2 may be executed on any suitable training environment (e.g. a helicopter simulator) before it is applied to real data (e.g. a real helicopter). The permanent memory is updated offline, but the transient memory is updated online. Dyna-2 provides a principled mechanism for combining offline and online knowledge(Gelly & Silver, 2007); the permanent memory provides prior knowledge and a baseline for fast learning. Our examples of Dyna-2 in Computer Go operate in this manner.

[1]The number of entries in the table can increase over time, to give a tree-like expansion.

5. Dyna-2 in Computer Go

In domains with spatial coherence, binary features can be constructed to exploit spatial structure at multiple levels (Sutton, 1996). The game of Go exhibits strong spatial coherence: expert players describe positions using a broad vocabulary of shapes (Figure 1a). A simple way to encode basic shape knowledge is through a large set of *local shape features* which match a particular configuration within a small region of the board (Silver et al., 2007). We define the feature vector $\phi^{square(m)}$ to be the vector of local shape features for $m \times m$ square regions, for all possible configurations and square locations. For example, Figure 1a shows several local shape features of size 3×3. Combining local shape features of different sizes builds a representation spanning many levels of generality: we define the multi-level feature vector $\phi^{square(m,n)} = [\phi^{square(m)}; ...; \phi^{square(n)}]$. In 9×9 Go there are nearly a million $\phi^{square(1,3)}$ features, about 200 of which are non-zero at any given time.

Local shape features can be used as a permanent memory, to represent general domain knowledge. For example, local shape features can be learned offline, using temporal difference learning and training by self-play (Silver et al., 2007; Gelly & Silver, 2007). However, local shape features can also be used as a transient memory[2], by learning online from simulations from the current state. The representational power of local shape features is significantly increased when they can track the short-term circumstances (Sutton et al., 2007). A local shape may be bad in general, but good in the current situation (Figure 1b). By training from simulated experience, starting from the current state, we can focus learning on what works well *now*.

We apply the Dyna-2 algorithm to 9×9 Computer Go using local shape features $\phi(s, a) = \bar{\phi}(s, a) = \phi^{square(1,3)}(s \circ a)$, where $s \circ a$ indicates the *afterstate* following action a in state s (Sutton & Barto, 1998). We use a self-play model, an ϵ-greedy policy, and default parameters of $\lambda = \bar{\lambda} = 0.4$, $\alpha(s, a) = 0.1/|\phi(s, a)|$, $\bar{\alpha}(s, a) = 0.1/|\bar{\phi}(s, a)|$, and $\epsilon = 0.3$. We modify the Dyna-2 algorithm slightly to utilise the logistic function and to minimise a cross-entropy loss function, by replacing the value function approximation in (4) and (5),

$$Q(s, a) = \sigma(\phi(s, a)^T \theta) \quad (6)$$

$$\bar{Q}(s, a) = \sigma(\phi(s, a)^T \theta + \bar{\phi}(s \circ a)^T \bar{\theta}) \quad (7)$$

where $\sigma(x) = \frac{1}{1+e^{-x}}$ is the logistic function.

[2]Symmetric local shape features share weights in the permanent memory, but not in the transient memory.

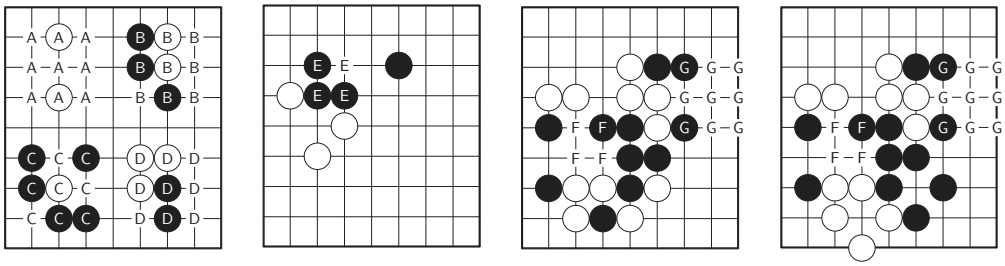

Figure 1. a) Examples of 3×3 local shape features, matching common shapes known to Go players: the *one-point jump* (A), *hane* (B), *net* (C) and *turn* (D). b) The *empty triangle* (E) is normally considered a bad shape; it can be learned by the permanent memory. However, in this position the empty triangle makes a good shape, known as *guzumi*; it can be learned by the transient memory. c) White threatens to cut blacks stones apart at F and G. 2×2 and 3×3 local shape features can represent the local consequences of cutting at F and G respectively. d) A position encountered when searching from (c): Dyna-2 is able to generalise, using local shape features in its transient memory, and can re-use its knowledge about cutting at F and G. UCT considers each state uniquely, and must re-search each continuation.

In addition we ignore local shape features consisting of entirely empty intersections; we clear the eligibility trace for exploratory actions; and we use the default policy described in (Gelly et al., 2006) after the first $D = 10$ moves of each simulation. We refer to the complete algorithm as *Dyna-2-Shape*, and implement this algorithm in our program *RLGO*, which executes almost 2000 complete episodes of simulation per second on a 3 GHz processor.

For comparison, we implemented the UCT algorithm, based on the description in (Gelly et al., 2006). We use an identical default policy to the Dyna-2-Shape algorithm, to select moves when outside of the search tree, and a first play urgency of 1. We evaluate both programs by running matches against GnuGo, a standard benchmark program for Computer Go.

We compare the performance of local shape features in the permanent memory alone; in the transient memory alone; and in both the permanent and transient memories. We also compare the performance of local shape features of different sizes (see Figure 3). Using only the transient memory, Dyna-2-Shape outperformed UCT by a small margin. Using Dyna-2-Shape with both permanent and transient memories provided the best results, and outperformed UCT by a significant margin.

Local shape features would normally be considered naive in the domain of Go: the majority of shapes and tactics described in Go textbooks span considerably larger regions of the board than 3×3 squares. Indeed, when used only in the permanent memory, the local shape features win just 5% of games against GnuGo. However, when used in the transient memory, even the $\phi^{square(1,2)}$ features achieve performance comparable to UCT. Unlike UCT, the transient memory can generalise in terms of local responses: for example, it quickly learns the importantance of black connecting when white threatens to cut (Figures 1c and 1d).

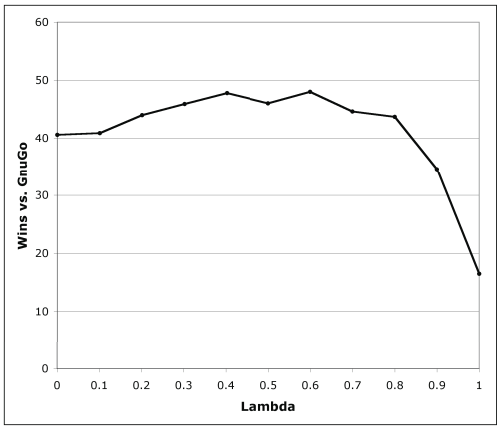

Figure 2. Winning rate of RLGO against GnuGo 3.7.10 (level 0) in 9×9 Go, using Dyna-2-Shape with 1000 simulations/move, for different values of $\bar{\lambda}$. Each point represents the winning percentage over 1000 games.

We also study the effect of the temporal difference parameter $\bar{\lambda}$ in the search procedure (see Figure 2). We see that bootstrapping ($\bar{\lambda} < 1$) provides significant benefits. Previous work in sample-based search has largely been restricted to Monte-Carlo methods (Tesauro & Galperin, 1996; Kocsis & Szepesvari, 2006; Gelly et al., 2006; Gelly & Silver, 2007; Coulom, 2007). Our results suggest that generalising these approaches to temporal difference learning methods may provide significant benefits when value function approximation is used.

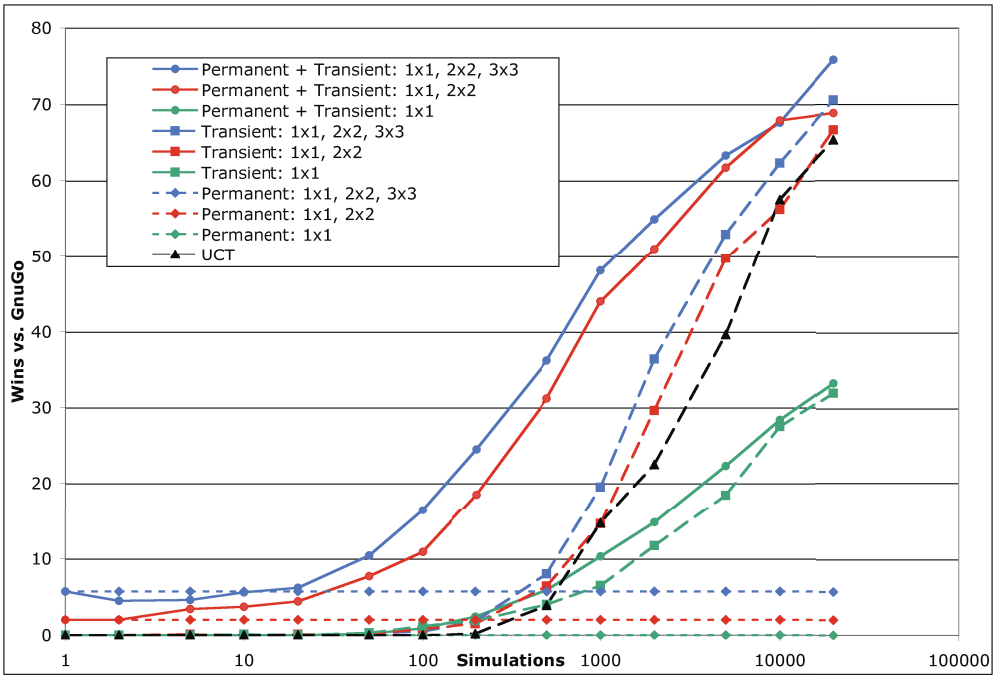

Figure 3. Winning rate of RLGO against GnuGo 3.7.10 (level 0) in 9×9 Go, using Dyna-2-Shape for different simulations/move. Local shape features are used in either the permanent memory (dotted lines), the transient memory (dashed lines), or both memories (solid lines). The permanent memory is trained offline from 100,000 games of self-play. Local shape features varied in size from 1×1 up to 3×3. Each point represents the winning percentage over 1000 games.

6. Dyna-2 and Heuristic Search

In games such as Chess, Checkers and Othello, master level play has been achieved by combining a heuristic evaluation function with α-β search. The heuristic is typically approximated by a linear combination of binary features, and can be learned offline by temporal-difference learning and self-play (Baxter et al., 1998; Schaeffer et al., 2001; Buro, 1999). Similarly, in the permanent memory of our architecture, the value function is approximated by a linear combination of binary features, learned offline by temporal-difference learning and self-play (Silver et al., 2007). Thus it is natural to compare Dyna-2 with approaches based on α-β search.

Dyna-2 combines a permanent memory with a transient memory, using sample-based search. In contrast, the classical approach uses the permanent memory $Q(s, a)$ as an evaluation function for α-β search. A hybrid approach is also possible, in which the combined value function $\bar{Q}(s, a)$ is used as an evaluation function for α-β search, including both permanent and transient memories. This can be viewed as searching with a dynamic evaluation function that evolves according to the current context. We compare all three approaches in Figure 4.

Dyna-2 outperformed classical search by a wide margin. In the game of Go, the consequences of a particular move (for example, playing good shape as in Figure 1a) may not become apparent for tens or even hundreds of moves. In a full-width search these consequences remain beyond the horizon, and will only be recognised if represented by the evaluation function. In contrast, sample-based search only uses the permanent memory as an initial guide, and learns to identify the consequences of particular patterns in the current situation. The hybrid approach successfully combines this knowledge with the precise lookahead provided by full-width search.

Using the hybrid approach, our program RLGO established an Elo rating of 2130 on the Computer Go Online Server, more than any handcrafted or traditional search program.

7. Related work

The Computer Go program MoGo uses the heuristic UCT algorithm (Gelly & Silver, 2007) to achieve *dan*-level performance. This algorithm can be viewed as an instance of Dyna-2 with local shape features in the permanent memory, and table lookup in the transient memory. It uses a step-size of $\bar{\alpha}(s, a) =$

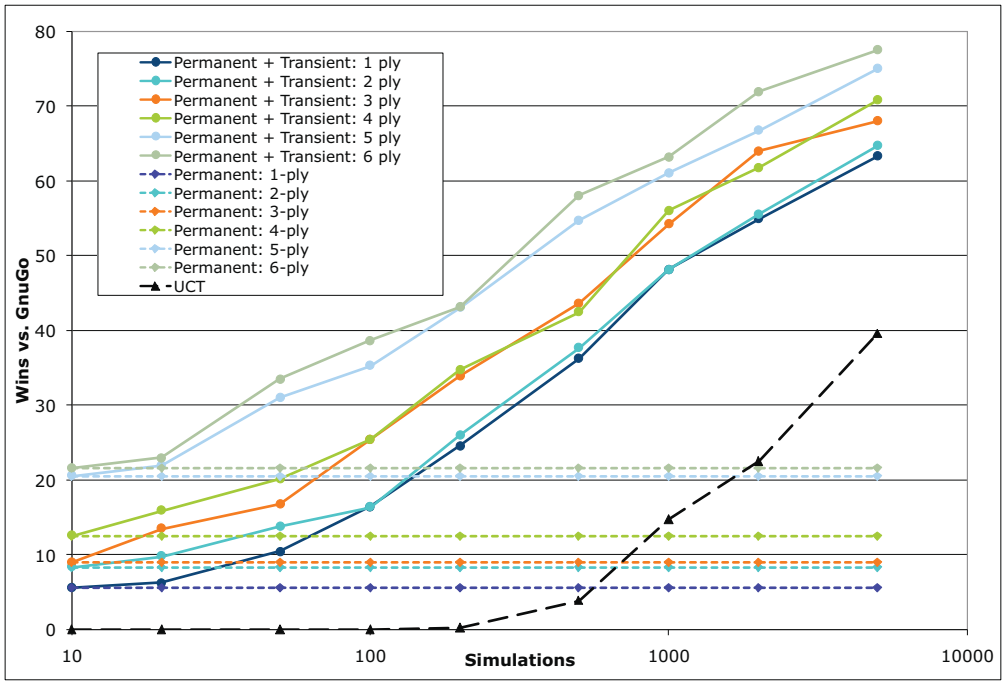

Figure 4. Winning rate of RLGO against GnuGo 3.7.10 (level 0) in 9×9 Go, using Dyna-2-Shape. A full-width α-β search is used for move selection, using a value function based on either the permanent memory (dotted lines), or both memories (solid lines). A 1-ply search corresponds to the usual move selection procedure in Dyna-2. For comparison, a 5-ply search takes approximately the same computation time as 1000 simulations. The permanent memory is trained offline from 100,000 games of self-play. Each point represents the winning percentage over 1000 games.

$1/(n_{prior}(s,a)+n(s,a))$. The confidence in the permanent memory is specified by n_{prior} in terms of *equivalent experience*, i.e. the worth of the permanent memory, measured in episodes of simulated experience.

In addition, MoGo uses the *Rapid Action Value Estimate* (RAVE) algorithm in its transient memory (Gelly & Silver, 2007). This algorithm can also be viewed as a special case of the Dyna-2 architecture, but using features of the full history h_t and not just the current state s_t and action a_t.

We define a history to be a sequence of states and actions $h_t = s_1 a_1 ... s_t a_t$, including the current action a_t. An individual RAVE feature $\phi_{sa}^{RAVE}(h)$ is a binary feature of the history h that matches a particular state s and action a. The binary feature is on iff s occurs in the history and a matches the current action a_t,

$$\phi_{sa}^{RAVE}(s_1 a_1 ... s_t a_t) = \begin{cases} 1 & \text{if } a_t = a \text{ and } \exists i \text{ s.t. } s_i = s; \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

Thus the RAVE algorithm provides a simple abstraction over classes of related histories. The implementation of RAVE used in MoGo makes two additional simplifications. First, MoGo estimates a value for each RAVE feature independently of any other RAVE features, set to the average outcome of all simulations in which the RAVE feature ϕ_{sa}^{RAVE} is active. Second, for action selection, MoGo only evaluates the single RAVE feature $\phi_{s_t a_t}^{RAVE}$ corresponding to the current state s_t and candidate action a_t. This somewhat reduces the generalisation power of RAVE, but allows for a particularly efficient update procedure.

8. Conclusion

Reinforcement learning is often considered a slow procedure. Outstanding examples of success have, in the past, learned a value function from months of offline computation. However, this does not need to be the case. Many reinforcement learning methods are fast, incremental, and scalable. When such a reinforcement learning algorithm is applied to simulated experience, using a transient memory, it becomes a high performance search algorithm. This search procedure can be made more efficient by generalising across states; and it can be combined with long-term learning, using a permanent memory.

Monte-Carlo tree search algorithms, such as UCT, have recently received much attention. However, this

is just one example of a sample-based search algorithm. There is a spectrum of algorithms that vary from table-lookup to function approximation; from Monte-Carlo learning to bootstrapping; and from permanent to transient memories. Function approximation provides rapid generalisation in large domains; bootstrapping is advantageous in the presence of function approximation; and permanent and transient memories allow general knowledge about the past to be combined with specific knowledge about the expected future. By varying these dimensions, we have achieved a significant improvement over the UCT algorithm.

In 9×9 Go, programs based on extensions to the UCT algorithm have achieved *dan*-level performance. Our program RLGO, based on the Dyna-2 architecture, is the strongest program not based on UCT, and suggests that the full spectrum of sample-based search methods merits further investigation. For larger domains, such as 19×19 Go, generalising across states becomes increasingly important. Combining state abstraction with sample-based search is perhaps the most promising avenue for achieving human-level performance in this challenging domain.

Abstract

Inspired by co-training, many multi-view semi-supervised kernel methods implement the following idea: find a function in each of multiple Reproducing Kernel Hilbert Spaces (RKHSs) such that (a) the chosen functions make similar predictions on unlabeled examples, and (b) the average prediction given by the chosen functions performs well on labeled examples. In this paper, we construct a single RKHS with a data-dependent "co-regularization" norm that reduces these approaches to standard supervised learning. The reproducing kernel for this RKHS can be explicitly derived and plugged into any kernel method, greatly extending the theoretical and algorithmic scope of co-regularization. In particular, with this development, the Rademacher complexity bound for co-regularization given in (Rosenberg & Bartlett, 2007) follows easily from well-known results. Furthermore, more refined bounds given by localized Rademacher complexity can also be easily applied. We propose a co-regularization based algorithmic alternative to manifold regularization (Belkin et al., 2006; Sindhwani et al., 2005a) that leads to major empirical improvements on semi-supervised tasks. Unlike the recently proposed transductive approach of (Yu et al., 2008), our RKHS formulation is truly semi-supervised and naturally extends to unseen test data.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

1. Introduction

In semi-supervised learning, we are given a few labeled examples together with a large collection of unlabeled data from which to estimate an unknown target function. Suppose we have two hypothesis spaces, $\mathcal{H}^1$ and $\mathcal{H}^2$, each of which contains a predictor that well-approximates the target function. We know that *predictors that agree with the target function also agree with each other on unlabeled examples*. Thus, any predictor in one hypothesis space that does not have an "agreeing predictor" in the other can be safely eliminated from consideration. Due to the resulting reduction in the complexity of the joint learning problem, one can expect improved generalization performance.

These conceptual intuitions and their algorithmic instantiations together constitute a major line of work in semi-supervised learning. One of the earliest approaches in this area was "co-training" (Blum & Mitchell, 1998), in which $\mathcal{H}^1$ and $\mathcal{H}^2$ are defined over different representations, or "views", of the data, and trained alternately to maximize mutual agreement on unlabeled examples. More recently, several papers have formulated these intuitions as joint complexity regularization, or *co-regularization*, between $\mathcal{H}^1$ and $\mathcal{H}^2$ which are taken to be Reproducing Kernel Hilbert Spaces (RKHSs) of functions defined on the input space $\mathcal{X}$. Given a few labeled examples $\{(\boldsymbol{x}_i, y_i)\}_{i\in L}$ and a collection of unlabeled data $\{\boldsymbol{x}_i\}_{i\in U}$, co-regularization learns a prediction function,

$$f_\star(\boldsymbol{x}) = \frac{1}{2}\big(f^1_\star(\boldsymbol{x}) + f^2_\star(\boldsymbol{x})\big) \tag{1}$$

where $f^1_\star \in \mathcal{H}^1$ and $f^2_\star \in \mathcal{H}^2$ are obtained by solving the following optimization problem,

$$(f^1_\star, f^2_\star) = \operatorname*{argmin}_{f^1\in\mathcal{H}^1, f^2\in\mathcal{H}^2} \gamma_1||f^1||^2_{\mathcal{H}^1} + \gamma_2||f^2||^2_{\mathcal{H}^2} + \mu\sum_{i\in U}[f^1(\boldsymbol{x}_i) - f^2(\boldsymbol{x}_i)]^2 + \sum_{i\in L} V\left(y_i, f(\boldsymbol{x}_i)\right) \tag{2}$$

In this objective function, the first two terms measure complexity by the RKHS norms $\|\cdot\|^2_{\mathcal{H}_1}$ and $\|\cdot\|^2_{\mathcal{H}_2}$ in $\mathcal{H}_1$ and $\mathcal{H}_2$ respectively, the third term enforces agreement among predictors on unlabeled examples, and the final term evaluates the empirical loss of the mean function $f = (f^1 + f^2)/2$ on the labeled data with respect to a loss function $V(\cdot,\cdot)$. The real-valued parameters γ_1, γ_2, and μ allow different tradeoffs between the regularization terms. L and U are index sets over labeled and unlabeled examples respectively.

Several variants of this formulation have been proposed independently and explored in different contexts: linear logistic regression (Krishnapuram et al., 2005), regularized least squares classification (Sindhwani et al., 2005b), regression (Brefeld et al., 2006), support vector classification (Farquhar et al., 2005), Bayesian co-training (Yu et al., 2008), and generalization theory (Rosenberg & Bartlett, 2007).

The main theoretical contribution of this paper is the construction of a new "co-regularization RKHS," in which standard supervised learning recovers the solution to the co-regularization problem of Eqn. 2. Theorem 2.2 presents the RKHS and gives an explicit formula for its reproducing kernel. This "co-regularization kernel" can be plugged into any standard kernel method giving convenient and immediate access to two-view semi-supervised techniques for a wide variety of learning problems. Utilizing this kernel, in Section 3 we give much simpler proofs of the results of (Rosenberg & Bartlett, 2007) concerning bounds on the Rademacher complexity and generalization performance of co-regularization. As a more algorithmic application, in Section 4 we consider the semi-supervised learning setting where examples live near a low-dimensional manifold embedded in a high dimensional ambient euclidean space. Our approach, manifold co-regularization (CoMR), gives major empirical improvements over the manifold regularization (MR) framework of (Belkin et al., 2006; Sindhwani et al., 2005a).

The recent work of (Yu et al., 2008) considers a similar reduction. However, this reduction is strictly transductive and does not allow prediction on unseen test examples. By contrast, our formulation is truly semi-supervised and provides a principled out-of-sample extension.

2. An RKHS for Co-Regularization

We start by reformulating the co-regularization optimization problem, given in Eqn. 1 and Eqn. 2, in the following equivalent form where we directly solve for the final prediction function $f_\star$:

$$f_\star = \operatorname*{argmin}_f \min_{\substack{f=f^1+f^2 \\ f^1\in\mathcal{H}^1, f^2\in\mathcal{H}^2}} \frac{\gamma_1}{2}||f^1||^2_{\mathcal{H}^1} + \frac{\gamma_2}{2}||f^2||^2_{\mathcal{H}^2} + \frac{\mu}{2}\sum_{i\in U}[f^1(\boldsymbol{x}_i) - f^2(\boldsymbol{x}_i)]^2 + \frac{1}{2}\sum_{i\in L} V\left(y_i, \frac{1}{2}f(\boldsymbol{x}_i)\right) \quad (3)$$

Consider the sum space of functions, $\tilde{\mathcal{H}}$, given by,

$$\begin{aligned}\tilde{\mathcal{H}} &= \mathcal{H}^1 \oplus \mathcal{H}^2 \quad (4)\\ &= \{f | f(\boldsymbol{x}) = f^1(\boldsymbol{x}) + f^2(\boldsymbol{x}), f^1 \in \mathcal{H}^1, f^2 \in \mathcal{H}^2\}\end{aligned}$$

and impose on it a data-dependent norm,

$$\|f\|^2_{\tilde{\mathcal{H}}} = \min_{\substack{f=f^1+f^2 \\ f^1\in\mathcal{H}^1, f^2\in\mathcal{H}^2}} \gamma_1\|f^1\|^2_{\mathcal{H}^1} + \gamma_2\|f^2\|^2_{\mathcal{H}^2} + \mu\sum_{i\in U}\left[f^1(\boldsymbol{x}_i) - f^2(\boldsymbol{x}_i)\right]^2 \quad (5)$$

The minimization problem in Eqn. 3 can then be posed as standard supervised learning in $\tilde{\mathcal{H}}$ as follows,

$$f_\star = \operatorname*{argmin}_{f\in\tilde{\mathcal{H}}} \gamma\|f\|^2_{\tilde{\mathcal{H}}} + \frac{1}{2}\sum_{i\in L} V\left(y_i, \frac{1}{2}f(\boldsymbol{x}_i)\right) \quad (6)$$

where $\gamma = \frac{1}{2}$. Of course, this reformulation is not really useful unless $\tilde{\mathcal{H}}$ itself is a valid new RKHS. Let us recall the definition of an RKHS.

Definition 2.1 (RKHS). *A reproducing kernel Hilbert space (RKHS) is a Hilbert Space $\mathcal{F}$ that possesses a reproducing kernel,* i.e., *a function $k : \mathcal{X}\times\mathcal{X} \to \mathcal{R}$ for which the following hold: (a) $k(\boldsymbol{x}, .) \in \mathcal{F}$ for all $\boldsymbol{x} \in \mathcal{X}$, and (b) $\langle f, k(\boldsymbol{x}, .)\rangle_{\mathcal{F}} = f(\boldsymbol{x})$ for all $\boldsymbol{x} \in \mathcal{X}$ and $f \in \mathcal{F}$, where $\langle\cdot,\cdot\rangle_{\mathcal{F}}$ denotes inner product in $\mathcal{F}$.*

In Theorem 2.2, we show that $\tilde{\mathcal{H}}$ is indeed an RKHS, and moreover we give an explicit expression for its reproducing kernel. Thus, it follows that although the domain of optimization in Eqn. 6 is nominally a function space, by the Representer Theorem we can express it as a finite-dimensional optimization problem.

2.1. Co-Regularization Kernels

Let $\mathcal{H}^1, \mathcal{H}^2$ be RKHSs with kernels given by k^1, k^2 respectively, and let $\tilde{\mathcal{H}} = \mathcal{H}^1 \oplus \mathcal{H}^2$ as defined in Eqn. 4. We have the following result.

Theorem 2.2. *There exists an inner product on $\tilde{\mathcal{H}}$ for which $\tilde{\mathcal{H}}$ is a RKHS with norm defined by Eqn. 5 and reproducing kernel $\tilde{k} : \mathcal{X}\times\mathcal{X} \to \mathcal{R}$ given by,*

$$\tilde{k}(\boldsymbol{x}, \boldsymbol{z}) = s(\boldsymbol{x}, \boldsymbol{z}) - \mu\mathbf{d}_{\boldsymbol{x}}^T H \mathbf{d}_{\boldsymbol{z}} \quad (7)$$

where $s(\boldsymbol{x}, \boldsymbol{z})$ is the (scaled) sum of kernels given by,

$$s(\boldsymbol{x}, \boldsymbol{z}) = \gamma_1^{-1} k^1(\boldsymbol{x}, \boldsymbol{z}) + \gamma_2^{-1} k^2(\boldsymbol{x}, \boldsymbol{z}),$$

and $\mathbf{d}_{\boldsymbol{x}}$ is a vector-valued function that depends on the difference in views measured as,

$$\mathbf{d}_{\boldsymbol{x}} = \gamma_1^{-1} \mathbf{k}^1_{U\boldsymbol{x}} - \gamma_2^{-1} \mathbf{k}^2_{U\boldsymbol{x}},$$

where $\mathbf{k}^i_{U\boldsymbol{x}} = \left[k^i(\boldsymbol{x}, \boldsymbol{x}_j), j \in U\right]^T$, and H is a positive-definite matrix given by $H = (I + \mu S)^{-1}$. Here, S is the gram matrix of $s(\cdot, \cdot)$, i.e., *$S = \left(\gamma_1^{-1} K^1_{UU} + \gamma_2^{-1} K^2_{UU}\right)$ where $K^i_{UU} = k^i(U, U)$ denotes the Gram matrices of k^i over unlabeled examples.*

We give a rigorous proof in Appendix A.

2.2. Representer Theorem

Theorem 2.2 says that $\tilde{\mathcal{H}}$ is a valid RKHS with kernel $\tilde{k}$. By the Representer Theorem, the solution to Eqn.6 is given by

$$f_\star(\boldsymbol{x}) = \sum_{i \in L} \alpha_i \tilde{k}(\boldsymbol{x}_i, \boldsymbol{x}) \tag{8}$$

The corresponding components in $\mathcal{H}^1, \mathcal{H}^2$ can also be retrieved as,

$$f^1_\star(\boldsymbol{x}) = \sum_{i \in L} \alpha_i \gamma_1^{-1} \left(k^1(\boldsymbol{x}_i, \boldsymbol{x}) - \mu \mathbf{d}^T_{\boldsymbol{x}_i} H k^1_{U\boldsymbol{x}}\right) \tag{9}$$

$$f^2_\star(\boldsymbol{x}) = \sum_{i \in L} \alpha_i \gamma_2^{-1} \left(k^2(\boldsymbol{x}_i, \boldsymbol{x}) + \mu \mathbf{d}^T_{\boldsymbol{x}_i} H k^2_{U\boldsymbol{x}}\right) \tag{10}$$

Note that $\mathcal{H}^1$ and $\mathcal{H}^2$ are defined on the same domain $\mathcal{X}$ so that taking the mean prediction is meaningful. In a two-view problem one may begin by defining $\mathcal{H}^1, \mathcal{H}^2$ on different view spaces $\mathcal{X}^1, \mathcal{X}^2$ respectively. Such a problem can be mapped to our framework by extending $\mathcal{H}^1, \mathcal{H}^2$ to $\mathcal{X} = \mathcal{X}^1 \times \mathcal{X}^2$ by re-defining $f^1(\boldsymbol{x}^1, \boldsymbol{x}^2) = f^1(\boldsymbol{x}^1), f^1 \in \mathcal{H}^1$; similarly for $\mathcal{H}^2$. While we omit these technical details, it is important to note that in such cases, Eqns. 9 and 10 can be reinterpreted as predictors defined on $\mathcal{X}^1, \mathcal{X}^2$ respectively.

3. Bounds on Complexity and Generalization

By eliminating all predictors that do not collectively agree on unlabeled examples, co-regularization intuitively reduces the complexity of the learning problem. It is reasonable then to expect better test performance for the same amount of labeled training data. In (Rosenberg & Bartlett, 2007), the size of the co-regularized function class is measured by its empirical Rademacher complexity, and tight upper and lower bounds are given on the Rademacher complexity of the co-regularized hypothesis space. This leads to generalization bounds in terms of the Rademacher complexity. In this section, we derive these complexity bounds in a few lines using Theorem 2.2 and a well-known result on RKHS balls. Furthermore, we present improved generalization bounds based on the theory of localized Rademacher complexity.

3.1. Rademacher Complexity Bounds

Definition 3.1. *The empirical Rademacher complexity of a function class $\mathcal{A} = \{f : \mathcal{X} \to \mathcal{R}\}$ on a sample $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_\ell \in \mathcal{X}$ is defined as*

$$\hat{R}_\ell(\mathcal{A}) = E^\sigma \left[\sup_{f \in \mathcal{A}} \left| \frac{2}{\ell} \sum_{i=1}^{\ell} \sigma_i f(\boldsymbol{x}_i) \right| \right],$$

where the expectation is with respect to $\sigma = \{\sigma_1, \ldots, \sigma_\ell\}$, and the σ_i are i.i.d. Rademacher random variables, that is, $P(\sigma_i = 1) = P(\sigma_i = -1) = \frac{1}{2}$.

Let $\mathcal{H}$ be an arbitrary RKHS with kernel $k(\cdot, \cdot)$, and denote the standard RKHS supervised learning objective function by $Q(f) = \sum_{i \in L} V(y_i, f(\boldsymbol{x}_i)) + \lambda ||f||^2_{\mathcal{H}}$. Let $f_\star = \operatorname{argmin}_{f \in \mathcal{H}} Q(f)$. Then $Q(f_\star) \leq Q(0) = \sum_{i \in L} V(y_i, 0)$. It follows that $\|f_\star\|^2_{\mathcal{H}} \leq Q(0)/\lambda$. Thus if we have some control *a priori* on $Q(0)$, then we can restrict the search for $f_\star$ to a ball in $\mathcal{H}$ of radius $r = \sqrt{Q(0)/\lambda}$.

We now cite a well-known result about the Rademacher complexity of a ball in an RKHS (see *e.g.* (Boucheron et al., 2005)). Let $\mathcal{H}_r := \{f \in \mathcal{H} : ||f||_{\mathcal{H}} \leq r\}$ denote the ball of radius r in $\mathcal{H}$. Then we have the following:

Lemma 3.2. *The empirical Rademacher complexity on the sample $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_\ell \in \mathcal{X}$ for the RKHS ball $\mathcal{H}_r$ is bounded as follows: $\frac{1}{\sqrt[4]{2}} \frac{2r}{\ell} \sqrt{\mathrm{tr} K} \leq \hat{R}_\ell(\mathcal{H}_r) \leq \frac{2r}{\ell} \sqrt{\mathrm{tr} K}$ where $K = \left(k(\boldsymbol{x}_i, \boldsymbol{x}_j)\right)_{i,j=1}^{\ell}$ is the kernel matrix.*

For the co-regularization problem described in Eqns. 3 and 6, we have $f_\star \in \tilde{\mathcal{H}}_r$ where $r^2 = \ell \sup_y V(0, y)$, where ℓ is number of labeled examples. We now state and prove bounds on the Rademacher complexity of $\tilde{\mathcal{H}}_r$. The bounds here are exactly the same as those given in (Rosenberg & Bartlett, 2007). However, while they have a lengthy "bare-hands" approach, here we get the result as a simple corollary of Theorem 2.2 and Lemma 3.2.

Theorem 3.3. *The empirical Rademacher complexity on the labeled sample $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_\ell \in \mathcal{X}$ for the RKHS ball $\tilde{\mathcal{H}}_r$ is bounded as follows:*

$$\frac{1}{\sqrt[4]{2}} \frac{2r}{\ell} \sqrt{\mathrm{tr} \tilde{K}} \leq \hat{R}_\ell(\tilde{\mathcal{H}}_r) \leq \frac{2r}{\ell} \sqrt{\mathrm{tr} \tilde{K}},$$

where
$\tilde{K} = \gamma_1^{-1} K^1_{LL} + \gamma_2^{-1} K^2_{LL} - \mu D^T_{UL} (I + \mu S)^{-1} D_{UL}$ *and*
$D_{UL} = \left(\gamma_1^{-1} K^1_{UL} - \gamma_2^{-1} K^2_{UL}\right)$

Proof. Note that $\tilde{K}$ is just the kernel matrix for the co-regularization kernel $\tilde{k}(\cdot,\cdot)$ on the labeled data. Then the bound follows immediately from Lemma 3.2. □

3.2. Co-Regularization Reduces Complexity

The co-regularization parameter μ controls the extent to which we enforce agreement between f^1 and f^2. Let $\tilde{\mathcal{H}}(\mu)$ denote the co-regularization RKHS for a particular value of μ. From Theorem 3.3, we see that the Rademacher complexity for a ball of radius r in $\tilde{\mathcal{H}}(\mu)$ decreases with μ by an amount determined by

$$\Delta(\mu) = \operatorname{tr}\left[\mu D^T_{UL} (I + \mu S)^{-1} D_{UL}\right] \quad (11)$$

$$= \sum_{i=1}^{\ell} \rho^2 \left(\mathbf{k}^1_{U\boldsymbol{x}_i} \mathbf{k}^2_{U\boldsymbol{x}_i}\right) \quad (12)$$

where $\rho(\cdot,\cdot)$ is a metric on $\mathcal{R}^{|U|}$ defined by
$\rho^2(\mathbf{s},\mathbf{t}) = \mu(\gamma_1^{-1}\mathbf{s} - \gamma_2^{-1}\mathbf{t})' (I + \mu S)^{-1} (\gamma_1^{-1}\mathbf{s} - \gamma_2^{-1}\mathbf{t})$

We see that the complexity reduction, $\Delta(\mu)$, grows with the ρ-distance between the two different representations of the labeled points. Note that the metric ρ is determined by S, which is the weighted sum of the gram matrices of the two kernels on unlabeled data.

3.3. Generalization Bounds

With Theorem 2.2 allowing us to express multi-view co-regularization problems as supervised learning in a data-dependent RKHS, we can now bring a large body of theory to bear on the generalization performance of co-regularization methods. We start by quoting the theorem proved in (Rosenberg & Bartlett, 2007). Next, we state an improved bound based on localized Rademacher complexity. Below, we denote the unit ball in $\tilde{\mathcal{H}}$ by $\tilde{\mathcal{H}}_1$.

Condition 1. The loss $V(\cdot,\cdot)$ is Lipschitz in its first argument, i.e., there exists a constant A such that $\forall y, \hat{y}_1, \hat{y}_2$: $|V(\hat{y}_1, y) - V(\hat{y}_2, y)| \leq A\,|\hat{y}_1 - \hat{y}_2|$

Theorem 3.4. *Suppose $V : \mathcal{Y}^2 \to [0,1]$ satisfies Condition 1. Then conditioned on the unlabeled data, for any $\delta \in (0,1)$, with probability at least $1-\delta$ over the sample of labeled points $(\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_\ell, y_\ell)$ drawn i.i.d. from P, we have for any predictor $f \in \tilde{\mathcal{H}}_1$ that*

$$P[V(\varphi(\boldsymbol{x}), y)] \leq \frac{1}{\ell}\sum_{i=1}^{\ell} V(\varphi(\boldsymbol{x}_i), y_i) + 2B\hat{R}_\ell(\tilde{\mathcal{H}}_1) + \frac{1}{\sqrt{\ell}}\left(2 + 3\sqrt{\ln(2/\delta)/2}\right)$$

We need two more conditions for the localized bound:

Condition 2. For any probability distribution P, there exists $f_\star \in \tilde{\mathcal{H}}_1$ satisfying $P[V(f_\star(\boldsymbol{x}), y)] = \inf_{f \in \tilde{\mathcal{H}}_1} P[V(f(\boldsymbol{x}), y)]$

Condition 3. There is a constant $B \geq 1$ such that for every probability distribution P and every $f \in \tilde{\mathcal{H}}_1$ we have, $P(f - f_*)^2 \leq BP(V[f(\boldsymbol{x}), y] - V[f_\star(\boldsymbol{x}), y])$

In the following theorem, let P_ℓ denote the empirical probability measure for the labeled sample of size ℓ.

Theorem 3.5. *[Cor. 6.7 from (Bartlett et al., 2002)] Assume that $\sup_{\boldsymbol{x}\in\mathcal{X}} k(\boldsymbol{x},\boldsymbol{x}) \leq 1$ and that V satisfies the 3 conditions above. Let $\hat{f}$ be any element of $\tilde{\mathcal{H}}_1$ satisfying $P_\ell V[\hat{f}(\boldsymbol{x}), y] = \inf_{f\in\tilde{\mathcal{H}}_1} P_\ell V[f(\boldsymbol{x}), y]$. There exist a constant c depending only on A and B s.t. with probability at least $1 - 6e^{-\nu}$,*

$$P\left(V[\hat{f}(\boldsymbol{x}), y] - V[f_\star(\boldsymbol{x}), y]\right) \leq c\left(\hat{r}^* + \frac{\nu}{\ell}\right),$$

where $\hat{r}^* \leq \min_{0\leq h\leq \ell}\left(\frac{h}{\ell} + \frac{1}{\ell}\sqrt{\sum_{i>h}\lambda_i}\right)$ and where $\lambda_1, \ldots, \lambda_\ell$ are the eigenvalues of the labeled-data kernel matrix $\tilde{K}_{LL}$ in decreasing order.

Note that while Theorem 3.4 bounds the gap between expected and empirical performance of an arbitrary $f \in \tilde{\mathcal{H}}_1$, Theorem 3.5 bounds the gap between the empirical loss minimizer over $\tilde{\mathcal{H}}_1$ and true risk minimizer in $\tilde{\mathcal{H}}_1$. Since the localized bound only needs to account for the capacity of the function class in the neighborhood of f_*, the bounds are potentially tighter. Indeed, while the bound in Theorem 3.4 is in terms of the trace of the kernel matrix, the bound in Theorem 3.5 involves the tail sum of kernel eigenvalues. If the eigenvalues decay very quickly, the latter is potentially much smaller.

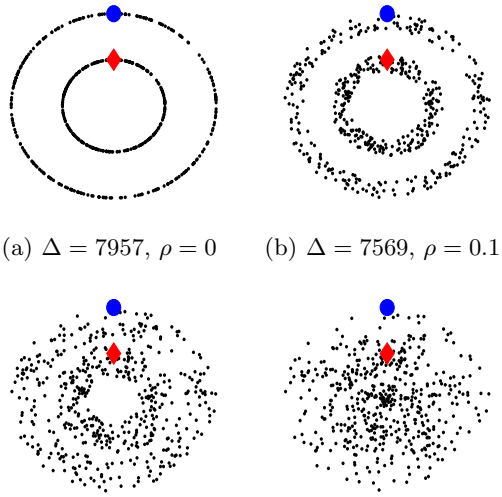
4. Manifold Co-Regularization

Consider the picture shown in Figure 1(a) where there are two classes of data points in the plane ($\mathcal{R}^2$) lying on one of two concentric circles. The large, colored points are labeled while the smaller, black points are unlabeled. The picture immediately suggests two notions of distance that are very natural but radically different. For example, the two labeled points are close in the *ambient* euclidean distance on $\mathcal{R}^2$, but infinitely apart in terms of *intrinsic* geodesic distance measured along the circles.

Suppose for this picture one had access to two kernel functions, k^1, k^2 that assign high similarity to nearby points according to euclidean and geodesic distance respectively. Because of the difference in ambient and intrinsic representations, by co-regularizing the associated RKHSs one can hope to get good reductions in

complexity, as suggested in section 3.2. In Figure 1, we report the value of complexity reduction (Eqn. 12) for four point clouds generated at increasing levels of noise off the two concentric circles. When noise becomes large, the ambient and intrinsic notions of distance converge and the amount of complexity reduction decreases.

Figure 1. Complexity Reduction $\Delta(\mu = 1)$ (Eqn. 12) with respect to noise level ρ. The choice of k^1, k^2 is discussed in the following subsections.



(a) $\Delta = 7957$, $\rho = 0$ (b) $\Delta = 7569$, $\rho = 0.1$

(c) $\Delta = 3720$, $\rho = 0.2$ (d) $\Delta = 3502$, $\rho = 0.5$

The setting where data lies on a low-dimensional submanifold $\mathcal{M}$ embedded in a higher dimensional ambient space $\mathcal{X}$, as in the concentric circles case above, has attracted considerable research interest recently, almost orthogonal to multi-view efforts. The main assumption underlying manifold-motivated semi-supervised learning algorithms is the following: *two points that are close with respect to geodesic distances on $\mathcal{M}$ should have similar labels.* Such an assumption may be enforced by an *intrinsic* regularizer that emphasizes complexity along the manifold.

Since $\mathcal{M}$ is truly unknown, the intrinsic regularizer is empirically estimated from the point cloud of labeled and unlabeled data. In the graph transduction approach, an *nn*-nearest neighbor graph $\mathcal{G}$ is constructed which serves as an empirical substitute for $\mathcal{M}$. The vertices $\mathcal{V}$ of this graph are the set of labeled and unlabeled examples. Let $\mathcal{H}_\mathcal{I}$ denote the space of all functions mapping $\mathcal{V}$ to $\mathcal{R}$, where the subscript $\mathcal{I}$ implies "intrinsic." Any function $f \in \mathcal{H}_\mathcal{I}$ can be identified with the vector $\boldsymbol{f} = [f(\boldsymbol{x}_i), \boldsymbol{x}_i \in \mathcal{V}]^T$. One can impose a norm $\|\boldsymbol{f}\|_\mathcal{I}^2 = \sum_{ij} W_{ij} \left[f(\boldsymbol{x}_i) - f(\boldsymbol{x}_j)\right]^2$ on $\mathcal{H}_\mathcal{I}$ that provides a natural measure of smoothness for $\boldsymbol{f}$ with respect to the graph. Here, W denotes the adjacency matrix of the graph. When $\mathcal{X}$ is a euclidean space, a typical W is given by $W_{ij} = \exp(-\frac{\|\boldsymbol{x}_i - \boldsymbol{x}_j\|^2}{2\sigma^2})$ if i and j are nearest neighbors and 0 otherwise. In practice, one may use a problem dependent similarity matrix to set these edge weights. This norm can be conveniently written as a quadratic form $\boldsymbol{f}^T M \boldsymbol{f}$, where M is the graph Laplacian matrix defined as $M = D - W$, and D is a diagonal degree matrix with entrees $D_{ii} = \sum_j W_{ij}$.

It turns out that $\mathcal{H}_\mathcal{I}$ with the norm $\|\cdot\|_\mathcal{I}$ is an RKHS whose reproducing kernel $k_\mathcal{I} : \mathcal{V} \times \mathcal{V} \to \mathcal{R}$ is given by $k_\mathcal{I}(\boldsymbol{x}_i, \boldsymbol{x}_j) = M^\dagger_{ij}$, where $M^\dagger$ denotes the pseudo-inverse of the Laplacian. Given $\mathcal{H}_\mathcal{I}$ with its reproducing kernel, graph transduction solves the standard RKHS regularization problem, $f_\star = \operatorname{argmin}_{f \in \mathcal{H}_I} \gamma \|f\|_\mathcal{I}^2 + \sum_{i \in L} V(y_i, f(\boldsymbol{x}_i))$, where y_i is the label associated with the node $\boldsymbol{x}_i$. Note that the solution $f_\star$ is only defined over $\mathcal{V}$, the set of labeled and unlabeled examples. Since graph transduction does not provide a function whose domain is the ambient space $\mathcal{X}$, it is not clear how to make predictions on unseen test points $\boldsymbol{x} \in \mathcal{X}$. Possessing a principled "out-of-sample extension" distinguishes semi-supervised methods from transductive procedures.

4.1. Ambient and Intrinsic Co-Regularization

We propose a co-regularization solution for out-of-sample prediction. Conceptually, one may interpret the manifold setting as a multi-view problem where each labeled or unlabeled example appears in two "views": (a) an ambient view in $\mathcal{X}$ in terms of euclidean co-ordinates $\boldsymbol{x}$ and (b) an intrinsic view in $\mathcal{G}$ as a vertex index i. Let $\mathcal{H}_\mathcal{A} : \mathcal{X} \times \mathcal{X} \to \mathcal{R}$ be an RKHS defined over the ambient domain with an associated kernel $k_\mathcal{A} : \mathcal{X} \times \mathcal{X} \to \mathcal{R}$. We can now combine ambient and intrinsic views by co-regularizing $\mathcal{H}_\mathcal{A}, \mathcal{H}_\mathcal{I}$. This can be done by setting $k^1 = k_\mathcal{A}$ and $k^2 = k_\mathcal{I}$ in Eqn. 7 and solving Eqn. 6. The combined prediction function $f_\star$ given by Eqn. 8 is the mean of an ambient component $f^1_\star$ given by Eqn. 9 and an intrinsic component $f^2_\star$ given by Eqn. 10. Even though $f_\star$ is transductive and only defined on labeled and unlabeled examples, the ambient component $f^1_\star$ can be used for out-of-sample prediction. Due to co-regularization, this ambient component is (a) smooth in $\mathcal{H}_\mathcal{X}$ and (b) in agreement with a smooth function on the data manifold. We call this approach manifold co-regularization, and abbreviate it as CoMR.

4.2. Manifold Regularization

In the manifold regularization (MR) approach of (Belkin et al., 2006; Sindhwani et al., 2005a), the

following optimization problem is solved:

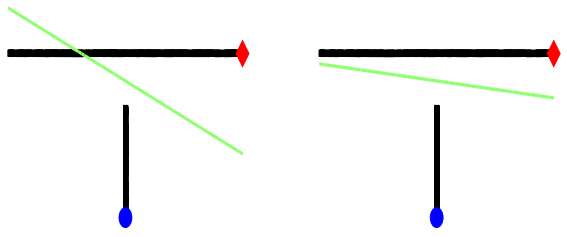
$$f^\star = \underset{f\in\mathcal{H}_\mathcal{A}}{\operatorname{argmin}}\, \gamma_1\|f\|^2_{\mathcal{H}_A} + \gamma_2 \boldsymbol{f}^T M \boldsymbol{f} + \sum_{i\in L} V(y_i, f(\boldsymbol{x}_i)) \quad (13)$$

where $\boldsymbol{f} = [f(\boldsymbol{x}_i), i \in L, U]^T$. The solution, $f^\star$ is defined on $\mathcal{X}$, and can therefore be used for out-of-sample prediction.

In Figure 2, we show a simple two-dimensional dataset where MR provably fails when $\mathcal{H}_\mathcal{A}$ is the space of linear functions on $\mathcal{R}^2$. The LINES dataset consists of two classes spread along perpendicular lines. In MR the intrinsic regularizer is enforced directly on $\mathcal{H}_\mathcal{A}$. It can be easily shown that the intrinsic norm of a linear function $f(\boldsymbol{x}) = \mathbf{w}^T\boldsymbol{x}$ along the perpendicular lines is exactly the same as the ambient norm, *i.e.*, $\|f\|^2_{\mathcal{H}_\mathcal{I}} = \|f\|^2_{\mathcal{H}_\mathcal{A}} = \mathbf{w}^T\mathbf{w}$. Due to this, MR simply ignores unlabeled data and reduces to supervised training with the regularization parameter $\gamma_1 + \gamma_2$.

The linear function that gives maximally smooth predictions on one line also gives the maximally non-smooth predictions on the other line. One way to remedy this restrictive situation is to introduce slack variables $\boldsymbol{\xi} = (\xi_i)_{i\in L\cup U}$ in Eqn. 13 with an ℓ_2 penalty, and instead solve: $f^\star = \operatorname{argmin}_{\boldsymbol{f}\in\mathcal{H}_\mathcal{A},\boldsymbol{\xi}}\, \gamma_1\|f\|^2_{\mathcal{H}_A} + \gamma_2(\boldsymbol{f}+\boldsymbol{\xi})^T M(\boldsymbol{f}+\boldsymbol{\xi}) + \mu\|\boldsymbol{\xi}\|^2 + \sum_{i\in L} V(y_i, f(\boldsymbol{x}_i))$. Re-parameterizing $\mathbf{g} = \boldsymbol{f} + \boldsymbol{\xi}$, we can re-write the above problem as, $f^\star = \operatorname{argmin}_{f\in\mathcal{H}_\mathcal{A}, g\in\mathcal{H}_\mathcal{I}}\, \gamma_1\|f\|^2_{\mathcal{H}_A} + \gamma_2\|g\|^2_{\mathcal{H}_\mathcal{I}} + \mu\|\boldsymbol{f}-\mathbf{g}\|^2 + \sum_{i\in L} V(y_i, f(\boldsymbol{x}_i))$, which may be viewed as a variant of the co-regularization problem in Eqn. 2 where empirical loss is measured for f alone. Thus, this motivates the view that CoMR adds extra slack variables in the MR objective function to better fit the intrinsic regularizer. Figure 2 shows that CoMR achieves better separation between classes on the LINES dataset.

Figure 2. Decision boundaries of MR and CoMR (using the quadratic hinge loss) on the LINES dataset



(a) MR (b) CoMR

4.3. Experiments

In this section, we compare MR and CoMR. Similar to our construction of the co-regularization kernel, (Sindhwani et al., 2005a) provide a data-dependent kernel that reduces manifold regularization to standard supervised learning in an associated RKHS. We write the manifold regularization kernel in the following form,

$$\tilde{k}^{mr}(\boldsymbol{x},\boldsymbol{z}) = \bar{s}(\boldsymbol{x},\boldsymbol{z}) - \bar{\mathbf{d}}_{\boldsymbol{x}}^T \bar{H} \bar{\mathbf{d}}_{\boldsymbol{z}} \quad (14)$$

where we have, $\bar{s} = \gamma_1^{-1}k^1(\boldsymbol{x},\boldsymbol{z})$, $\bar{\mathbf{d}}_{\boldsymbol{x}} = \gamma_1^{-1}k^1_{U\boldsymbol{x}}$ and $\bar{H} = \left(\gamma_1^{-1}\bar{K^1} + \gamma_2^{-1}\bar{K^2}\right)^{-1}$, where $\bar{K^1}$ is the Gram Matrix of $k^1 = k_\mathcal{A}$ over labeled and unlabeled examples, and $\bar{K^2} = M^\dagger$. We use the notation $\bar{s}, \bar{\mathbf{d}}, \bar{H}$ so that the kernel can be easily compared with corresponding quantities in the co-regularization kernel Eqn. 7. In this section we empirically compare this kernel with the co-regularization kernel of Eqn. 7 for exactly the same choice of k^1, k^2. Semi-supervised classification experiments were performed on 5 datasets described in table 1.

Table 1. Datasets with d features and c classes. 10 random data splits were created with l labeled, u unlabeled, t test, and v validation examples.

PCMAC	7511	2	50	1385	461	50

The LINES dataset is a variant of the two-dimensional problem shown in Figure 2 where we added random noise around the two perpendicular lines. The G50C, USPST, COIL20, and PCMAC datasets are well known and have frequently been used for empirical studies in semi-supervised learning literature. They were used for benchmarking manifold regularization in (Sindhwani et al., 2005a) against a number of competing methods. G50C is an artificial dataset generated from two unit covariance normal distributions with equal probabilities. The class means are adjusted so that the Bayes error is 5%. COIL20 consists of 32×32 gray scale images of 20 objects viewed from varying angles. USPST is taken from the test subset of the USPS dataset of images containing 10 classes of handwritten digits. PCMAC is used to setup binary text categorization problems drawn from the 20-newsgroups dataset.

For each of the 5 datasets, we constructed random splits into labeled, unlabeled, test and validation sets. The sizes of these sets are given in table 1. For all datasets except LINES, we used Gaussian am-

Table 2. Error Rates (in percentage) on Test Data

bient kernels $k^1(\boldsymbol{x}, \boldsymbol{z}) = \exp(-\frac{\|\boldsymbol{x}-\boldsymbol{z}\|^2}{2\sigma^2})$, and intrinsic graph kernel whose gram matrix is of the form $K_2 = (M^p + 10^{-6}I)^{-1}$. Here, M is the normalized Graph Laplacian constructed using nn nearest neighbors and p is an integer. These parameters are tabulated in Table 4 for reproducibility. For more details on these parameters see (Sindhwani et al., 2005a).

We chose squared loss for $V(\cdot,\cdot)$. Manifold regularization with this choice is also referred to as Laplacian RLS and empirically performs as well as Laplacian SVMs. For multi-class problems, we used the one-versus-rest strategy. γ_1, γ_2 were varied on a grid of values: $10^{-6}, 10^{-4}, 10^{-2}, 1, 10, 100$ and chosen with respect to validation error. The chosen parameters are also reported in Table 4. Finally, we evaluated the MR solution and the ambient component of CoMR on an unseen test set. In Tables 2 and 3 we report the mean and standard deviation of error rates on test and unlabeled examples with respect to 10 random splits. We performed a paired t-test at 5% significance level to assess the statistical significance of the results. Results shown in bold are statistically significant.

Our experimental protocol makes MR and CoMR exactly comparable. We find that CoMR gives major empirical improvements over MR on all datasets except G50C where both methods approach the Bayes error rate.

5. Conclusion

In this paper, we have constructed a single, new RKHS in which standard supervised algorithms are immediately turned into multi-view semi-supervised learners. This construction brings about significant theoretical simplifications and algorithmic benefits, which we have demonstrated in the context of generalization analysis and manifold regularization respectively.

Table 4. Parameters Used. Note $\mu = 1$ for CoMR. Linear kernel was used for LINES dataset.

A. Proof of Theorem 2.2

This theorem generalizes Theorem 5 in (Bertinet & Thomas-Agnan, 2004).

The Product Hilbert Space We begin by introducing the product space,

$$\mathcal{F} = \mathcal{H}^1 \times \mathcal{H}^2 = \{(f^1, f^2) : f^1 \in \mathcal{H}^1, f^2 \in \mathcal{H}^2\},$$

and an inner product on $\mathcal{F}$ defined by,

$$\left\langle (f^1, f^2), (g^1, g^2) \right\rangle_{\mathcal{F}} = \gamma_1 \langle f^1, g^1 \rangle_{\mathcal{H}^1} + \gamma_2 \langle f^2, g^2 \rangle_{\mathcal{H}^2} + \mu \sum_{i \in U} \left(f^1(\boldsymbol{x}_i) - f^2(\boldsymbol{x}_i)\right)\left(g^1(\boldsymbol{x}_i) - g^2(\boldsymbol{x}_i)\right) \quad (15)$$

It's straightforward to check that $\langle \cdot, \cdot \rangle_{\mathcal{F}}$ is a valid inner product. Moreover, we have the following:

Lemma A.1. *$\mathcal{F}$ is a Hilbert space.*

Proof. (Sketch.) We need to show that $\mathcal{F}$ is complete. Let (f_n^1, f_n^2) be a Cauchy sequence in $\mathcal{F}$. Then f_n^1 is Cauchy in $\mathcal{H}^1$ and f_n^2 is Cauchy in $\mathcal{H}^2$. By the completeness of $\mathcal{H}^1$ and $\mathcal{H}^2$, we have $f_n^1 \to f^1$ in $\mathcal{H}^1$ and $f_n^2 \to f^2$ in $\mathcal{H}^2$, for some $(f^1, f^2) \in \mathcal{F}$. Since $\mathcal{H}^1$ and $\mathcal{H}^2$ are RKHSs, convergence in norm implies pointwise convergence, and thus the co-regularization part of the distance also goes to zero. □

$\tilde{\mathcal{H}}$ is a Hilbert Space Recall the definition of $\tilde{\mathcal{H}}$ in Eqn. 4. Define the map $u : \mathcal{F} \to \tilde{\mathcal{H}}$ by $u(f^1, f^2) = \frac{1}{2}\left(f^1 + f^2\right)$. The map's kernel $N := u^{-1}(0)$ is a closed subspace of $\mathcal{F}$, and thus its orthogonal complement $N^\perp$ is also a closed subspace. We can consider $N^\perp$ as a Hilbert space with the inner product that is the natural restriction of $\langle \cdot, \cdot \rangle_{\mathcal{F}}$ to $N^\perp$. Define $v : N^\perp \to \tilde{\mathcal{H}}$ as the restriction of u to $N^\perp$. Then v is a bijection, and we define an inner product on $\tilde{\mathcal{H}}$ by

$$\langle f, g \rangle_{\tilde{\mathcal{H}}} = \langle v^{-1}(f), v^{-1}(g) \rangle_{\mathcal{F}}. \quad (16)$$

We conclude that $\tilde{\mathcal{H}}$ is a Hilbert space isomorphic to $N^\perp$.

The Co-Regularization Norm Fix any $f \in \tilde{\mathcal{H}}$, and note that $u^{-1}(f) = \left\{v^{-1}(f) + n \mid n \in N\right\}$. Since $v^{-1}(f)$ and N are orthogonal, it's clear by the Pythagorean theorem that $v^{-1}(f)$ is the element of $u^{-1}(f)$ with minimum norm. Thus

$$||f||_{\tilde{\mathcal{H}}}^2 = ||v^{-1}(f)||_{\mathcal{F}}^2 = \min_{(f^1, f^2) \in u^{-1}(f)} ||(f^1, f^2)||_{\mathcal{F}}^2$$

We see that the inner product on $\tilde{\mathcal{H}}$ induces the norm claimed in the theorem statement.

We next check the two conditions for validity of an RKHS (see Definition 2.1).

(a) $\tilde{k}(\boldsymbol{z}, \cdot) \in \tilde{\mathcal{H}} \quad \forall \boldsymbol{z} \in \mathcal{X}$ Recall from Eqn. 7 that the co-regularization kernel is defined as

$$\tilde{k}(\boldsymbol{x}, \boldsymbol{z}) = \gamma_1^{-1} k^1(\boldsymbol{x}, \boldsymbol{z}) + \gamma_2^{-1} k^2(\boldsymbol{x}, \boldsymbol{z}) - \mu \left(\gamma_1^{-1} \mathbf{k}_{U\boldsymbol{x}}^1 - \gamma_2^{-1} \mathbf{k}_{U\boldsymbol{x}}^2\right)^T \beta_{\boldsymbol{z}}$$

where $\beta_{\boldsymbol{z}} = H\mathbf{d}_z = (I + \mu S)^{-1}\left(\gamma_1^{-1}\mathbf{k}_{U\boldsymbol{z}}^1 - \gamma_2^{-1}\mathbf{k}_{U\boldsymbol{z}}^2\right)$. Define $h^1(\boldsymbol{x}) = \gamma_1^{-1}k^1(\boldsymbol{x}, \boldsymbol{z}) - \mu\gamma_1^{-1}\mathbf{k}_{U\boldsymbol{x}}^1\beta_{\boldsymbol{z}}$ and $h^2(\boldsymbol{x}) = \gamma_2^{-1}k^2(\boldsymbol{x}, \boldsymbol{z}) + \mu\gamma_2^{-1}k^2(\boldsymbol{x}, U)\beta_{\boldsymbol{z}}$. Note that, $h^1 \in \text{span}\left\{k^1(\boldsymbol{z}, \cdot), k^1(\boldsymbol{x}_1, \cdot), \ldots, k^1(\boldsymbol{x}_u, \cdot)\right\} \subset \mathcal{H}^1$, and similarly, $h^2 \in \mathcal{H}^2$. It's clear that $\tilde{k}(\boldsymbol{z}, \cdot) = \left[h^1(\cdot) + h^2(\cdot)\right]$, and thus $\tilde{k}(\boldsymbol{z}, \cdot) \in \tilde{\mathcal{H}}$.

(b) Reproducing Property For convenience, we collect some basic properties of h^1 and h^2 in the following lemma:

Lemma A.2 (Properties of h^1 and h^2)**.** *Writing $h^1(U)$ for the column vector with entries $h^1(\boldsymbol{x}_i)$ $\forall i \in U$, and similarly for other functions on $\mathcal{X}$, we have the following:*

$$\left\langle f^1, h^1 \right\rangle_{\mathcal{H}^1} = \gamma_1^{-1} f^1(\boldsymbol{z}) - \mu\gamma_1^{-1} f^1(U)^T \beta_{\boldsymbol{z}} \quad (17)$$

$$\left\langle f^2, h^2 \right\rangle_{\mathcal{H}^2} = \gamma_2^{-1} f^2(\boldsymbol{z}) + \mu\gamma_2^{-1} f^2(U)^T \beta_{\boldsymbol{z}} \quad (18)$$

$$h^1(U) - h^2(U) = \beta_{\boldsymbol{z}} \quad (19)$$

Proof. The first two equations follow from the definitions of h^1 and h^2 and the reproducing kernel property. The last equation is derived as follows:

$$\begin{aligned} h^1(U) - h^2(U) =& \gamma_1^{-1}k^1(U, \boldsymbol{z}) - \mu\gamma_1^{-1}k^1(U, U)\beta_{\boldsymbol{z}} \\ & - \gamma_2^{-1}k^2(U, \boldsymbol{z}) - \mu\gamma_2^{-1}k^2(U, U)\beta_{\boldsymbol{z}} \\ =& \mathbf{d}_z - \mu S(I + \mu S)^{-1}\mathbf{d}_z \\ =& \left(I - \mu S(I + \mu S)^{-1}\right)\mathbf{d}_z \\ =& (I + \mu S)^{-1}\,\mathbf{d}_z = \beta_{\boldsymbol{z}} \end{aligned}$$

where the last line follows from the Sherman-Morrison-Woodbury inversion formula. □

Since $\tilde{k}(\boldsymbol{z}, \cdot) = h_1(\cdot) + h_2(\cdot)$, it is clear that $(h_1, h_2) = v^{-1}\left(\tilde{k}(\boldsymbol{z}, \cdot)\right) + n$, for some $n \in N$. Since $v^{-1}(f) \in N^\perp$, we have

$$\begin{aligned} \left\langle f, \tilde{k}(\boldsymbol{z}, \cdot) \right\rangle_{\tilde{\mathcal{H}}} =& \left\langle v^{-1}(f), v^{-1}(\tilde{k}(\boldsymbol{z}, \cdot)) \right\rangle_{\mathcal{F}} \\ =& \left\langle v^{-1}(f), (h_1, h_2) - n \right\rangle_{\mathcal{F}} \\ =& \left\langle v^{-1}(f), (h_1, h_2) \right\rangle_{\mathcal{F}} \\ =& \gamma_1 \left\langle f^1, h^1 \right\rangle_{\mathcal{H}_1} + \gamma_2 \left\langle f_2, h_2 \right\rangle_{\mathcal{H}_2} \\ & + \mu \left[h^1(U) - h^2(U)\right]^T \left[f^1(U) - f^2(U)\right] \\ =& f^1(\boldsymbol{z}) + f^2(\boldsymbol{z}) - \mu \left[f^1(U) - f^2(U)\right]^T \beta_{\boldsymbol{z}} \\ & + \mu \left[f^1(U) - f^2(U)\right]^T \beta_{\boldsymbol{z}} \text{ (from A.2)} \\ =& f(\boldsymbol{z}) \end{aligned}$$

Abstract

Semi-supervised learning aims at taking advantage of unlabeled data to improve the efficiency of supervised learning procedures. For discriminative models however, this is a challenging task. In this contribution, we introduce an original methodology for using unlabeled data through the design of a simple semi-supervised objective function. We prove that the corresponding semi-supervised estimator is asymptotically optimal. The practical consequences of this result are discussed for the case of the logistic regression model.

1. Introduction

In most real-world pattern classification problems (e.g., for text, image or audio data), unannotated data is plentiful and can be collected at almost no cost, whereas labeled data are comparatively rarer, and more costly to gather. A sensible question is thus to find ways to exploit the unlabeled data in order to improve the performance of supervised training procedures. Many proposals have been made in the recent years to devise effective semi-supervised training schemes (see (Chapelle et al., 2006) for an up-to-date panorama). In this contribution, we focus on methods applicable to probabilistic classifiers, that is, classifiers designed to provide a probabilistic confidence measure associated with each decision. These classifiers do not necessarily perform better than other alternatives – particularly since probabilistic classification and minimum error classification are related, but different, tasks – but are important in some applications, for instance when it comes to predicting the generalization error, dealing with uneven error costs, ranking, combining decisions from multiple sources, etc.

Probabilistic generative models fare easily with the use of unlabeled data, usually through Expectation-Maximization (see, e.g., (Nigam et al., 2000; Klein & Manning, 2004) for successful implementations of this idea). It is however an extensively documented fact that discriminative models perform better than Generative models for classification tasks (Ng & Jordan, 2002). Integrating unlabeled data into discriminative models is however a much more challenging issue. Put in probabilistic terms, when learning to predict an output y from an observation x, a discriminative model attempts to fit $P(y|x;\theta)$, where θ denotes the parameter. The role to be played by any available prior knowledge about the marginal probability $P(x)$ in this context is not obvious. Several authors indeed claim that knowledge of $P(x)$ is basically useless (Seeger, 2002; Lasserre et al., 2006), although one of the contribution of this paper will be to show that this intuition relies on the implicit assumption that the model is *well-specified*, in the sense of allowing a perfect fit of the conditional probability.

The most common approach is to make the unknown parameter vector θ depend on the unlabeled data, either directly or indirectly. One way to achieve this goal is to use the unlabeled data to enforce constraints on the shape of $P(y|x)$: the *cluster assumption*, for instance, stipulates that the decision boundary should be located in low density regions (Seeger, 2002; Chapelle & Zien, 2005). (Grandvalet & Bengio, 2004) use this intuition to devise a semi-supervised training method (termed *entropy regularization*), which combines the usual log-likelihood term with an entropy-based penalty; see also (Jiao et al., 2006), who extend this methodology to Conditional Random Fields, (Laf-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

ferty et al., 2001), or (Corduneanu & Jaakkola, 2003) for related ideas. This approach, as any attempt to distort the supervised training criterion with supplementary terms faces two risks: (i) to turn a well-behaved convex optimization problem into a non-convex one, fraught with local optima, thus making the results highly dependent of a proper initialization; (ii) to loose the asymptotic consistency property of the usual (conditional maximum likelihood) estimator. As a result, these methods are not guaranteed to improve over a trivial baseline which would only use the available annotated data. They furthermore require a fine tuning of the various optimization parameters (Mann & McCallum, 2007). The cluster assumption is also used in graph-based methods, which exploit the intuition that unlabeled data points should receive the same label as their labeled neighbors: in (Zhu & Ghahramani, 2002), a neighborhood graph is used to iteratively propagate labels from labeled to unlabeled data points until convergence.

(Lasserre et al., 2006) explores yet another avenue, introducing two sets of parameters: one for the conditional $P(y|x;\theta)$, and one for the marginal $P(x;\nu)$: the case where θ and ν are unrelated corresponds to the purely discriminative model, where unlabeled data are of no help; taking $\theta = \nu$ recovers the traditional generative model; introducing (via their Bayesian prior distribution) dependencies between (θ, ν) allows to build a full range of hybrid models. Finally, we also mention (Mann & McCallum, 2007) who try to also exploit prior knowledge on the distribution of the labels Y, which may be available in some specific applications.

In this paper, we try to challenge the view that unlabeled data cannot help purely discriminative models by exhibiting a semi-supervised estimator of the parameter θ which is asymptotically optimal and, in some situations, preferable to the usual maximum (conditional) likelihood estimator. To this aim, we make the simplifying assumption that the marginal $P(x)$ is fully known, which is true in the limit of infinitely many unlabeled data. An interesting observation about the proposed method is that it is most efficient when the Bayes error is very small which correlates well with the intuition underlying most semi-supervised approaches that unlabeled data is most useful if one can assume that the classes are "well-separated". In addition to the asymptotic results, we also discuss a number of empirical findings pertaining to logistic regression.

This paper is organized as follows: in Section 2, we introduce our formal framework and formulate the main result of the paper (Theorem 1), which is first exposed in its full generality, then particularized to the case of the logistic regression. Experiments with the logistic regression model are discussed in Section 3. Concluding remarks and perspectives close the paper.

2. Semi-Supervised Estimator

Let $g(y|x;\theta)$ denote the conditional probability density function (pdf) corresponding to a discriminative probabilistic model parameterized by $\theta \in \Theta$. In the following, we will always assume that the class variable Y takes its values in a finite set, $\mathcal{Y}$, with a special interest for the binary case where $\mathcal{Y} = \{0, 1\}$. We will further assume that the input (or explanatory) variable X also takes its values in a finite set $\mathcal{X}$, which may be arbitrary large.

The training procedure has access to a set of n i.i.d. *labeled* observations, $(X_i, Y_i)_{1 \leq i \leq n}$, as well as to a potentially unlimited number of unlabeled observations, where the quantity of unlabeled data is so large that we can consider that the marginal probability of X is fully known.

Finally, for a function $f : \mathbb{R}^p \mapsto \mathbb{R}$, we denote by $\nabla_z f(z_\star)$ the $p \times 1$ gradient vector and by $\nabla_{z^\mathrm{T}} \nabla_z f(z_\star)$ the $p \times p$ Hessian matrix in $z_\star$. When $f : \mathbb{R}^p \mapsto \mathbb{R}^r$, the notation $\nabla_{z^\mathrm{T}} f(z_\star)$ will be used to denote the $r \times p$ Jacobian matrix in $z_\star$.

2.1. Preliminary: A Simple Case

We first consider the case where the "model" of interest is very basic and simply consists in estimating the complete joint probability of X and Y, which is denoted by $\pi(x, y)$. We will also denote by $\eta(y|x)$ and $q(x)$, respectively, the conditional and the marginal probabilities associated with π. Although this case is not directly of interest for real-life statistical learning tasks, it highlights the role played by the knowledge of the marginal q in semi-supervised learning.

It is well known that the maximum-likelihood estimator of $\pi(x, y)$ defined by

$$\hat{\pi}_n(x, y) = \frac{1}{n} \sum_{i=1}^{n} \mathbf{1}\{X_i = x, Y_i = y\} \qquad (1)$$

is asymptotically efficient with asymptotic variance $\upsilon(x, y) = \pi(x, y)(1 - \pi(x, y))$ (assuming that $0 < \pi(x, y) < 1$).

Assume now that we are given $q(x)$, the marginal distribution of X, and that $0 < q(x) < 1$. It is easily checked that the maximum-likelihood estimator of $\pi(x, y)$ subject to the marginal constraint that

$\sum_{y\in\mathcal{Y}}\pi(x,y)=q(x)$ is given by

$$\hat{\pi}_n^s(x,y)=\frac{\sum_{i=1}^n \mathbf{1}\{X_i=x,Y_i=y\}}{\sum_{i=1}^n \mathbf{1}\{X_i=x\}}q(x) \qquad (2)$$

where the superscript s stands for "semi-supervised" and the ratio is recognized as the maximum-likelihood estimate of the *conditional probability* $\eta(y|x)$. As $\hat{\pi}_n^s(x,y)$ is a ratio of two simple estimators, its asymptotic variance can be computed using the δ-method, yielding

$$\upsilon^s(x,y)=\pi(x,y)(1-\pi(x,y)/q(x))$$

As $0<\pi(x,y)\leq q(x)<1$, $\upsilon^s(x,y)$ is less than $\upsilon(x,y)$. Hence, in general the semi-supervised estimator $\hat{\pi}_n^s(x,y)$ and $\hat{\pi}_n(x,y)$ are not asymptotically equivalent, and $\hat{\pi}_n^s(x,y)$ is preferable. More precisely, $\upsilon^s(x,y)/\upsilon(x,y)=(1-\pi(x,y)/q(x))/(1-\pi(x,y))$ which tends to zero as $\pi(x,y)$ gets closer to $q(x)$. In other words, the performance of $\hat{\pi}_n^s(x,y)$ is all the more appreciable, compared to that of $\hat{\pi}_n(x,y)$, that y is a frequent label for x. In this case, knowledge of the marginal $q(x)$ makes it possible to obtain a precise estimate of $\hat{\pi}_n^s(x,y)\approx q(x)$ even with a very limited number of observations of x.

2.2. General Discriminative Model

We now consider the extension of the previous simple observation to the case of a general discriminative probabilistic model; the main difference being the fact that a given parametric model $\{g(y|x;\theta)\}_{\theta\in\Theta}$ will generally not be able to fit exactly the actual conditional distribution $\eta(y|x)$ of the data. As in the fully-specified case above, it is nonetheless possible to exhibit a semi-supervised estimator which is asymptotically optimal and preferable to the usual conditional maximum likelihood estimator defined by

$$\hat{\theta}_n=\arg\min_{\theta\in\Theta}\frac{1}{n}\sum_{i=1}^n \ell(Y_i|X_i;\theta) \qquad (3)$$

where $\ell(y|x;\theta)=-\log g(y|x;\theta)$ denotes the inverse of the conditional log-likelihood function.

Under the (classical) assumptions of Theorem 1 below, $\frac{1}{n}\sum_{i=1}^n \ell(Y_i|X_i;\theta)$ tends, uniformly in θ, to $\mathrm{E}_\pi[\ell(Y|X;\theta)]$ and thus the limiting value of $\hat{\theta}_n$ is given by

$$\theta_\star=\arg\min_{\theta\in\Theta}\mathrm{E}_\pi[\ell(Y|X;\theta)] \qquad (4)$$

The maximum likelihood estimator in (3) may also be interpreted as $\hat{\theta}_n=\arg\min_{\theta\in\Theta}\mathrm{E}_{\hat{\pi}_n}[\ell(Y|X;\theta)]$ where

$$\hat{\pi}_n(x,y)=\frac{1}{n}\sum_{i=1}^n \mathbf{1}\{X_i=x,Y_i=y\}$$

denotes the empirical measure associated with the sample $(X_i,Y_i)_{1\leq i\leq n}$, which also coincides with the maximum likelihood estimate of $\pi(x,y)$ defined in (1).

If we now assume that the marginal $q(x)$ is available, we know that $\hat{\pi}_n(x,y)$ is dominated (asymptotically) by the estimator $\hat{\pi}_n^s(x,y)$ defined in (2), which we here particularize to

$$\hat{\pi}_n^s(x,y)=\begin{cases}\frac{\sum_{i=1}^n \mathbf{1}\{X_i=x,Y_i=y\}}{\sum_{i=1}^n \mathbf{1}\{X_i=x\}}q(x) & \text{if } \sum_{i=1}^n \mathbf{1}\{X_i=x\}>0\\ 0 & \text{otherwise}\end{cases} \qquad (5)$$

By analogy with the construction used in the absence of information on q, we now define the corresponding semi-supervised estimator as $\hat{\theta}_n^s=\arg\min_{\theta\in\Theta}\mathrm{E}_{\hat{\pi}_n^s}[\ell(Y|X;\theta)]$, where the notation $\mathrm{E}_{\hat{\pi}_n^s}[f(Y,x)]=\sum_{x\in\mathcal{X}}\sum_{y\in\mathcal{Y}}\hat{\pi}_n^s(x,y)f(x,y)$ is used somewhat loosely here as it may happen that, for finite n, $\sum_{x\in\mathcal{X}}\sum_{y\in\mathcal{Y}}\hat{\pi}_n(x,y)<1$, although $\hat{\pi}_n(x,y)$ sums to one with probability one, for sufficiently large n. It is easily checked that $\hat{\theta}_n^s$ may also be rewritten as

$$\hat{\theta}_n^s=\arg\min_{\theta\in\Theta}\sum_{i=1}^n \frac{q(X_i)}{\sum_{j=1}^n \mathbf{1}\{X_j=X_i\}}\ell(Y_i|X_i;\theta) \qquad (6)$$

Eq. (6) is a weighted version of (3) where the weight given to observations that share the same input x is common and reflects our prior knowledge on the marginal $q(x)$.

Theorem 1 *Let the joint probability of X and Y factorize as $\pi(x,y)=\eta(y|x)q(x)$, where q is known, and define the following matrices*

$$H(\theta_\star)=\mathrm{E}_q\left(\mathrm{V}_\eta\left[\nabla_\theta\ell(Y|X;\theta_\star)|X\right]\right) \qquad (7)$$

$$I(\theta_\star)=\mathrm{E}_q\left[\nabla_\theta\ell(Y|X;\theta_\star)\left\{\nabla_\theta\ell(Y|X;\theta_\star)\right\}^{\mathrm{T}}\right] \qquad (8)$$

$$J(\theta_\star)=\mathrm{E}_q\left[\nabla_{\theta^{\mathrm{T}}}\nabla_\theta\ell(Y|X;\theta_\star)\right] \qquad (9)$$

Assume that (1) $\mathcal{X}$ and $\mathcal{Y}$ are finite sets; (2) $\pi(x,y)>0$ for all $(x,y)\in\mathcal{X}\times\mathcal{Y}$; (3) for all $(x,y)\in\mathcal{X}\times\mathcal{Y}$, $\ell(y|x;\theta)$ is bounded on Θ; (4) $\theta_\star$ is the unique minimizer of $\mathrm{E}_\pi[\ell(Y|X;\theta)]$ on Θ; (5) for all $(x,y)\in\mathcal{X}\times\mathcal{Y}$, $\ell(y|x;\theta)$ is twice continuously differentiable on Θ; (6) the matrices $H(\theta_\star)$ and $J(\theta_\star)$ are non singular.

Then, $\hat{\theta}_n$ and $\hat{\theta}_n^s$ are consistent and asymptotically normal estimators of $\theta_\star$, which satisfy

$$\sqrt{n}\left(\hat{\theta}_n-\theta_\star\right)\xrightarrow{L}\mathcal{N}\left(0,J^{-1}(\theta_\star)I(\theta_\star)J^{-1}(\theta_\star)\right) \qquad (10)$$

$$\sqrt{n}\left(\hat{\theta}_n^s-\theta_\star\right)\xrightarrow{L}\mathcal{N}\left(0,J^{-1}(\theta_\star)H(\theta_\star)J^{-1}(\theta_\star)\right) \qquad (11)$$

Furthermore, $\hat{\theta}_n^s$ is asymptotically efficient.

Theorem 1 asserts that the asymptotic covariance matrix associated with $\hat{\theta}_n^s$ is optimal. Understanding the relations between $H(\theta_\star)$ and $I(\theta_\star)$ is thus important to assess the asymptotic performance achievable by *any* semi-supervised training method which assumes prior knowledge of $q(x)$. Indeed, the well-known Rao-Blackwell variance decomposition shows that

$$I(\theta_\star) - H(\theta_\star) = \mathrm{V}_q\left(\mathrm{E}_\eta\left[\nabla_\theta \ell(Y|X;\theta_\star)|X\right]\right)$$

As a result, the difference between both estimators will mostly depend on whether $\mathrm{E}_\eta\left[\nabla_\theta \ell(Y|X;\theta_\star)|X=x\right]$ varies significantly or not around 0 as a function of x, given that, by definition, $\theta_\star$ is such that $\mathrm{E}_q\left(\mathrm{E}_\eta\left[\nabla_\theta \ell(Y|X;\theta_\star)|X\right]\right) = 0$.

Note that in the particular case where the model is *well-specified*, in the sense that $\theta_\star$ is such that $g(y|x;\theta_\star) = \eta(y|x)$ for all $(x,y) \in \mathcal{X}\times\mathcal{Y}$, not only is $\mathrm{E}_q\left(\mathrm{E}_\eta\left[\nabla_\theta \ell(Y|X;\theta_\star)|X\right]\right)$ null but one indeed has the stronger result that *for all* $x \in \mathcal{X}$, $\mathrm{E}_\eta\left[\nabla_\theta \ell(Y|X;\theta_\star)|X=x\right] = 0$. This is the only case for which $H(\theta_\star) = I(\theta_\star)$, and hence, where both estimators are asymptotically equivalent; it is also well known that in this case $J(\theta_\star) = I(\theta_\star)$ so that all asymptotic covariance matrices coincide with the usual expression of the inverse of the Fisher information matrix for θ. Theorem 1 gives formal support to the intuition that it is impossible to improve over the classic maximum likelihood estimator for large n's when the model is well-specified, even when the marginal q is known.

The results of Theorem 1 are stated in terms of parameter estimation which is usually not the primary interest for statistical learning tasks. Due to the non-differentiability of the 0–1 loss, it is not directly possible to derive results pertaining to the error probability from Theorem 1. One may however state the following result in terms of the *logarithmic risk*, in which the negated log-likelihood $\ell(y|x;\theta)$ is interpreted as a loss function.

Corollary 2 *In addition to the assumptions of Theorem 1, assume that $\ell(y|x;\theta)$ has bounded second derivative on Θ. Then, the logarithmic risk admits the following asymptotic equivalent:* $\mathrm{E}_{\pi^{\otimes n}}\{\mathrm{E}_\pi[\ell(Y|X;\hat{\theta}_n)]\} = \mathrm{E}_\pi[\ell(Y|X;\theta_\star)] + \frac{1}{2n}\operatorname{trace}\left\{I(\theta_\star)J^{-1}(\theta_\star)\right\} + o\left(\frac{1}{n}\right)$, *where* $\mathrm{E}_{\pi^{\otimes n}}$ *denotes the expectation with respect to the training data* $(X_i,Y_i)_{1\le i\le n}$*; for the semi-supervised estimator* $\hat{\theta}_n^s$*, the first order term is given by* $\frac{1}{2n}\operatorname{trace}\left\{H(\theta_\star)J^{-1}(\theta_\star)\right\}$.

As a final comment on Theorem 1, note that the form of the semi-supervised estimator in (6) shows that $\hat{\theta}_n^s$ will be consistent also in the presence of covariate shift (i.e., when the marginal distribution of the training sample differs from q), whereas the logistic regression estimates can only be consistent in this case if we assume that the model is well-specified (Shimodaira, 2000). In the presence of covariate shift however, the expressions of the asymptotic covariance matrices will be different.

2.3. Application to Logistic Regression

To gain further insight into the results summarized in Theorem 1, we consider the example of the logistic regression model with binary labels Y and input variables X in $\mathbb{R}^p$; the parameter θ is thus p-dimensional. In this model, the negative log-likelihood function is given by $\ell(y|x;\theta) = -y\theta^{\mathrm{T}}x + \log(1+\mathrm{e}^{\theta^{\mathrm{T}}x})$[1]. Thus, the estimation equation which implicitly defines the value of the optimal fit $\theta_\star$ as the value for which $\mathrm{E}_\pi\left[\nabla_\theta \ell(Y|X;\theta_\star)\right] = 0$ may be rewritten as

$$\mathrm{E}_q\left[X\left(g(1|X;\theta_\star) - \eta(1|X)\right)\right] = 0 \tag{12}$$

Similar direct calculations yield

$$H(\theta_\star) = \mathrm{E}_q\left[\eta(1|X)(1-\eta(1|X))XX^{\mathrm{T}}\right] \tag{13}$$

$$I(\theta_\star) = \mathrm{E}_q\big[\big\{\eta(1|X)(1-\eta(1|X)) + (\eta(1|X) - g(1|X;\theta_\star))^2\big\}XX^{\mathrm{T}}\big] \tag{14}$$

$$J(\theta_\star) = \mathrm{E}_q\left[g(1|X;\theta_\star)\{1-g(1|X;\theta_\star)\}XX^{\mathrm{T}}\right] \tag{15}$$

$J(\theta_\star)$ is the Fisher information matrix traditionally found in logistic regression. Interestingly, $H(\theta_\star)$ is recognized as the Fisher information matrix for $\theta_\star$ corresponding to the fully supervised logistic regression model in the well-specified case (i.e. assuming that $g(y|x;\theta_\star) = \eta(y|x)$), although we made no such assumption here.

For logistic regression, the difference

$$I(\theta_\star) - H(\theta_\star) = \mathrm{E}_q\left[\{\eta(1|X) - g(1|X;\theta_\star)\}^2 XX^{\mathrm{T}}\right]$$

is clearly a term that is all the more significant that the fit achievable by the model is poor. The second important factor that can lead to substantial differences between the asymptotic performances of $\hat{\theta}_n$ and $\hat{\theta}_n^s$ is revealed by the following observation: for a given distribution π, the largest (in a matrix sense) achievable value for $I(\theta_\star)$ is given by

$$I(\theta_\star) = \mathrm{E}_q\left[\max\{\eta(1|X), 1-\eta(1|X)\}XX^{\mathrm{T}}\right]$$

whereas $H(\theta_\star)$ in (13) may be rewritten as

$$H(\theta_\star) = \mathrm{E}_q\big[\max\{\eta(1|X),1-\eta(1|X)\}\min\{\eta(1|X),1-\eta(1|X)\}XX^{\mathrm{T}}\big]$$

[1] Or $\log(1+\mathrm{e}^{-\theta^{\mathrm{T}}yx})$ when the labels are coded as $\{-1,1\}$ rather than $\{0,1\}$.

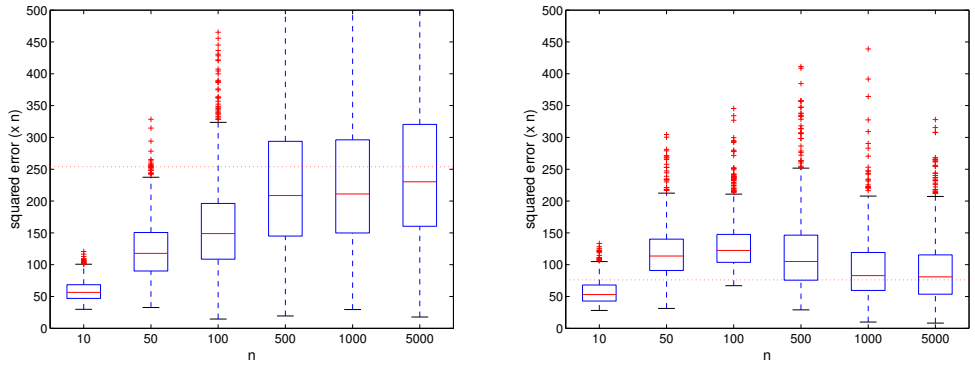

Figure 1. Boxplots of the scaled squared parameter estimation error as a function of the number of observations. Left: for logistic regression, $n\|\hat{\theta}_n - \theta_\star\|^2$; right: for the semi-supervised estimator, $n\|\hat{\theta}^s_n - \theta_\star\|^2$.

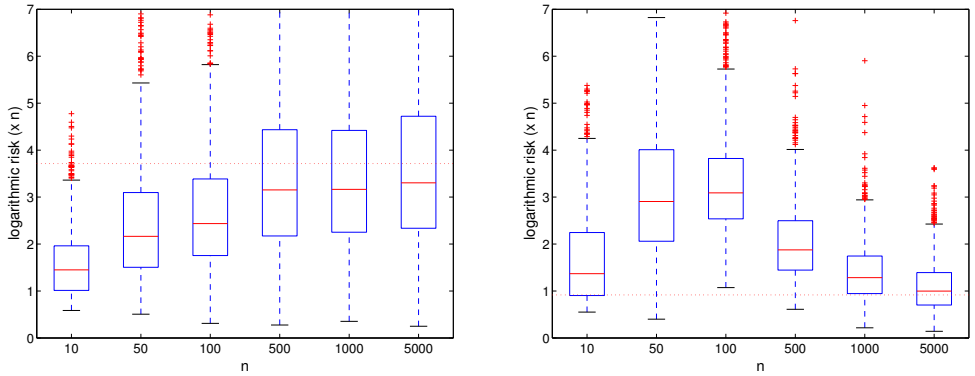

Figure 2. Boxplots of the scaled excess logarithmic risk as a function of the number of observations. Left: for logistic regression, $n(\mathrm{E}_{\pi^{\otimes n}}\{\mathrm{E}_\pi[\ell(Y|X;\hat{\theta}_n)]\} - \mathrm{E}_\pi[\ell(Y|X;\theta_\star)])$; right: for the semi-supervised estimator, $n(\mathrm{E}_{\pi^{\otimes n}}\{\mathrm{E}_\pi[\ell(Y|X;\hat{\theta}^s_n)]\} - \mathrm{E}_\pi[\ell(Y|X;\theta_\star)])$.

Hence the difference between $I(\theta_\star)$ and $H(\theta_\star)$ can only become very significant in cases where $\min\{\eta(1|X = x), 1 - \eta(1|X = x)\}$ is small, that is, when the probability of incorrect decision is small, for some values of x. The overall effect will be all the more significant that this situation happens for many values of x, or, in other words, that the Bayes error associated with π is small.

3. Experiments

3.1. A Small Scale Experiment

We consider here experiments on artificial data which correspond to the case of binary logistic regression discussed in Section 2.3. We focus on a small-scale problem where it is possible to exactly compute error probabilities and risks so as to completely bypass the empirical evaluation of trained classifiers. This setting makes it possible to obtain an accurate assessment of the performance as the only source of Monte Carlo error lies in the choice of the training corpus. More precisely, we consider the case where each observation consists of a vector of $p = 10$ positive counts which sums to $k = 3$. Hence the logistic regression parameter θ is ten-dimensional and the set $\mathcal{X}$ of possible count vectors contains exactly $\frac{(p+k-1)!}{(p-1)!k!} = 220$ different vectors.

In this case, it is well-known that one can simulate data from well-specified logistic models by resorting to mixture of multinomial distributions. Denote by α_1 the prior probability of class 1, and by β_0 and β_1 the vectors of multinomial parameters. Count vectors X generated from the mixture of multinomial have marginal probabilities $q(x) = \alpha_1 \,\mathrm{mult}(x;\beta_1) + (1-\alpha_1)\,\mathrm{mult}(x;\beta_0)$ and conditional probabilities $\mathrm{P}(Y = 1|X = x) = \{1 + \exp -[(\log \beta_1 - \log \beta_0)^{\mathrm{T}} x + \log \frac{\alpha_1}{1-\alpha_1}]\}^{-1}$, where the log is to be understood componentwise. In the following, we take $\alpha_1 = 0.5$, i.e., balanced classes, so as to avoid the bias term.

In order to generate misspecified scenarios, we simply

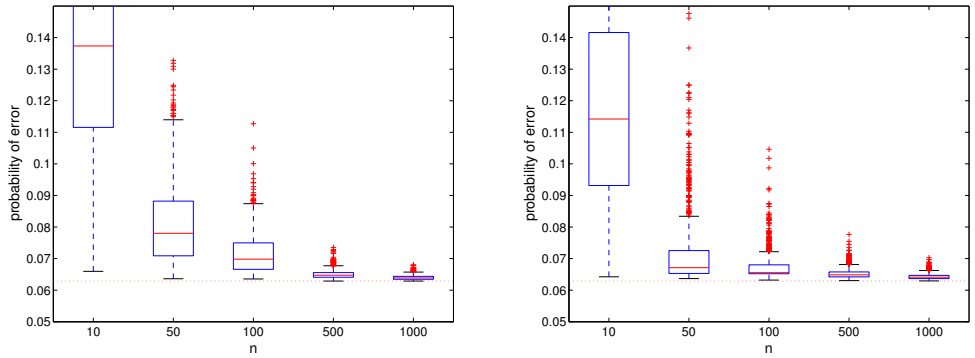

Figure 3. Boxplots of the probability of error as a function of the number of observations for a well-specified model. Left: for the logistic regression; right: for the semi-supervised estimator.

flipped the labels of a few (three in the case shown on figures. 1–2) x's taken among the most likely ones. This label flipping transformation leaves the Bayes error unchanged to that of the underlying unperturbed logistic model but the performance achievable by logistic regression is of course reduced. Figures 1 and 2 correspond to a case where the underlying unperturbed logistic model has a Bayes error of 1.7% and the probability of error associated with the best fitting logistic model is of 9.4%. Remember that in these figures, the only source of randomness is due to the choice of the training sample, which is repeated 1000 times independently for each size of the training sample, from $n = 10$ to $n = 5000$ observations.

As logistic regression is very sensitive to the use of regularization for small sample sizes (here, when n is less than one thousand), both (3) and (6) were regularized by adding a L^2 penalty term of the form $\rho_n \|\theta\|^2$, where ρ_n has been calibrated independently for each value of n. This being said, the optimal regularization parameter was always found to be within a factor 2 of $\rho_n = 1/n$ for (3) and $\rho_n = \frac{1}{n} \sum_{\{x:\sum_{i=1}^{1} \mathbf{1}\{X_i=x\}>0\}} q(x)$ for (6). The effect of regularization is also negligible for the two rightmost boxplots in each graph (i.e., when n is greater than 1000). On figures 1 and 2, the superimposed horizontal dashed lines correspond to the theoretical averages computed from Theorem 1 and Corollary 2, respectively.

When n is larger than one thousand, figures 1 and 2 perfectly correlate with the theory which predicts some advantage for the semi-supervised estimator as we are considering a case where the Bayes error is small and the model misspecification is significant. For large values of n, the semi-supervised estimator not only achieves better average performance but also does so more constantly, with a reduced variability. For smaller values of n, the picture is more contrasted, particularly when n ranges from 50 to 100 where the semi-supervised estimator may perform comparatively worse than the logistic regression. In this example, in terms of the probability of error, the semi-supervised estimator performs marginally better than logistic regression when $n = 10$ and $n = 5000$ (although the difference is bound to be very small in the latter case) and somewhat worse in between.

As expected, the difference between both approaches for large values of n decreases for scenarios with larger error probabilities. In those scenarios, the semi-supervised estimator performs worse than logistic regression for smaller values of n and equivalently for large values of n. A finding of interest is the fact that for well-specified models (i.e., with data generated from a multinomial mixture model) with low Bayes error, the semi-supervised approach does perform better than logistic regression, *for small values of* n. This effect can be significant even when considering the probability of error of the trained classifiers, as exemplified on Figure 3 in a case where the Bayes error is 6.3%. This observation is promising and deserves further investigation as the analysis of Section 2 only explains the behavior observed for large values of n, which in the case of well-specified models results in the two approaches being equivalent.

3.2. Text Classification Experiment

To evaluate our methodology on a more realistic test bed, we have used a simple binary classification task, consisting in classifying mails as spam or ham based on their textual content. The corpus used is the SpamAssassin corpus (Mason, 2002), which contains approximately 6 000 documents. Adapting our technique to real-world data requires to provide an estimate for the marginal $q(x)$. This was carried out by performing a discrete quantification of the data vectors as fol-

lows. We first use unsupervised clustering techniques to partition the available unlabeled collection of documents in k clusters. More specifically, we used a mixture of multinomial model as in (Nigam et al., 2000) with $k = 10$ components. We then simply adapt (6) by replacing $q(X_i)$ by the empirical frequency of the cluster to which X_i belongs, likewise the denominator $\sum_{j=1}^{n} \mathbf{1}\{X_j = X_i\}$ is replaced by the number *of training documents* belonging to the same cluster as X_i. We believe that this methodology is very general and makes the proposed approach applicable to a large variety of data. In effect, observations belonging to clusters which are underrepresented in the training corpus have higher relative weights, while the converse if true for observations belonging to overrepresented clusters. Note that, at this stage, no attempts have been made at tuning the number k of clusters, although intuition suggests that it would probably be reasonable to increase k (slowly) with n.

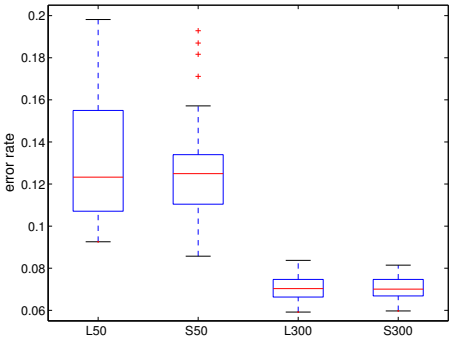

Figure 4. Boxplots of the error rates for, L50: logistic regression with $n = 50$; S50: semi-supervised estimator with $n = 50$; L300 and S300, idem with $n = 300$.

We tested the method with $n = 50$ and $n = 300$ randomly chosen training documents, the remaining mails serving as the test set; each trial gave rise to 50 Monte Carlo replications. For each value of n, the best regularization parameter was determined experimentally both for the usual logistic regression and the semi-supervised estimator. Each document is here represented as a count vector of dimension 1500. The resulting error rates are plotted as boxplots on Figure 4. Although the difference between both methods is certainly not very significant in this preliminary experiment, we note that, as in the simple case of Section 3.1, the semi-supervised estimator provides a more less variable performance when n is small.

4. Conclusion

In this contribution, we have tried to address the problem of semi-supervised learning without using any prior idea on what type of information is to be provided by the unlabeled data. The result of Theorem 1 provides both proper theoretical support for the claim that the unlabeled data does not matter asymptotically *when the model is well-specified* and a better understanding of the cases where the unlabeled data does matter. In particular, it confirms the intuition that unlabeled data is most useful when the Bayes error is small. One advantage of the proposed method is that it does not compromise the simplicity of the maximum likelihood approach because the weighted semi-supervised criterion stays convex. In addition, one could easily incorporate prior knowledge as used in other semi-supervised approaches: for instance the "cluster assumption" can be implemented by modifying (5) so as to incorporate a Bayesian prior that connects conditional probabilities for neighboring values of the input vector. In Section 3.2, we suggested a means by which the method can be extended to larger scales problem, including applications in which the feature vector is either continuous or has a more complex structure. We are in particular currently investigating the extension of the proposed approach to the case of sequence labelling with conditional random fields. Another open issue is the theoretical analysis of the behavior of the proposed criterion when n is small, which cannot be deduced from the asymptotic analysis presented here.

Appendix: Sketch of Proofs

First note that (10) is the well-known result that pertains to the behavior of the maximum likelihood estimator in misspecified models – see, for instance, (White, 1982) or Lemma 1 of (Shimodaira, 2000).

Now, the fact that $\hat{\theta}_n^s = \arg\min_{\theta\in\Theta} \mathrm{E}_{\hat{\pi}_n^s}[\ell(Y|X;\theta)]$ implicitly defines the semi-supervised estimator $\hat{\theta}_n^s$ as a function of the maximum-likelihood estimator of the conditional probabilities

$$\hat{\eta}_n(y|x) = \frac{\sum_{i=1}^{n} \mathbf{1}\{X_i = x, Y_i = y\}}{\sum_{i=1}^{n} \mathbf{1}\{X_i = x\}}$$

In our setting, the conditional probability η may be represented by a finite dimensional vector block defined by $\boldsymbol{\eta} = (\boldsymbol{\eta}(x_1), \ldots, \boldsymbol{\eta}(x_d))^{\mathrm{T}}$, where $\boldsymbol{\eta}(x_i) = (\eta(y_1|x_i), \ldots, \eta(y_k|x_i))^{\mathrm{T}}$, $\{x_1, \ldots, x_d\}$ denote the elements of $\mathcal{X}$, and, $\{y_0, \ldots, y_k\}$ denote the elements of $\mathcal{Y}$. As usual in polytomous regression models, we omit one of the possible values of Y (by convention, y_0) due to the constraint that $\sum_{y\in\mathcal{Y}} \eta(y|x) = 1$, for all $x \in \mathcal{X}$. The estimator $\hat{\boldsymbol{\eta}}_n$ is defined similarly with $\hat{\eta}_n(y|x)$ substituted for $\eta_n(y|x)$. $\hat{\boldsymbol{\eta}}_n$ is the maximum likelihood estimator of $\boldsymbol{\eta}$ and it is asymptotically efficient with

asymptotic covariance matrix given by $K^{-1}(\boldsymbol{\eta})$, the inverse of the Fisher information matrix for $\boldsymbol{\eta}$, block-defined by

$$K^{-1}(\boldsymbol{\eta}) = \operatorname{diag}\left(K^{-1}(x_1;\boldsymbol{\eta}), \ldots, K^{-1}(x_d;\boldsymbol{\eta})\right)$$

where

$$K^{-1}(x_i;\boldsymbol{\eta}) = q(x_i)^{-1}\left\{\operatorname{diag}\left(\boldsymbol{\eta}(x_i)\right) - \boldsymbol{\eta}(x_i)\boldsymbol{\eta}^{\mathrm{T}}(x_i)\right\}$$

To obtain the asymptotic behavior of the semi-supervised estimator $\hat{\theta}_n^s$, remark that $\hat{\theta}_n^s$ is obtained as a function ψ of $\hat{\boldsymbol{\eta}}_n$, where ψ is implicitly defined by the optimality equation $s(\boldsymbol{\eta}, \psi(\boldsymbol{\eta})) = 0$ where s is the (negative of the) score function defined by

$$s(\boldsymbol{\eta}, \theta) = \nabla_\theta \mathrm{E}_\pi\left[\nabla_\theta \ell(Y|X;\theta)\right] = \sum_{x\in\mathcal{X}} q(x) \sum_{y\in\mathcal{Y}} \eta(y|x) \nabla_\theta \ell(y|x;\theta) \quad (16)$$

Because $\theta_\star = \psi(\boldsymbol{\eta})$ and $\hat{\theta}_n^s = \psi(\hat{\boldsymbol{\eta}}_n)$, $\hat{\theta}_n^s$ is an asymptotically efficient estimator of $\theta_\star$ with asymptotic covariance matrix given by $\nabla_{\boldsymbol{\eta}^{\mathrm{T}}}\psi(\boldsymbol{\eta}) K^{-1}(\boldsymbol{\eta}) \left\{\nabla_{\boldsymbol{\eta}^{\mathrm{T}}}\psi(\boldsymbol{\eta})\right\}^{\mathrm{T}}$. The Jacobian matrix $\nabla_{\boldsymbol{\eta}^{\mathrm{T}}}\psi(\boldsymbol{\eta})$ may be evaluated thanks to the implicit function theorem as

$$\nabla_{\boldsymbol{\eta}^{\mathrm{T}}}\psi(\boldsymbol{\eta}) = \left\{\nabla_{\theta^{\mathrm{T}}} s(\boldsymbol{\eta}, \theta_\star)\right\}^{-1} \nabla_{\boldsymbol{\eta}^{\mathrm{T}}} s(\boldsymbol{\eta}, \theta_\star)$$

From the definition of the score function in (16), it is obvious that $\nabla_{\theta^{\mathrm{T}}} s(\boldsymbol{\eta}, \theta_\star) = J(\theta_\star)$. In order to calculate $\nabla_{\boldsymbol{\eta}^{\mathrm{T}}} s(\boldsymbol{\eta}, \theta_\star)$, we differentiate the rightmost expression in (16) using the fact that $\eta(y_0|x) = 1 - \sum_{y\neq y_0} \eta(y|x)$ to obtain

$$\frac{\partial s(\boldsymbol{\eta}, \theta)}{\partial \eta(x|y)} = q(x)\left[\nabla_\theta \ell(y|x;\theta) - \nabla_\theta \ell(y_0|x;\theta)\right]$$

The expression given in Theorem 1 or the asymptotic variance of $\hat{\theta}_n^s$ follows by computing the product $\nabla_{\boldsymbol{\eta}^{\mathrm{T}}} s(\boldsymbol{\eta}, \theta_\star) K^{-1}(x_i;\boldsymbol{\eta}) \left\{\nabla_{\boldsymbol{\eta}^{\mathrm{T}}} s(\boldsymbol{\eta}, \theta_\star)\right\}^{\mathrm{T}}$ – which factories into blocks of size k – and using the fact that $\eta(y_0|x) = 1 - \sum_{y\neq y_0} \eta(y|x)$.

Corollary 2 is based on the classical asymptotic expansion of $\mathrm{E}_\pi[\ell(Y|X;\hat{\theta}_n)] - \mathrm{E}_\pi[\ell(Y|X;\theta_\star)]$ as $\frac{1}{2}(\hat{\theta}_n - \theta_\star)^T J(\theta_\star)(\hat{\theta}_n - \theta_\star) + o_p(\frac{1}{n})$, see, for instance, (Bach, 2006).

Abstract

Moment matching is a popular means of parametric density estimation. We extend this technique to nonparametric estimation of mixture models. Our approach works by embedding distributions into a reproducing kernel Hilbert space, and performing moment matching in that space. This allows us to tailor density estimators to a function class of interest (i.e., for which we would like to compute expectations). We show our density estimation approach is useful in applications such as message compression in graphical models, and image classification and retrieval.

1. Introduction

Density estimation is a key element of statistician's toolbox, yet it remains a challenging problem. A popular class of methods relies on mixture models, such as Parzen windows (Parzen, 1962; Silverman, 1986) or mixtures of Gaussians or other basis functions (McLachlan & Basford, 1988). These models are normally learned using the likelihood. However, density estimation is often not the ultimate goal but rather an intermediate step in solving another problem. For instance, we may ultimately want to compute the expectation of a random variable or functions thereof. In this case it is not clear whether likelihood is the ideal objective, especially when the training sample size is small.

A second class of density estimators employ exponential family models and are based on the duality between maximum entropy and maximum likelihood estimation (Barndorff-Nielsen, 1978; Dudík et al., 2004; Altun & Smola, 2006). These methods match the moments of the estimators to those of the data, which helps focus the models on certain aspects of the data for particular applications. However, these parametric moment based methods can be too limited in terms of the class of distributions. Furthermore, exponential families tend to require highly nontrivial integration of high-dimensional distributions to ensure proper normalization. We desire to overcome these drawbacks and extend this technique to a larger class of models.

In this paper, we generalize moment matching to nonparametric mixture models. Our major aim is to tailor these density estimators for a particular function class, and provide uniform convergence guarantees for approximating the function expectations. The key idea is if we have good knowledge of the function class, we can tightly couple the density estimation with this knowledge. Rather than performing a full density estimation where we leave the function class and subsequent operations arbitrary, we restrict our attention to a smaller set of functions and the expectation operator. By exploiting this kind of domain knowledge, we make the hard density estimation problem easier.

Our approach is motivated by the fact that distributions can be represented as points in the marginal polytope in reproducing kernel Hilbert spaces (RKHS) (Wainwright & Jordan, 2003; Smola et al., 2007). By projecting data and density estimators into RKHS via kernel mean maps, we match them in that space (also referred to as the feature space). Choosing the kernel determines how much information about the density is retained by the kernel mean map, and thus which aspects (*e.g.*, moments) of a density are considered important in the matching process. The matching process, and thus our density estimation procedure, amounts to the solution of a convex quadratic program. We demonstrate the application of our approach in experiments, and show that it can lead to improvements in more complicated applications such as particle filtering and image processing.

2. Background

Let $\mathcal{X}$ be a compact domain and $X = \{x_1, \ldots, x_m\}$ be a sample of size m drawn independently and identically distributed (iid.) from a distribution p over $\mathcal{X}$. We aim to find an approximation $\hat{p}$ of p based on the sample X.

Let $\mathcal{H}$ be a reproducing kernel Hilbert space (RKHS) on

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

$\mathcal{X}$ with kernel $k : \mathcal{X} \times \mathcal{X} \mapsto \mathbb{R}$ and associated feature map $\phi : \mathcal{X} \mapsto \mathcal{H}$ such that $k(x, x') = \langle \phi(x), \phi(x') \rangle_{\mathcal{H}}$. By design $\mathcal{H}$ has the reproducing property, that is, for any $f \in \mathcal{H}$ we have $f(x) = \langle f, k(x, \cdot) \rangle_{\mathcal{H}}$. A kernel k is called *universal* if $\mathcal{H}$ is dense in the space of bounded continuous functions $C^0(\mathcal{X})$ on the compact domain $\mathcal{X}$ in the L_∞ norm (Steinwart, 2002). Examples of such kernels include Gaussian kernel $\exp(-\|x - x'\|^2 / 2\theta^2)$ and Laplace kernel $\exp(-\|x - x'\| / 2\theta^2)$.

The *marginal polytope* is the range of the expectation of the feature map ϕ under all distributions in a set $\mathcal{P}$, *i.e.*, $\mathcal{M} := \{\mu[p] | p \in \mathcal{P}, \mu[p] := \mathbb{E}_{x \sim p}[\phi(x)]\}$ (Wainwright & Jordan, 2003). The map $\mu : \mathcal{P} \mapsto \mathcal{H}$ associates a distribution to an element in the RKHS. For universal kernels, the elements of the marginal polytope uniquely determine distributions:

Theorem 1 (Gretton et al. (2007)) *Let k be universal and $\mathcal{P}$ denote the set of Borel probability measures p on $\mathcal{X}$ with $\mathbb{E}_{x \sim p}[k(x, x)] < \infty$. Then the map μ is injective.*

3. Kernel Moment Matching

Given a finite sample X from p, $\mu[p]$ can be approximated by the empirical mean map $\mu[X] := \frac{1}{m} \sum_{i=1}^m \phi(x_i)$. This suggests that a good estimate $\hat{p}$ of p should be chosen such that $\mu[\hat{p}]$ matches $\mu[X]$: this is the key idea of the paper. The flow of reasoning works as follows:

$$\begin{aligned} \text{density } p \rightarrow \text{ sample } X \rightarrow \text{ empirical mean } \mu[X] \\ \rightarrow \text{ density estimation via } \mu[\hat{p}] \approx \mu[X] \end{aligned} \quad (1)$$

The first line of this reasoning was established in (Altun & Smola, 2006, Theorem 15). Let $R_m(\mathcal{H}, p)$ be the Rademacher average (Bartlett & Mendelson, 2002) associated with p and $\mathcal{H}$ via

$$R_m(\mathcal{H}, p) := \frac{1}{m} \mathbb{E}_X \mathbb{E}_\omega \left[\sup_{\|f\|_{\mathcal{H}} \leq 1} \left| \sum_{i=1}^m \omega_i f(x_i) \right| \right].$$

where $\omega \in \{\pm 1\}$ is uniformly random. We use it to bound the deviation between empirical means and expectations:

Theorem 2 (Altun & Smola (2006)) *Assume $\|f\|_\infty \leq R$ for all $f \in \mathcal{H}$ with $\|f\|_{\mathcal{H}} \leq 1$. Then for $\epsilon > 0$ with probability at least $1 - \exp(-\epsilon^2 m R^{-2}/2)$ we have $\|\mu[p] - \mu[X]\|_{\mathcal{H}} \leq 2R_m(\mathcal{H}, p) + \epsilon$.*

This ensures that $\mu[X]$ is a good proxy for $\mu[p]$. To carry out the last step of (1) we assume the density estimator $\hat{p}$ is a mixture of a set of candidate densities p_i (or prototypes):

$$\hat{p} = \sum_{i=1}^n \alpha_i p_i \text{ where } \alpha^\top \mathbf{1} = 1 \text{ and } \alpha_i \geq 0, \quad (2)$$

where $\mathbf{1}$ is a vector of all ones. Here the goal is to obtain good estimates for the coefficients α_i and to obtain performance guarantees which specify how well $\hat{p}$ is capable of estimating p. This can be cast as an optimization problem:

$$\min_\alpha \|\mu[X] - \mu[\hat{p}]\|_{\mathcal{H}}^2 \text{ s.t. } \alpha^\top \mathbf{1} = 1 \,, \alpha_i \geq 0. \quad (3)$$

To prevent overfitting, we add a regularizer $\Omega[\alpha]$, such as $\frac{1}{2}\|\alpha\|^2$, and weight it by a regularization constant $\lambda > 0$. Using the expansion of $\hat{p}$ in (2) we obtain a quadratic program (QP) for α

$$\min_\alpha \tfrac{1}{2} \alpha^\top (\mathbf{Q} + \lambda \mathbf{I}) \alpha - \mathbf{l}^\top \alpha \text{ s.t. } \alpha^\top \mathbf{1} = 1 \,, \alpha_i \geq 0, \quad (4)$$

where $\mathbf{I}$ is the identity matrix. $\mathbf{Q} \in \mathbb{R}^{n \times n}$ and $\mathbf{l} \in \mathbb{R}^n$ are given by

$$\mathbf{Q}_{ij} = \langle \mu[p_i], \mu[p_j] \rangle_{\mathcal{H}} = \mathbb{E}_{x \sim p_i, x' \sim p_j}[k(x, x')], \quad (5)$$

$$\mathbf{l}_j = \langle \mu[X], \mu[p_j] \rangle_{\mathcal{H}} = \tfrac{1}{m} \sum_{i=1}^m \mathbb{E}_{x \sim p_j}[k(x_i, x)]. \quad (6)$$

By construction $\mathbf{Q} \succeq 0$ is positive semidefinite, hence the program (4) is convex. We will discuss examples of kernels k and prototypes p_i where $\mathbf{Q}$ and $\mathbf{l}$ have closed form in Section 5. In many cases, the prototypes p_i also contain tunable parameters. We can also optimize them via gradient methods. Before doing so, we first explain our theoretical basis for tailoring density estimators.

4. Tailoring Density Estimators

Given functions $f \in \mathcal{H}$, a key question is to bound how well the expectations of f with respect to p can be approximated by $\hat{p}$. We have the following lemma:

Lemma 3 *Let $\epsilon > 0$ and $\epsilon' := \|\mu[X] - \mu[\hat{p}]\|_{\mathcal{H}}$. Under the assumptions of Theorem 2 we have with probability at least $1 - \exp(-\epsilon^2 m R^{-2}/2)$*

$$\sup_{\|f\|_{\mathcal{H}} \leq 1} |\mathbb{E}_{x \sim p}[f(x)] - \mathbb{E}_{x \sim \hat{p}}[f(x)]| \leq 2R_m(\mathcal{H}, p) + \epsilon + \epsilon'.$$

Proof In the RKHS, we have $\mathbb{E}_{x \sim p}[f(x)] = \langle f, \mu[p] \rangle_{\mathcal{H}}$ and $\mathbb{E}_{x \sim \hat{p}}[f(x)] = \langle f, \mu[\hat{p}] \rangle_{\mathcal{H}}$. Hence the LHS of the bound equates to $\sup_{\|f\|_{\mathcal{H}} \leq 1} |\langle \mu[p] - \mu[\hat{p}], f \rangle|$, which is given by $\|\mu[p] - \mu[\hat{p}]\|_{\mathcal{H}}$. Using the triangle inequality, our assumption on $\mu[\hat{p}]$ and Theorem 2 completes the proof. ■

This means that we have good control over the behavior of the expectations, as long as the function class is "smooth" on $\mathcal{X}$ in terms of the Rademacher average. It also means that $\|\mu[X] - \mu[\hat{p}]\|_{\mathcal{H}}$ is a sensible objective to minimize if we are only interested in approximating well the expectations over functions f.

This bound also provides the basis for tailoring density estimators. Essentially, if we have good knowledge of the function class used in an application, we can choose the corresponding RKHS or the mean map. This is equivalent to filtering the data and extracting only certain moments. Then the density estimator $\hat{p}$ can focus on matching p only up to these moments.

5. Examples

We now give concrete examples of density estimation. A number of existing methods are special cases of our setting.

Discrete Prototype or Discrete Kernel The simplest case is to represent p by a convex combination of Dirac

Table 1. Expansions for $\mathbf{Q}_{ij}$ and $\mathbf{l}_j$ when using Gaussian prototypes and various kernels in combination. Let $c := \langle x_i, x_j \rangle + 1$.

Kernel	$\mathbf{Q}_{ij}$	$\mathbf{l}_j$
Linear kernel $\langle x, x' \rangle$	$\langle x_i, x_j \rangle$	$\frac{1}{m}\sum_{i=1}^m \langle x_i, x_j \rangle$
Degree 2 polynomial kernel $(\langle x, x' \rangle + 1)^2$	$c^2 + \operatorname{tr}\Sigma_i\Sigma_j + x_i^\top \Sigma_j x_i + x_j^\top \Sigma_i x_j$	$\frac{1}{m}\sum_{i=1}^m (c^2 + x_i^\top \Sigma_j x_i)$
Degree 3 polynomial kernel $(\langle x, x' \rangle + 1)^3$	$c^3 + 6x_i^\top \Sigma_i\Sigma_j x_j + 3c(\operatorname{tr}\Sigma_i\Sigma_j + x_i^\top \Sigma_j x_i + x_j^\top \Sigma_i x_j)$	$\frac{1}{m}\sum_{i=1}^m (c^3 + 3c x_i^\top \Sigma_j x_i)$
Gaussian RBF kernel $e^{-\frac{1}{2\theta^2}\|x-x'\|^2}$	$\theta^d \left\|\Sigma_i + \Sigma_j + \theta^2\mathbf{I}\right\|^{-\frac{1}{2}} e^{-\frac{1}{2}\|x_i - x_j\|^2_{(\Sigma_i+\Sigma_j+\theta^2\mathbf{I})}}$	$\frac{1}{m}\theta^d \left\|\Sigma_j + \theta^2\mathbf{I}\right\|^{-\frac{1}{2}} \sum_{i=1}^m e^{-\frac{1}{2}\|x_i - x_j\|^2_{(\Sigma_j+\theta^2\mathbf{I})}}$

measures $p_i(x) = \delta_{x_i}$. Particle filters (Doucet et al., 2001) use this choice when approximating distributions. For instance, we could choose x_i to be the set of training points. In this case $\mathbf{Q}$ defined in (5) equals the kernel matrix and $\mathbf{l}$ is the vector of empirical kernel averages:

$$\mathbf{Q}_{ij} = k(x_i, x_j) \text{ and } \mathbf{l}_j = \frac{1}{m}\sum_{i=1}^m k(x_i, x_j). \quad (7)$$

The key difference between an unweighted set as used in particle filtering and our setting is that our expansion is specifically optimized towards good estimates with respect to functions drawn from $\mathcal{H}$.

The problem of data squashing (DuMouchel et al., 1999) can likewise be seen as a special case of kernel mean matching. Here one aims to approximate a potentially large set X by a smaller set $X' = \{(x_1, \alpha_1), \ldots, (x_n, \alpha_n)\}$ of *weighted* observations. We want to discard X and only retain X' for all further processing. If $\|\mu[X] - \mu[X']\|_{\mathcal{H}}$ is small, we expect X' to be a good proxy for X.

Instead of using generic kernels k and discrete measures δ_{x_i} as prototypes for density estimation, we may reverse their roles. That is, we may pick generic densities p_i and a Dirac kernel $k(x, x') = \delta(x = x')$. Note this is only well defined for discrete domains $\mathcal{X}$.[1] In this case the mean operator simply maps a distribution into itself and we obtain $\langle \mu[p], \mu[p'] \rangle_{\mathcal{H}} = \int_{\mathcal{X}} p(x)p'(x)\mathrm{d}x$. Using (5) we have

$$\mathbf{Q}_{ij} = \int_{\mathcal{X}} p_i(x)p_j(x)\mathrm{d}x \text{ and } \mathbf{l}_j = \frac{1}{m}\sum_{i=1}^m p_j(x_i). \quad (8)$$

Gaussian Prototype In general we will neither pick discrete prototypes nor discrete kernels for density estimation. We now give explicit expressions for Gaussian prototypes

$$p_i(x) = (2\pi)^{-\frac{d}{2}} |\Sigma_i|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}\|x - x_i\|^2_{\Sigma_i}\right), \quad (9)$$

where d is the dimension of the data, $\Sigma_i \succ 0$ is a covariance matrix, and $\|x - x'\|^2_{\Sigma_i} := (x - x')^\top \Sigma_i^{-1}(x - x')$ is the squared Mahalanobis distance. When used in conjunction with different kernels, we have the expansions in Table 1.

Other Prototypes and Kernels Other combinations of kernels and prototypes also lead to closed form expansions. For instance, similar expressions also holds for a Laplacian kernel. However, this involves more tedious integrals of the form $\int e^{-\lambda(|x|+|x-a|)}\mathrm{d}x = \lambda^{-1} + e^{-\lambda|a|}$. Another example is to use indicator functions on unit intervals centered at x_i as p_i and a Gaussian RBF kernel. In this case, both $\mathbf{Q}$ and $\mathbf{l}$ can be expressed using the error function (erf).

[1] On continuous domains such a kernel does not correspond to an RKHS since the point evaluation is not continuous.

Furthermore, Jebara et al. (2004) introduced kernels on probability functions which effectively used definition (5). While they were not motivated by the connection between kernels and density estimation, their results for rich classes of densities, such as HMMs, can be used directly to compute our $\mathbf{Q}$ and $\mathbf{l}$.

6. Related Work

Our work is related to the density estimators of Vapnik & Mukherjee (2000) and Shawe-Taylor & Dolia (2007). The main difference lies in the function space chosen to measure the approximation properties. The former uses the Banach space of functions of bounded variation, while the latter uses the space $L_1(q)$, where q denotes a distribution over test functions. For spherically invariant distributions over test functions our approach and the latter approach are identical, with a key difference (to our advantage) that our optimization is a simple QP which does not require constraint sampling to make the optimization feasible.

Support Vector Density Estimation The model of Vapnik & Mukherjee (2000) can be summarized as follows: let $F[\hat{p}]$ be the cumulative distribution function of $\hat{p}$ and let $F[X]$ be its empirical counterpart. Assume $\hat{p}$ is given by (2), and that we have a regularizer $\Omega[\alpha]$ as previously discussed. In this case the Support Vector Density Estimation problem can be written as

$$\min_{\alpha \text{ feasible}} \frac{1}{m}\sum_{i=1}^m |F[\hat{p}](x_i) - F[X](x_i)| + \lambda\Omega[\alpha]. \quad (10)$$

That is, we minimize the ℓ_1 distance between the empirical and estimated cumulative distribution functions when evaluated on the set of observations X.

To integrate this into our framework we need to extend our setting from Hilbert spaces to Banach spaces. Denote by $\mathcal{B}$ a Banach space, let $\mathcal{X}$ be a domain furnished with probability measures p, p', and let $\phi : \mathcal{X} \mapsto \mathcal{B}$ be a feature map into $\mathcal{B}$. Analogously, we define the mean map $\mu : \mathcal{P} \mapsto \mathcal{B}$ as $\mu[p] := \mathbb{E}_{x\sim p(x)}[\phi(x)]$. Moreover, we define a distance between distributions p and p' via $D(p, p') := \|\mu[p] - \mu[p']\|_{\mathcal{B}}$. If we choose $\phi(x) = \left(\chi_{(-\infty,x]}(x_1), \ldots, \chi_{(-\infty,x]}(x_m)\right)^\top$ where χ is the indicator function, and use the ℓ_1^m norm on ϕ we recover SV density estimation as a special case.

Expected Deviation Estimation Shawe-Taylor & Dolia (2007) defined a distance between distributions as follows: let $\mathcal{H}$ be a set of functions on $\mathcal{X}$ and q be a probability distribution over $\mathcal{F}$. Then the distance between two distributions p and p' is given by

$$D(p, p') := \mathbb{E}_{f\sim q(f)} \left| \mathbb{E}_{x\sim p}[f(x)] - \mathbb{E}_{x\sim p'}[f(x)] \right|. \quad (11)$$

That is, we compute the average distance between p and p' with respect to a distribution of test functions.

Lemma 4 *Let $\mathcal{H}$ be a reproducing kernel Hilbert space, $f \in \mathcal{H}$, and assume $q(f) = q(\|f\|_{\mathcal{H}})$ with finite $\mathbb{E}_{f\sim q}[\|f\|_{\mathcal{H}}]$. Then $D(p, p') = C \|\mu[p] - \mu[p']\|_{\mathcal{H}}$ for some constant C which depends only on $\mathcal{H}$ and q.*

Proof Note that by definition $\mathbb{E}_{x\sim p}[f(x)] = \langle \mu[p], f\rangle_{\mathcal{H}}$. Using linearity of the inner product, Equation (11) equals

$$\int |\langle \mu[p] - \mu[p'], f\rangle_{\mathcal{H}}| \, \mathrm{d}q(f)$$

$$= \|\mu[p] - \mu[p']\|_{\mathcal{H}} \int \left| \left\langle \frac{\mu[p] - \mu[p']}{\|\mu[p] - \mu[p']\|_{\mathcal{H}}}, f \right\rangle_{\mathcal{H}} \right| \mathrm{d}q(f),$$

where the integral is independent of p, p'. To see this, note that for any p, p', $\frac{\mu[p]-\mu[p']}{\|\mu[p]-\mu[p']\|_{\mathcal{H}}}$ is a unit vector which can be turned into, say, the first canonical basis vector by a rotation which leaves the integral invariant, bearing in mind that q is rotation invariant. ■

The above result covers a large number of interesting function classes. To go beyond Hilbert spaces, let $\phi : \mathcal{X} \mapsto \mathcal{B}$ be the transformation from x into $f(x)$ for all $f \in \mathcal{H}$ and $\|z\|_{\mathcal{B}} := \mathbb{E}_{f\sim q(f)}[|z_f|]$ be the $L_1(q)$ norm. Then (11) can also be written as $\|\mu[p] - \mu[p']\|_{\mathcal{B}}$, where μ is the mean map into Banach spaces. Its main drawback is the nontrivial computation for constraint sampling (de Farias & Roy, 2004) and the additional uniform convergence reasoning required. In Hilbert spaces no such operations are needed.

7. Experiments

We focus on two aspects: first, our method performs well as a density estimator *per se*; and second, it can be tailored towards the expectation over a particular function class.

7.1. Methods for Comparison

Gaussian Mixture Model (GMM)[2] The density was represented as a convex sum of Gaussians. GMM was initialized with k-means clustering. The centers, covariances and mixing proportions of the Gaussians were optimized using the EM algorithm. We used diagonal covariances in all our experiments. We always employed 50 random restarts for k-means, and returned the results from the best restart.

Parzen Windows (PZ) The density was represented as an average of a set of normalized RBF functions, with each centered on a data point. The bandwidths of the RBF functions were identical and tuned via the likelihood using leave-one-out cross validation.

Reduced Set Density Estimation (RSDE)[3] Girolami & He (2003) compressed a Parzen window estimator using RBF functions of larger bandwidths. The reduced representation was produced by minimizing an integrated squared distance between the two densities.

[2]GMM codes from: http://www.datalab.uci.edu/resources/gmm/

[3]PZ and RSDE from: http://ttic.uchicago.edu/∼ihler/code/

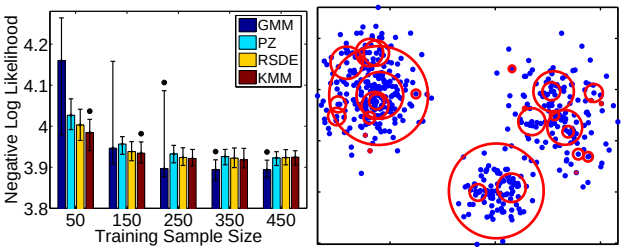

Figure 1. **Left**: Negative log-likelihood using a mixture of 3 Gaussians. The height of the bars represents the median of the scores from 100 repeats, and the whiskers correspond to the quartiles. We mark the best method with a black dot above the whiskers. **Right**: Sparsity of KMM solution. Blue dots are data points. Red circles represent prototypes selected by KMM. The size of a circle is proportional to the magnitude of its weight α_i.

Kernel Moment Matching (KMM) In applying our method, we used Gaussians with diagonal covariances as our prototypes p_i. The regularization parameter λ in our algorithm was fixed at 10^{-10} throughout. Since KMM may be tailored for different RKHS, we instantiated it with the four different kernels in Table 1. We denote them as LIN, POL2, POL3 and RBF, respectively. Our choice of kernel corresponded to the function class where we evaluated the expectations. The initialization of the prototypes will be further discussed below.

7.2. Evaluation Criterion

We compared various density estimators in terms of two criteria: negative log-likelihood and discrepancy between function expectations on test data. Since different algorithms are optimized using different criteria, we expect that each will win with respect to the criterion it employs. The benefit of our density estimator is that we can explicitly tailor for different classes of functions. For this reason, we will focus on the second criterion.

Given a function f, the discrepancy between function expectations is computed as follows: (*i*) Evaluate function expectation using test points, *i.e.*, $\frac{1}{m}\sum_{i=1}^{m} f(x_i)$; (*ii*) Evaluate function expectation using estimated density $\hat{p}$, *i.e.*, $\mathbb{E}_{x\sim\hat{p}}[f(x)]$. (*iii*) Calculate $\left|\frac{1}{m}\sum_{i=1}^{m} f(x_i) - \mathbb{E}_{x\sim\hat{p}}[f(x)]\right|$ and normalize it by $\left|\frac{1}{m}\sum_{i=1}^{m} f(x_i)\right|$.

We will compare various methods either by repeated random instantiation or random split of the data (which we will make clear in context). For both cases, we will perform paired sign tests at the significance level of 0.01 on the results obtained from the randomizations. We will always present the median of the results in subsequent tables, and highlight in boldface those statistically equivalent methods that are significantly better than the rest.

7.3. Synthetic Dataset

In this experiment, we use synthetic datasets to compare various methods as the sample size changes. We also show

Table 2. Sparsity of the solution of RSDE and KMM. We show the median of the number of retained prototypes from 100 random initializations. Also shown are median percentages of retained prototypes after optimization.

Sample Size	50	150	250	350	450
RSDE	12 (25.0%)	35 (23.3%)	62 (24.8%)	90 (25.9%)	124 (27.5%)
KMM	**10 (20.0%)**	**21 (14.0%)**	**30 (12.0%)**	**36 (10.3%)**	**42 (9.3%)**

that KMM leads to sparse solutions.

Data Generation We generated 2 dimensional mixtures of 3 Gaussians with centers $(0,0)^\top$, $(3,3)^\top$ and $(-6,4)^\top$, and covariances $0.8^2\mathbf{I}$, $1.2^2\mathbf{I}$ and $\mathbf{I}$ respectively. The mixing proportions were 0.2, 0.3 and 0.5 respectively. We varied the training sample size while always testing on samples of size 1000. For each fixed training size, we randomly instantiated the experiments 100 times.

Experimental Protocol All training data points were used as prototypes for RSDE and KMM. Their initial covariances were set to be identical, and were initialized in both cases using the approach of RSDE. We used the RBF instance of KMM and set the bandwidth θ of the kernel to be the same as that for the prototypes. GMM used 3 centers.

Negative Log Likelihood The results are plotted in Figure 1. GMM performs best in general, while KMM is superior for small sample sizes. This is not surprising since we used a correct generative model of the data for GMM. When the sample size is small (less than 30 data points for each cluster), GMM is susceptible to local maxima and does not result in good estimates.

Sparsity of the Solution KMM also leads to sparse solutions (*e.g.*, Figure 1). When using all data points as candidate prototypes, KMM automatically prunes away most of them and results in a much reduced representation of the data. In terms of both likelihood and sparsity, KMM is superior to other reduction method such as RSDE (Table 2).

7.4. UCI Dataset

We used 15 UCI datasets to compare various methods based on the discrepancies between function expectations.

Data Description We only included real-valued dimensions of the data, and normalized each dimension of the data separately to zero mean and unit variance. For each dataset, we randomly shuffled the data points for 50 times. In each shuffle, we used the first half of the data for training and the remaining data for testing. In each shuffle, we randomly generated 100 functions f to evaluate the discrepancy criterion, *i.e.*, $f = \sum_{i=1}^{m_0} w_i k(x_i, \cdot)$ where $m_0 \in \mathbb{N}$ was uniformly random in $[1, m]$, $w_i \in \mathbb{R}$ was uniformly random in $[-1, 1]$, and the x_i were uniformly sampled from the test points. Thus, each method resulted in 5000 numbers for each dataset.

Experimental Protocol Both GMM and KMM used 10 prototypes and diagonal covariances, and both were initialized using k-means clustering. We used all four instances of KMM, namely LIN, POL2, POL3 and RBF, for the experiments, depending on the function class where we evaluated the expectations. When we used the RBF instance of KMM, we set the bandwidth θ of the kernel to the median of the distances between data points. Besides optimizing the mixing proportions of the prototypes of KMM, we also used conjugate gradient descent to optimize the center positions and covariances of the prototypes.

[a] Some numbers are negative, which is possible since unlike probability mass function, density can take values greater than 1.

Negative Log Likelihood Kernel moment matching can be a very different objective from the likelihood (Table 3). Except for the LIN instance, KMM results in much larger negative log-likelihood. This suggests that if the purpose of density estimation is to approximate the function expectations, likelihood is no longer a good criterion. We confirm this observation in our next experiment.

Discrepancy between Function Expectations We used four classes of functions corresponding to the RKHS of the LIN, POL2, POL3 and RBF instances of KMM. For nonlinear functions KMM clearly outperforms other density estimators, while for linear functions KMM has equivalent performance to PZ and GMM (Table 4). These results are not surprising, since KMM is explicitly optimized for approximating the function expectations well. Note that PZ is the second best for polynomial functions. This is reasonable since PZ retains all training points in the density, and should perform better than compressed representations such as GMM and RSDE. We also applied this new experimental protocol to the synthetic mixture of 3 Gaussians from the last section. We instantiate the synthetic data with 3 different sample sizes: 100, 500 and 1000. The results are shown in the last three rows of Table 3 and 4, which are consistent with those for UCI data. A closer view of the difference between GMM and KMM using "covertype" dataset is shown in Figure 2. We chose to compare GMM and KMM because they are initialized similarly.

As an aside, we remark that PZ and GMM also match the

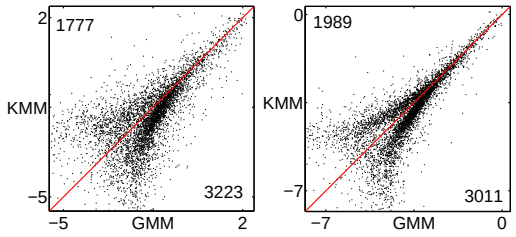

Figure 2. Scatter plot of the discrepancies between function expectations (in log scale) for the 'covertype' dataset, with GMM discrepancies on the horizontal axis and KMM discrepancies on the vertical axis. **Left**: plot for polynomial functions ($d = 2$); **Right**: plot for RBF functions. The distribution of the points is skewed below the red diagonal line, which means KMM is better. The numbers near the corners count respectively the number of points falling above and below the red diagonal.

empirical mean $\frac{1}{m}\sum_{j=1}^{m} x_j$. This is obvious for PZ. For GMM, in each EM iteration, the centers μ_i and weights α_i of each p_i are updated via $\mu_i \leftarrow \sum_{j=1}^{m} \tau_j^i x_j / \sum_{j=1}^{m} \tau_j^i$ and $\alpha_i \leftarrow \frac{1}{m}\sum_{j=1}^{m} \tau_j^i$. Here τ_j^i is the probability of x_j being generated by p_i. It follows that $\mathbb{E}_p[x] = \sum_i \alpha_i \mu_i$ also matches $\frac{1}{m}\sum_{j=1}^{m} x_j$.

8. Applications

In this section, we employ KMM for two different applications: message compression in graphical models, and image processing. The common feature of these two applications is that they involve density estimation for computing the expectation of a function, which is the relevant setting for KMM.

8.1. Message Compression

We use density estimation to compress messages in graphical models. This is of particular interest for applications such as distributed inference in sensor networks. It is our desire to compress the messages to cater for limited power supply and communication bandwidth. We will use a particle filtering example to compare GMM and KMM only, since they performed best in our earlier experiments.

We model a one dimensional time series y_t ($t = 1 \ldots 100$) as being conditionally independent given an unobserved state s_t, which is itself Markovian. This system evolves as follows:

$$s_t = f(s_{t-1}) = 1 + \sin(0.04\pi t) + 0.5 s_{t-1} + \xi \quad (12)$$

$$y_t = g(s_t) = \begin{cases} 0.2 s_t^2 + \zeta, & \text{if } t < 50, \\ 0.5 s_t - 2 + \zeta, & \text{otherwise.} \end{cases} \quad (13)$$

The random variables ξ and ζ represent process and measurement noise, respectively, and are modeled as mixtures of Gaussians,

$$\xi \sim \tfrac{1}{5}\sum_{i=1}^{5} \mathcal{N}(\mu_i, \sigma), \quad \zeta \sim \mathcal{N}(0, \sigma). \quad (14)$$

Throughout this experiment, we fix σ to 0.2 and choose μ_i to be $\{-1.5, -0.5, 0.5, 1.5, 2\}$. We initialize s_0 with ξ.

Note that our setting is a modification of de Freitas's demo[4] where we only change the process noise from a unimodal gamma distribution to a more complicated mixture model.

The task of particle filtering (Doucet et al., 2001) is to infer the hidden state given past and current observations. This can be carried out by estimating the filtering density $p(s_t|Y_t) := p(s_t|y_1, \ldots, y_t)$ recursively in a two-stage procedure. First, the current filtering density $p(s_t|Y_t)$ is propagated into the future via the transition density $p(s_{t+1}|s_t)$ to produce the prediction density $p(s_{t+1}|Y_t)$, *i.e.*,

$$\mathbb{E}_{s_t \sim p(s_t|Y_t)}[p(s_{t+1}|s_t)] := \int p(s_{t+1}|s_t) p(s_t|Y_t) \mathrm{d}s_t. \quad (15)$$

Second, $p(s_t|Y_t)$ is updated via Bayes' law,

$$p(s_{t+1}|Y_{t+1}) \propto p(y_{t+1}|s_{t+1}) p(s_{t+1}|Y_t). \quad (16)$$

The integral in (15) is usually intractable since the filtering density $p(s_t|Y_t)$ can take a complicated form. Therefore, $p(s_t|Y_t)$ is often approximated with a set of samples called particles. For distributed inference, it is these samples that need to be passed around. We want to compress the samples using density estimation such that we still do well in computing $\mathbb{E}_{s_t \sim p(s_t|Y_t)}[p(s_{t+1}|s_t)]$. In our example, $p(s_{t+1}|s_t)$ takes the form

$$p(s_{t+1}|s_t) \propto \sum_{i=1}^{5} \exp\left(-\tfrac{(s_{t+1} - f(s_t) - \mu_i)^2}{2\sigma^2}\right). \quad (17)$$

In terms of variable s_t, $p(s_{t+1}|s_t)$ is in the RKHS with kernel $k(x, x') = \exp\left(-\frac{(x-x')^2}{2(2\sigma)^2}\right)$. We can customize KMM using this kernel, and compress messages by targeting a good approximation of $\mathbb{E}_{s_t \sim p(s_t|Y_t)}[p(s_{t+1}|s_t)]$.

We use 5 centers for both GMM and KMM to compress the messages. We compare the filtering results with the true states. The error is measured as the root mean square of the deviations. The results for compressing different numbers of particles are reported in Table 5. We find that filtering results after compression even outperform those obtained from the full set of particles (PF). In particular, the results for KMM are slightly better than those for GMM. By compression, we have extracted the information most essential to statistical inference, and actually made the inference more robust. If the compression is targeted to $\mathbb{E}_{s_t \sim p(s_t|Y_t)}[p(s_{t+1}|s_t)]$ (as we do in KMM), we can simply get better results.

The shortcomings of general purpose density estimation also arise in the more general settings of message passing and belief propagation. This is due to the way messages are constructed: given a clique, the incoming messages are multiplied by the clique potential and all variables not in the receiver are integrated out. In most cases, this makes the outgoing messages very complicated, causing significant computational problems. Popular methods include

particle filtering, which uses a discrete approximation of the messages, and expectation propagation, which uses a single Gaussian approximation of the messages (Minka, 2001). We plan to further investigate KMM in these general settings. Our key benefit is that we can customize the approximation properties for a particular graphical model.

8.2. Image Retrieval and Categorization

Following the work of (Rubner et al., 2000; Greenspan et al., 2002), we use density estimation as an intermediate step for image retrieval and categorization.

8.2.1. Image Retrieval

Image retrieval is the task of finding from a given database the set of images similar to a given query image. An image is normally characterized by the distribution over features (*e.g.*, color, texture) of pixels, patches, etc. It is thus helpful to compress the distribution by density estimation into more compact forms (*e.g.*, mixtures of Gaussians), on which the query is based. In particular, the advantage is that density estimation can be computed offline before the query takes place, thus offering computational and storage savings.

Method Greenspan et al. (2002) used GMM for density estimation; we propose KMM as an alternative. After density estimation, the dissimilarity between two distributions needs to be measured and the Earth Mover's Distance (EMD) is a state-of-the-art measure. Given two distributions represented by sets of weighted prototypes, EMD regards one collection as mass of earth spread in the feature space, while the other is a collection of holes. The EMD is defined as the least amount of work needed to fill the holes with earth. A unit of work corresponds to the ground distance between two prototypes. If we represent the distributions by mixtures of Gaussians, then a sensible ground distance $D(p_i, p'_j)$ between two Gaussians $p_i = \mathcal{N}(\mu_i, \Sigma_i)$ and $p'_j = \mathcal{N}(\mu'_j, \Sigma'_j)$ is the Fréchet distance used in (Greenspan et al., 2002),

$$D^2(p_i, p'_j) := |\mu_i - \mu'_j|^2 + \mathrm{tr}\left(\Sigma_i + \Sigma'_j - 2(\Sigma_i\Sigma'_j)^{1/2}\right).$$

Based on $D(p_i, p'_j)$, if $p = \sum_i \alpha_i p_i$ where p_i is a Gaussian and α_i is its weight, and similarly $p' = \sum_j \alpha'_j p'_j$, then the EMD between p and p' is

$$\mathrm{EMD}(p, p') := \min_{\gamma_{ij} \text{ feasible}} \sum_i \sum_j \gamma_{ij} D(p_i, p'_j),$$

where $\gamma_{ij} \geq 0$ is the flow between p_i and q_j. Feasibility means $\sum_i \gamma_{ij} \leq \alpha'_j$ and $\sum_j \gamma_{ij} \leq \alpha_i$ for all i and j.

Settings In this experiment, the distance measure is fixed to EMD. We plug the densities estimated by GMM and KMM into EMD[5], and compare the retrieval results. Parameters for KMM and GMM were chosen in the same way as in Section 7.4. Here KMM used POL3. For each image, we sampled 10^3 pixels and each pixel's feature vector was the CIE-Lab value of a 5×5 window centered on it.

Results We collected $L = 10537$ images from various sources including FIRE and CIRES[6]. The dataset included 10 labeled categories like horse, beach, and each category has 100 images. For each image $I_c(i)$ from class c ($c \in \{1, ..., 10\}$, $i \in \{1, ..., 100\}$), we retrieved r ($r \in \{1, ..., L\}$) closest images (in terms of EMD) from the whole database and counted how many among them are also from class c, denoted as $g_c(i, r)$ for GMM and $k_c(i, r)$ for KMM. For each c and r, we performed a paired sign test between $\{g_c(i, r)\}_{i=1}^{100}$ and $\{k_c(i, r)\}_{i=1}^{100}$. Since p-value is always in (0,1], we report in Figure 3 the log p-value if the median of $\{k_c(i, r) - g_c(i, r)\}_{i=1}^{100}$ is higher than 0. Otherwise, we plot the *negative* log p-value. Negative values are in favor of KMM. In Figure 3, performance of KMM is superior to or competitive with GMM in 8 categories and for most values of r (number of retrieved images).

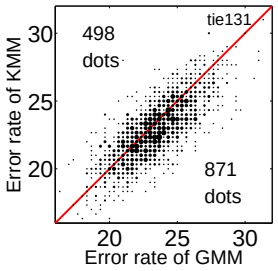

Figure 4. Error rate of image categorization using KMM and GMM.

It is important to note that the Fréchet distance is *not* in the class of functions used in KMM, and KMM still performs reasonably well. In the next section, we learn an image classifier using the *same* kernel as used in KMM.

8.2.2. Image Categorization

A closely related but different task is learning to categorize images using multi-class classification, particularly by SVM. Here all we need is a kernel between pairs of image densities p and q, which is readily given by $\langle \mu[p], \mu[q] \rangle_{\mathcal{H}}$. The SVM classifier takes the form $f(p_j) = \sum_i \gamma_i \langle \mu[p_i], \mu[p_j] \rangle = \mathbb{E}_{x \sim p_j}[\sum_i \gamma_i \mu[p_i](x)]$ for some $\gamma_i \in \mathbb{R}$. Since $\sum_i \gamma_i \mu[p_i] \in \mathcal{H}$, KMM ensures that p_j is estimated such that this expectation is well approximated.

Our 10-class classification used 1000 images from the 10 categories. We randomly divided each category into 70 images for training and 30 images for testing. We used LibSVM to train a multi-class SVM with one-against-one criterion on the combined 700 training images. The loss and regularization tradeoff parameter was determined by an inner loop 10-fold cross validation on the training data. Finally we test the accuracy of the learned model on the 300 test images. The whole process is repeated for 1500 times. We use POL3 for both KMM and SVM, because for both GMM and KMM, POL3 significantly outperforms POL2 and RBF in practice[7]. By using paired sign test, KMM yields lower error rate than GMM at significance level 0.01. Figure 4 shows the scatter plot of the resulting error rates.

Abstract

Discovering additive structure is an important step towards understanding a complex multi-dimensional function because it allows the function to be expressed as the sum of lower-dimensional components. When variables interact, however, their effects are not additive and must be modeled and interpreted simultaneously. We present a new approach for the problem of interaction detection. Our method is based on comparing the performance of unrestricted and restricted prediction models, where restricted models are prevented from modeling an interaction in question. We show that an additive model-based regression ensemble, Additive Groves, can be restricted appropriately for use with this framework, and thus has the right properties for accurately detecting variable interactions.

1. Introduction

Many scientific inquiries seek to identify what variables are important and to describe their effects. Discovery of additive structure is an important step towards understanding a complex multi-dimensional function, because it allows for expressing this function as the sum of lower-dimensional components. When variables interact, their effects cannot be decomposed into independent lower-dimensional contributions and hence must be modeled simultaneously. In this paper we develop a methodology to automatically identify additive and interactive structure among large sets of variables.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

The term *statistical interaction* is used to describe the presence of non-additive effects among two or more variables in a function. Two variables are said to interact when the effect of one variable on the response depends on values of the other variable. Precisely, variables x_i and x_j interact in $F(\mathbf{x})$ when partial derivative $\frac{\partial F(\mathbf{x})}{\partial x_i}$ depends on x_j or, more generally, when the *"difference in the value of $F(\boldsymbol{x})$ for different values of x_i depends on the value of x_j"* (Friedman & Popescu, 2005). This is equivalent to the following definition:

Function $F(\mathbf{x})$, where $\mathbf{x} = (x_1, x_2, \ldots, x_n)$, shows no interaction between variables x_i and x_j if it can be expressed as the sum of two functions, $f_{\setminus j}$ and $f_{\setminus i}$, where $f_{\setminus j}$ does not depend on x_j and $f_{\setminus i}$ does not depend on x_i:

$$\begin{aligned} F(\mathbf{x}) &= f_{\setminus j}(x_1, \ldots, x_{j-1}, x_{j+1}, \ldots, x_n) \\ &\quad + f_{\setminus i}(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n) \end{aligned} \quad (1)$$

For example, $F(x_1, x_2, x_3) = \sin(x_1 + x_2) + x_1 x_3$ has interactions between x_1 and x_2 and also between x_1 and x_3, but no interaction between x_2 and x_3.[1]

Higher-order interactions between a larger number of variables are defined similarly. There is no K-way interaction between K variables in the function, if it can be represented as a sum of K (or fewer) functions, each of which does not depend on at least one variable in question. If such representation is not possible, we say that there is a K-way interaction. Function $x_1^{x_2+x_3}$ shows a 3-way interaction between x_1, x_2 and x_3, while $x_1x_2 + x_2x_3 + x_1x_3$ has all pairwise interactions, but not a 3-way interaction.

[1] It is important to stress that the concept of statistical interaction is completely unrelated to the dependence and independence of variable distributions. Some authors use "interaction" to refer to different types of dependencies between variables, e.g., correlation (Jakulin & Bratko, 2004). In this paper we discuss statistical (non-additive) interactions only, not correlation or statistical dependence.

Interaction detection has high practical importance because it provides valuable knowledge about a domain. For example, our experiments with bird abundance data (Section 7) demonstrate that detection of spatio-temporal interactions can signal changes in the environment. In this particular case, a fatal eye disease was spreading slowly from the Northeastern US to other regions. This disease affected the annual bird abundance differently depending on location, creating a strong interaction between time and location.

Interactions are also an important part of statistical analysis. Early methods for interaction detection were parametric and required explicit modeling of interactions, most often as multiplicative terms. As a consequence, only limited types of interactions could be detected. More general approaches were introduced recently (Friedman & Popescu, 2005; Hooker, 2007). These methods are based on building a model and detecting interactions in the function learned by the model. A major shortcoming of this approach is that the model may detect spurious interactions over regions of the input space where data is scarce, and known solutions to this problem are either inadequate or computationally expensive. (See (Hooker, 2007) and Section 8 of this paper for more details.)

We introduce a new approach to interaction detection. It is based on comparing the performance of *restricted* and *unrestricted* predictive models. This avoids the drawbacks of previous methods, because it does not require explicit modeling of interacting terms and reports only those interactions that are present in the actual input data. However, the choice of model and the restriction algorithm used are crucial for this framework. We explain why additive models are able to provide the required accurate restrictions and further show that Additive Groves (Sorokina et al., 2007), an additive model-based ensemble of regression trees, works well in this framework. We also investigate how correlations in the data complicate interaction detection and suggest how this problem can be dealt with via feature selection.

The advantage of our new approach for interaction detection, compared with traditional statistical approaches, is that it is more automatic and does not require limiting the functional form that interactions might take. Statistical methods often represent only multiplicative interactions and thus may miss other forms of interactions. When little is known about the system under study, data-driven scientific discovery requires the data to "speak for themselves" with a minimum of analyst input or assumptions. It is possible to conduct a fully nonparametric analysis with the method we propose in this paper, which is particularly valuable for exploratory analysis.

2. Estimating Interactions

Let $F^*(\mathbf{x})$ be an unknown target function and let $F(\mathbf{x})$ be a highly accurate model of F^* that can be learned from a given set of training data. Furthermore, let $R_{ij}(\mathbf{x})$ denote a *restricted* model of F^* that is learned from the same training data. It is restricted in the sense that it is not allowed to contain an interaction between x_i and x_j, but apart from this limitation should be as accurate a model of F^* as possible.

Our interaction estimation technique is based on the following observation. If x_i and x_j interact, then $F(\mathbf{x})$ should have significantly better predictive performance than $R_{ij}(\mathbf{x})$, because the latter cannot accurately capture the true functional dependency between x_i and x_j. On the other hand, if the two variables do not interact, then the absence of the interaction from the model should not hurt its quality. Hence in the absence of an interaction between x_i and x_j the predictive performance of the restricted and the unrestricted model should be comparable. Note that in order to get an adequate estimate of performance, we must measure it on test data not used for training.

Quantifying interaction strength. We can quantify I_{ij}, the degree of interaction between x_i and x_j, by the difference in performance between $F(\mathbf{x})$ and $R_{ij}(\mathbf{x})$. We measure performance as standardized RMSE: root mean squared error (RMSE) scaled by the standard deviation in the response function. Scaling is done to make the results comparable across different data sets; $\mathrm{StD}(F^*(\mathbf{x}))$ is calculated as standard deviation of the response values in the training data.

$$\mathrm{stRMSE}(F(\mathbf{x})) = \frac{\mathrm{RMSE}(F(\mathbf{x}))}{\mathrm{StD}(F^*(\mathbf{x}))} \quad (2)$$

$$I_{ij}(F(\mathbf{x})) = \mathrm{stRMSE}(F(\mathbf{x})) - \mathrm{stRMSE}(R_{ij}(\mathbf{x})) \quad (3)$$

Setting the threshold. To distinguish whether a positive value of I_{ij} indicates presence of an interaction or happened due to random variation, we measure whether the performance of $R_{ij}(\mathbf{x})$ is significantly different from the performance of $F(\mathbf{x})$. We follow common practice and define a difference of three standard deviations of the latter from its mean as significant. The distribution of $\mathrm{stRMSE}(F(\mathbf{x}))$ can come either from different random seeds for bagging or from different data samples (e.g., n-fold cross validation). The threshold for significant interactions then becomes:

$$I_{ij}(F(\mathbf{x})) > 3 \cdot \mathrm{StD}(\mathrm{stRMSE}(F(\mathbf{x}))) \quad (4)$$

Note that everything above naturally generalizes to higher-order interactions as long as there exists a method to restrict the model on a specific type of interaction.

3. Choosing a Prediction Model

To correctly estimate interaction strength with our model comparison technique, we have to make sure that a model has the following key properties:

1. High predictive performance when modeling interactions: if there is an interaction, it should be captured by the unrestricted model.
2. High predictive performance when the model is restricted on non-interacting variables: if there is no interaction, performance of the restricted model should be no worse than the performance of the corresponding unrestricted model.

The first requirement is satisfied by many learning techniques, e.g., bagged decision trees of adequate depth, SVMs, or neural nets. Boosted stumps, on the other hand, do not model interactions. Since they represent functions as the sum of components, each of which depends only on a single variable, boosted 1-level stumps cannot be used in our framework.

While many models satisfy the first requirement, the second requirement — that models perform as well when interaction between non-interacting variables is restricted — is far more challenging. Even when there is a straightforward way of explicitly preventing specific interactions, often the resulting restricted model will not perform as well as the unrestricted model because the restriction may hamper the search in model space compared to the unrestricted model.

Consider a single decision tree. Variables in the tree can interact only if they are used on the same branch of the tree. So the obvious way to restrict interaction between specific variables is to not use one of them if the other already was used earlier on this branch. Now suppose there is no interaction between variables A and B, but they both are important — if the tree does not use one of them, its performance drops. Assume further that A is more important than B. The tree will tend to choose A earlier than B on all branches (in the worst case it will use A at the root) and will then never be able to choose B. Since B is important, the performance of this restricted tree will drop even though there was no interaction between A and B.

One might be tempted to address this problem with an ensemble method like bagging. Unfortunately the situation will not improve much. In bagging, every tree tries to capture the same function from a different sample of the train set. If A is more important, most trees will choose A before B, use of B will be restricted, and performance will drop as before.

Additive models. To detect *absence of interactions* between important variables, we need to build a restricted model that uses these variables in different additive components of the function. There is a class of ensembles that allows us to do this: additive models. Each component in an additive model is trained on the residuals of predictions of all other previous models in the ensemble. The training set for the new model component is created as the difference between true function values and current predictions of the ensemble. This way, when the function has additive structure, different models (or groups of models) are forced to find and model different components of this structure as opposed to each modeling the whole function.

Not all models that fit residuals are suitable for this framework. Linear models do not model interactions, while generalized linear models disguise additive structure with a non-linear transformation. Neural networks pose problems because they either have additive structure (1 internal layer), or the ability to model complex non-linear functions (several layers), while we need an algorithm that combines both. Restricting interactions in a multi-level network splits it into subnets, ultimately leading to "groves of nets".

In this paper we use layered Additive Groves (Sorokina et al., 2007). There exist other methods that might work as well, e.g., gradient boosting trained to minimize least squares loss (Friedman, 2001). However, it is important to understand that the two requirements stated in the beginning of this section are crucial and many (most?) learning algorithms do not satisfy them.

4. Additive Groves of Regression Trees

Additive Groves is an ensemble of trees introduced in (Sorokina et al., 2007). The combination of the ability to model additive structure of the response and to also use large trees that capture complex interactions make Groves suitable for interaction detection.

A single Grove of trees is an additive model where each additive component is represented by a regression tree. Additive Groves use regression trees trained to minimize mean squared error. Tree size is controlled by a parameter α, the minimum fraction of train set cases in a non-leaf node. A single Grove is trained similar to an additive model: each tree is trained on the residuals of the sum of the predictions of the other trees. Trees are discarded and retrained in turn until the overall predictions converge to a stable function. For the pur-

Algorithm 1 Layered training of a single Grove

function Layered(α,N,$TrainSet\{\mathbf{x}, y\}$)
  $\alpha_0 = 0.5, \alpha_1 = 0.2, \alpha_2 = 0.1, \ldots, \alpha_{\max} = \alpha$
  for $i = 1$ **to** N **do**
    $\text{Tree}_i = 0$
  for $j = 0$ **to** max **do**
    repeat
      for $i = 1$ **to** N **do**
        $\text{newTrainSet} = \{\mathbf{x}, y - \sum_{k \neq i} \text{Tree}_k(\mathbf{x})\}$
        $\text{Tree}_i = \text{TrainTree}(\alpha_j, \text{newTrainSet})$
    until (change from the last iteration is small)

pose of interaction detection we use layered training of Additive Groves (Algorithm 1). The main difference between layered training and training classical additive models is the following: Additive Groves begin with an ensemble of very small trees; then during re-training we gradually increase tree size by adding more branches. This layered approach ensures fitting of additive structure of the response function. As with single trees, a single Grove can still overfit to the training data. Hence for the Additive Groves ensemble, we wrap bagging around the layered training algorithm: many single Groves are built on bootstrap samples of the training set and their results are averaged. This procedure reduces variance and yields a very powerful predictive model.

Additive models provide an intuitive and easy way for restricting interactions. Assume we want to restrict a single Grove to not contain interactions between x_i and x_j. Since the modeled function is computed as the sum of the predictions of the individual trees, we only have to enforce that none of the trees uses *both* x_i and x_j. To decide if a tree is not allowed to use x_i (or otherwise x_j), we use a greedy procedure. Each time we train a tree, we first construct two trees: one does not use x_i, the other does not use x_j. The one resulting in better performance is inserted into the model, the other one is discarded. For evaluating performance we use the out-of-bag samples, i.e., that part of the training data that did not get into the current sample and therefore was not used to train the trees.

If we need to restrict on a higher-order interaction (say, k-way interaction between k variables), we need to build k candidate trees instead of 2 every time: each tree is not allowed to use one of the variables. Note that the complexity of testing for a single k-way interaction depends only linearly on k.

(Sorokina et al., 2007) also suggest another, "dynamic programming", style of training for Additive Groves. The method starts with a single small tree. Then on every retraining stage it either increases tree size or adds another tree, which is decided by a heuristic. Although this method provides better performance for unrestricted models, we have encountered problems with it when training restricted models. Therefore we prefer layered Additive Groves for interaction detection. Note that we need to use layered training even for the unrestricted model in order for the performances to be comparable.

5. Feature Selection

Correlations among features are common and complicate the task of detecting interactions. Suppose there exists an interaction between variables x_i and x_j. At the same time, a third variable, x_k, is present in the data. Assume it is highly correlated with x_j, to such an extent that the model can freely use either x_k or x_j with similar results. In this case we will not be able to detect the interaction between x_i and x_j. When we restrict the model to prevent a tree from using x_j, it can use x_k instead and performance will not drop. The same will happen when we try to detect an interaction between x_i and x_k.

Correlation among features is an intrinsic problem of high dimensional data that confronts all methods for interaction detection. For example, methods based on partial dependence functions (Friedman & Popescu, 2005) suffer from a similar problem. The unrestricted prediction model might sometimes use x_j and sometimes x_k. As a result it will find only weak interaction between x_i and x_j and also between x_i and x_k, even though the true interactions are much stronger. If there are more than two correlated variables (again, this is common in high-dimensional datasets), the interaction can be spread out in tiny portions over all of them, making it virtually impossible to detect.

As a consequence, before attempting to detect interactions, we must eliminate correlations. This can be achieved by a feature selection process, which removes some of the variables. The final set of variables should be a compromise between two goals: (1) The performance of the unrestricted model should still be good, ideally at least as good as before feature selection. (2) Each variable should be important, i.e., if we remove it from the set of features, the performance of the unrestricted model should drop significantly. The second criterion also gives us an estimate of the maximum strength of interactions that we can detect: if the performance of the unrestricted model drops by δ when we remove x_i, then we cannot expect the performance of the best model restricted on x_i and x_j to drop by more than δ. The intuition here is that removing an

important variable is a stronger restriction than prohibiting its interactions.

We use a variant of backward elimination (Guyon & Elisseeff, 2003) for the feature selection process. The main idea is to greedily eliminate all features (variables) whose removal either improves performance or reduces performance by at most Δ compared to performance on the full-feature data set. In our experiments we estimated $d = \mathrm{StD}(\mathrm{RMSE}(F(\mathbf{x})))$, where $F(\mathbf{x})$ is the unrestricted model, before running feature selection and used $\Delta = 3d$.

The feature selection procedure is not stable—it depends on the order in which we test each feature. For example, if we consider two completely correlated variables x_j and x_k, we can remove x_j and leave x_k in the set of the features. Or we can do exactly the reverse, depending on which variable we tried to remove first during feature selection. If there is a strong notion of which features should stay in the data set after feature selection, i.e., if we want to test certain features for interactions, the feature selection process should be modified so that features of interest are not removed.

6. Complexity Issues

One concern about interaction detection is the need to conduct a separate test for each interaction. If we want to test for all possible interactions, in theory we need $O(n^k)$ tests, where n is the number of variables and k is the order of the interaction. However, such complexity is unlikely to be required in practice. First, the feature selection process usually leaves a relatively small set of features that makes it feasible to test all pairs for possible interactions. Second, as noted by (Hooker, 2004), interactions possess an important monotonicity property. A k-way interaction can only exist if all its corresponding $(k-1)$-interactions exist. This fact is a straightforward consequence from the definition of a k-way interaction. Hence after we have detected all 2-way interactions, we need to test for 3-way interactions only for those triples of variables that have all 3 pairwise interactions present, and so on. As complex interactions are rare in real datasets, in practice we usually need only few tests for higher-order interactions. Some domains do pose an exception, for example, see our experiments on the *kin8nm* dataset.

7. Experiments

We have applied our approach to both synthetic and real data sets. We can evaluate the performance of our algorithm on synthetic data because we know the true interactions; for real data we try to explain the detected interactions based on the data set description.

In all our experiments we used 100 iterations of bagging. Apart from that, Additive Groves requires two parameters to be set: N (number of trees in a single Grove) and α (fraction of train set cases in the leaf, controls size of a single tree). We determined the best values of α and N on a validation set and reported the performance of Additive Groves with these parameters on a test set. We ran each experiment for the unrestricted model 10 times, using different random seeds and therefore different bootstrap samples for bagging. From these results we estimated the distribution of performance and then calculated the interaction threshold using Equation 4. After that we ran the experiment for each unrestricted model only once. If the resulting estimate of the interaction was above the threshold, we considered it to be evidence of an interaction. Otherwise it was considered insignificantly different from zero, indicating absence of an interaction. Notice that due to variance, in the latter case the estimate could be even negative, but should always be close to zero.

7.1. Synthetic Data.

This data set was generated by a function that was previously used in (Hooker, 2004).

$$F(x) = \pi^{x_1 x_2}\sqrt{2x_3} - sin^{-1}(x_4) + log(x_3 + x_5) - \frac{x_9}{x_{10}}\sqrt{\frac{x_7}{x_8}} - x_2 x_7 \quad (5)$$

Variables x_1, x_2, x_3, x_6, x_7, x_9 are uniformly distributed between 0.0 and 1.0 and variables x_4, x_5, x_8 and x_{10} are uniformly distributed between 0.6 and 1.0. Training, validation and test set contain 1000 points each. Best parameters were detected as $\alpha = 0.02$ and $N = 8$. Feature selection eliminated variables x_6 (not present in the function) and x_8 (virtually no influence on the response). For each of the 28 pairs of remaining variables we constructed a restricted model and compared it to the unrestricted model. Figure 1 shows the interaction value for each variable pair as computed by Equation 2. The dashed line shows the threshold. We can see a group of strong interactions high above the threshold — pairs (x_1, x_2), (x_1, x_3), (x_2, x_3), (x_2, x_7), (x_7, x_9). All cases without interactions fall below the threshold. There are also several weak interactions in the data set: our estimate for (x_9, x_{10}) is barely above the threshold and we failed to detect interactions (x_3, x_5) and (x_7, x_{10}). By construction, x_5 and x_{10} have a small range and their interactions are not significant. There is only one triple of variables with 3 pairwise interactions detected: (x_1, x_2, x_3). A separate test correctly reveals that there is a 3-way interaction

between them. Note that this is the only higher-order interaction that we need to test to conclude the full analysis. The original formula has another 4-way interaction, (x_7, x_8, x_9, x_{10}), but interactions of x_8 and x_{10} turned out to be very weak in the data, so the model did not pick them up.

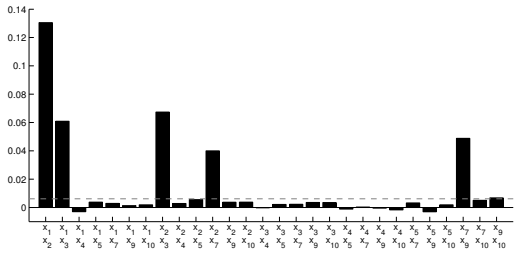

Figure 1. Interaction estimates on synthetic data

For more realistic results, we generated a version of the same data set with a 2 : 1 signal-to-noise ratio. Now feature selection left only 5 variables: x_1, x_2, x_3, x_5, x_7, and results of interaction detection between those variables were qualitatively the same as the correspondent results for the data set without noise.

7.2. Real data sets

We have run experiments on 5 real data sets, 4 of them are regression data sets from Luís Torgo's collection (Torgo, 2007), and the last one is a bird abundance data set from the Cornell Lab of Ornithology (Caruana et al., 2006). We used 4/5 of the data for training, 1/10 for validation and 1/10 for testing.

California Housing. California Housing is a regression data set introduced in (Pace & Barry, 1997). It describes how housing prices depend on different census data variables. Parameters used: $\alpha = 0.0005$, $N = 6$. Feature selection identified six variables as important: longitude, latitude, housingMedianAge, totalRooms, population and medianIncome. (Hooker, 2007) describes the joint effect of latitude and longitude on the response function. Our results confirm that there is a clear strong interaction between these two variables — the location effect on prices cannot be split into the sum of latitude and longitude effects. We have also found an evidence of interaction between population and totalRooms (Figure 2).

Elevators. This data set originates from an aircraft control task (Camacho, 1998). Parameters used: $\alpha = 0.02$ and $N = 18$. Feature selection left six variables: *climbRate*, *p*, *q*, *absRoll*, *diffRollRate*, *Sa*. We detected strong pairwise interactions in the triple (*absRoll*, *diffRollRate*, *Sa*) and a separate test confirmed

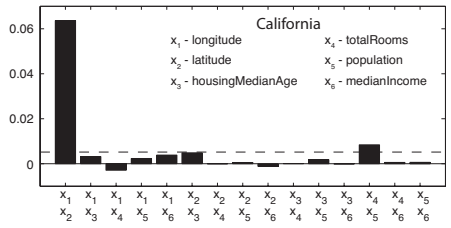

Figure 2. Interaction estimates for California Housing.

that this is indeed a strong 3-way interaction (Figure 3). No other interactions were found.

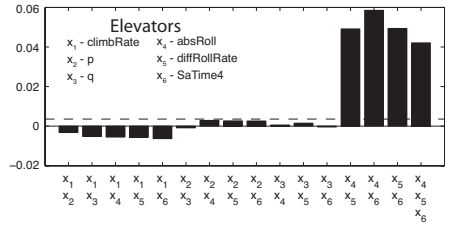

Figure 3. Interaction estimates for Elevators data.

Kinematics (kin8nm). The *kin8nm* dataset from the Delve repository (Rasmussen et al., 2003) describes a simulation of an 8-link robot arm movement. Its input variables correspond to the angular positions of the joints and it is classified as highly non-linear by its creators. Parameters used: $\alpha = 0.005$ and $N = 17$. Our analysis produced symmetrical results that reveal the simulation nature of the dataset: all 8 features turn out to be important, 2 of them do not interact with any other features and the other 6 are connected into a 6-way interaction (Figure 4). For brevity we show only results of tests for 2-way interactions and the final 6-way interaction, but we have also conducted tests for 20 3-way, 15 4-way and 6 5-way interactions between those 6 variables following the procedure described in Section 6. All tests confirmed the presence of interactions. *kin8nm* is the only data set where we had to test for many higher-order interactions. This is a property of the domain: the formula describing the end position of the arm based on joints angles results from interaction between most of the variables.

CompAct. Another dataset from the Delve repository, it describes the level of CPU activity in multiuser computer systems. Parameters used: $\alpha = 0.05$ and $N = 18$. Feature selection left 9 variables: *lread*, *scall*, *sread*, *exec*, *wchar*, *pgout*, *ppgin*, *vflt*, *freeswap*. This data set turns out to be very additive. Although there are many 2-way interactions, they all are relatively small (Figure 5). The largest interactions are (*freeswap*, *wchar*), describing the joint effect of the

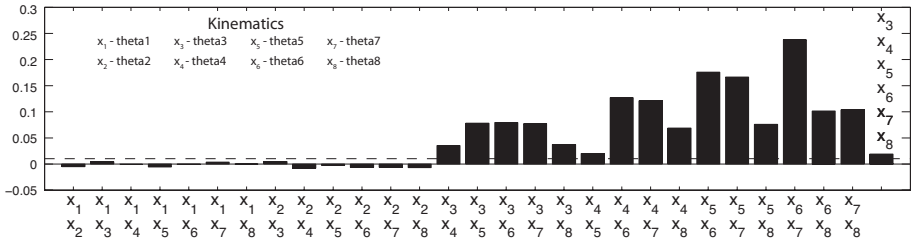

Figure 4. Interaction estimates for Kinematics (kin8nm) data.

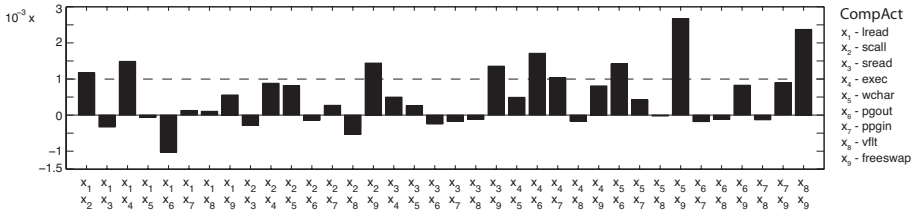

Figure 5. Interaction estimates for CPU Activity (CompAct) data set.

number of blocks available for swapping and system write call speed, and (*freeswap*, *vflt*), describing an interaction between the same available blocks variable and the number of page faults.

House Finch Abundance Data. We tested our approach on a dataset with sightings of House Finches in the North-Eastern US as introduced in (Caruana et al., 2006). The strongest interactions that we detected are between the following variables: (*latitude*, *longitude*, *elevation*) and (*year*, *latitude*, *longitude*). The first 3-way interaction describes the effect of geographical position which is expected to be non-additive. But the interactions between year and location is less trivial. Normally one would not expect that the effect of latitude or longitude on bird abundance would be very different in different years. However, it turns out that during the decade covered by the data set, the population of House Finches was suffering from an eye-disease that was spreading slowly and was responsible for changing the effect of geographical location on bird abundance over time. Our results show that interesting domain information like this can be discovered with the help of interaction detection analysis.

8. Previous Work

Interaction detection is regularly performed as part of statistical analysis (Christensen, 1996). Mostly parametric models are used where the analyst specifies the interaction as a parametric term, or perhaps several terms. In this setting interaction detection becomes a parameter estimation problem. More recently, techniques have been developed to detect interactions within semi-parametric models (Ruppert et al., 2003).

(Friedman & Popescu, 2005) developed tests for interaction detection for a very general class of prediction models, including fully nonparametric models. Their method makes use of the fact that in the absence of an interaction between x_i and x_j the following holds: $\frac{\partial F(\mathbf{X})^2}{\partial x_i \partial x_j} = \frac{\partial F(\mathbf{X})}{\partial x_i} + \frac{\partial F(\mathbf{X})}{\partial x_j}$. They estimate the partial dependence functions (Friedman & Popescu, 2005) of the model and then estimate the strength of an interaction as the difference between the right hand side and the left hand side of the equation above, scaled by variance in the response.

The drawback of that method is that in order to get accurate estimates of the partial dependence function, it relies on predictions for synthetic data points in sparse regions of the input space. As a result, decisions about presence of interactions can be made because of spurious interactions that happen only in those regions (Hooker, 2007). To demonstrate this effect, we generated two simple data sets for the function $F(\mathbf{x}) = x_1^3 + x_2^3$. In the first data set both x_1 and x_2 are distributed uniformly between -10 and 10. For the second data set we took the same points and removed those where both x_1 and x_2 were positive. Neither of the data sets contains interactions, but the estimates produced by Friedman's approach using RuleFit (Friedman, 2005) were 0.0243 for the first and 0.0824 for the second set. The presence of an unpopulated region in the input data increased the estimated strength of the presumed interaction by a

factor of three.

In order to deal with this extrapolation problem, (Friedman & Popescu, 2005) suggest comparing the estimated interaction strength produced by the method described above with a similar estimate on the same data, but for a different response function that does not contain any interactions. However, our experiments with RuleFit revealed several examples of unsatisfactory performance of this technique. For instance, we generated 5 data sets with response function $x_1^2+x_2^2$ without noise and for each of them generated 50 samples from the null distribution. For 3 of those data sets RuleFit produced results that indicated presence of an interaction, i.e., the original estimate was further from the mean of the null distribution than 3 standard deviations. In contrast, our method produced a confident estimation of the absence of interactions in all the cases described above.

(Hooker, 2007; Hooker, 2004) suggests another approach, based on estimating orthogonal components of the ANOVA decomposition. This method has higher computational complexity because it requires generating a full grid of data points with all possible combinations of values for those input variables that are tested for interaction. To overcome the problem of extrapolations over unpopulated regions of the input space, as well as problems caused by correlations, (Hooker, 2007) suggests imposing low weights for points from low-density regions. Unfortunately, this requires the use of external density estimation techniques and further increases complexity of the method.

We take a model comparison approach to interaction detection. In doing so, we do not need to calculate partial dependence functions to estimate predictor effects and we avoid the associated problem of spurious interactions from sparse regions. We believe this is a more direct approach to interaction detection.

9. Discussion

We presented a novel technique for detecting statistical interactions in complex data sets. The main idea is to compare the predictive performance of unrestricted models to restricted models, which do not contain the to-be-tested interaction. Although this idea is quite intuitive, there are significant practical challenges and few algorithms will work in this framework. We demonstrated that layered Additive Groves can be used in this approach due to its high predictive performance for both restricted and unrestricted models. Results on synthetic and real data indicate that we can reliably identify interactions.

Abstract

In this paper, we consider a smoothing kernel based classification rule and propose an algorithm for optimizing the performance of the rule by learning the bandwidth of the smoothing kernel along with a data-dependent distance metric. The data-dependent distance metric is obtained by learning a function that embeds an arbitrary metric space into a Euclidean space while minimizing an upper bound on the resubstitution estimate of the error probability of the kernel classification rule. By restricting this embedding function to a reproducing kernel Hilbert space, we reduce the problem to solving a semidefinite program and show the resulting kernel classification rule to be a variation of the k-nearest neighbor rule. We compare the performance of the kernel rule (using the learned data-dependent distance metric) to state-of-the-art distance metric learning algorithms (designed for k-nearest neighbor classification) on some benchmark datasets. The results show that the proposed rule has either better or as good classification accuracy as the other metric learning algorithms.

1. Introduction

Parzen window methods, also called smoothing kernel rules are widely used in nonparametric density estimation and function estimation, and are popularly known as kernel density and kernel regression estimates, respectively. In this paper, we consider these rules for classification. To this end, let us consider the binary classification problem of classifying $x \in \mathbb{R}^D$, given an i.i.d. training sample $\{(X_i, Y_i)\}_{i=1}^n$ drawn from some unknown distribution $\mathcal{D}$, where $X_i \in \mathbb{R}^D$ and $Y_i \in \{0, 1\}, \forall\, i \in [n] := \{1, \ldots, n\}$. The *kernel classification rule* (Devroye et al., 1996, Chapter 10) is given by

$$g_n(x) = \begin{cases} 0 & \text{if } \sum_{i=1}^n \mathbb{1}_{\{Y_i=0\}} K\left(\frac{x-X_i}{h}\right) \\ & \quad \geq \sum_{i=1}^n \mathbb{1}_{\{Y_i=1\}} K\left(\frac{x-X_i}{h}\right) \\ 1 & \text{otherwise,} \end{cases} \quad (1)$$

where $K : \mathbb{R}^D \to \mathbb{R}$ is a *kernel function*, which is usually nonnegative and monotone decreasing along rays starting from the origin. The number $h > 0$ is called the *smoothing factor*, or *bandwidth*, of the kernel function, which provides some form of distance weighting. We warn the reader not to confuse the kernel function, K, with the reproducing kernel (Schölkopf & Smola, 2002) of a reproducing kernel Hilbert space (RKHS), which we will denote with $\mathfrak{K}$.[1] When $K(x) = \mathbb{1}_{\{\|x\|_2 \leq 1\}}(x)$ (sometimes called the *naïve kernel*), the rule is similar to the k-nearest neighbor (k-NN) rule except that k is different for each X_i in the training set. The k-NN rule classifies each unlabeled example by the majority label among its k-nearest neighbors in the training set, whereas the kernel rule with the naïve kernel classifies each unlabeled example by the majority label among its neighbors that lie within a radius of h. Devroye and Krzyżak (1989) proved that for regular kernels (see Devroye et al., (1996, Definition 10.1)), if the smoothing parameter $h \to 0$ such that $nh^D \to \infty$ as $n \to \infty$, then the kernel classification rule is *universally consistent*. But, for a particular n, asymptotic results provide little guidance in the selection of h. On the other hand, selecting the wrong value of h may lead to very poor error rates. In fact, the crux of every nonparametric estimation problem is the choice of an appropriate smoothing factor. This is one of the questions that we address in this paper by proposing an algorithm to learn an optimal h.

The second question that we address is learning an optimal distance metric. For $x \in \mathbb{R}^D$, K is usually a function of $\|x\|_2$. Some popular kernels include the Gaussian kernel, $K(x) = e^{-\|x\|_2^2}$; the Cauchy kernel, $K(x) =$

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] Unlike $\mathfrak{K}$, K is not required to be a positive definite function. If K is a positive definite function, then it corresponds to a translation-invariant kernel of some RKHS defined on $\mathbb{R}^D$. In such a case, the classification rule in Eq. (1) is similar to the ones that appear in kernel machines literature.

$1/(1+\|x\|_2^{D+1})$; and the Epanechnikov kernel $K(x) = (1-\|x\|_2^2)\mathbb{1}_{\{\|x\|_2\leq 1\}}$.[2] Snapp and Venkatesh (1998) have shown that the finite-sample risk of the k-NN rule may be reduced, for large values of n, by using a weighted Euclidean metric, even though the infinite sample risk is independent of the metric used. This has been experimentally confirmed by Xing et al. (2003); Shalev-Shwartz et al. (2004); Goldberger et al. (2005); Globerson and Roweis (2006); Weinberger et al. (2006). They all assume the metric to be $\rho(x,y) = \sqrt{(x-y)^T\mathbf{\Sigma}(x-y)} = \|\mathbf{L}(x-y)\|_2$ for $x, y \in \mathbb{R}^D$, where $\mathbf{\Sigma} = \mathbf{L}^T\mathbf{L}$ is the weighting matrix, and optimize over $\mathbf{\Sigma}$ to improve the performance of the k-NN rule. Since the kernel rule is similar to the k-NN rule, one would expect that its performance can be improved by making K a function of $\|\mathbf{L}x\|_2$. Another way to interpret this is to find a linear transformation $\mathbf{L} \in \mathbb{R}^{d\times D}$ so that the transformed data lie in a Euclidean metric space.

Some applications call for natural distance measures that reflect the underlying structure of the data at hand. For example, when computing the distance between two images, *tangent distance* would be more appropriate than the Euclidean distance. Similarly, while computing the distance between points that lie on a low-dimensional manifold in $\mathbb{R}^D$, *geodesic distance* is a more natural distance measure than the Euclidean distance. Most of the time, since the true distance metric is either unknown or difficult to compute, Euclidean or weighted Euclidean distance is used as a surrogate. In the absence of prior knowledge, the data may be used to select a suitable metric, which can lead to better classification performance. In addition, instead of $x \in \mathbb{R}^D$, suppose $x \in (\mathcal{X}, \rho)$, where $\mathcal{X}$ is a metric space with ρ as its metric. One would like to extend the kernel classification rule to such $\mathcal{X}$. In this paper, we address these issues by learning a transformation that embeds the data from $\mathcal{X}$ into a Euclidean metric space while improving the performance of the kernel classification rule.

The rest of the paper is organized as follows. In §2, we formulate the multi-class kernel classification rule and propose learning a transformation, φ, (that embeds the training data into a Euclidean space) and the bandwidth parameter, h, by minimizing an upper bound on the resubstitution estimate of the error probability. To achieve this, in §3, we restrict φ to an RKHS and derive a representation for it by invoking the generalized representer theorem. Since the resulting optimization problem is non-convex, in §4, we approximate it with a semidefinite program when K is a naïve kernel. We present experimental results in §5, wherein we show on benchmark datasets that the proposed algorithm performs better than k-NN and state-of-the-art metric learning algorithms developed for the k-NN rule.

[2]The Gaussian kernel is a positive definite function on $\mathbb{R}^D$ while the Epanechnikov and naïve kernels are not.

2. Problem Formulation

Let $\{(X_i, Y_i)\}_{i=1}^n$ denote an i.i.d. training set drawn from some unknown distribution $\mathcal{D}$ where $X_i \in (\mathcal{X}, \rho)$ and $Y_i \in [L]$, with L being the number of classes. The multi-class kernel classification rule is given by

$$g_n(x) = \arg\max_{l\in[L]} \sum_{i=1}^{n} \mathbb{1}_{\{Y_i=l\}} K_{X_i,h}(x), \qquad (2)$$

where $K : \mathcal{X} \to \mathbb{R}_+$ and $K_{x_0,h}(x) = \chi\left(\frac{\rho(x,x_0)}{h}\right)$ for some nonnegative function, χ, with $\chi(0) = 1$. The probability of error associated with the above rule is $L(g_n) := \Pr_{(X,Y)\sim\mathcal{D}}(g_n(X) \neq Y)$ where Y is the true label associated with X. Since $\mathcal{D}$ is unknown, $L(g_n)$ cannot be computed directly but can only be estimated from the training set. The *resubstitution estimate*,[3] $\widehat{L}(g_n)$, which counts the number of errors committed on the training set by the classification rule, is given by $\widehat{L}(g_n) := \frac{1}{n}\sum_{i=1}^n \mathbb{1}_{\{g_n(X_i)\neq Y_i\}}$. As aforementioned, when $\mathcal{X} = \mathbb{R}^D$, ρ is usually chosen to be $\|.\|_2$. Previous works in distance metric learning learn a linear transformation $\mathbf{L} : \mathbb{R}^D \to \mathbb{R}^d$ leading to the distance metric, $\rho_{\mathbf{L}}(X_i, X_j) := \|\mathbf{L}X_i - \mathbf{L}X_j\|_2 = \sqrt{(X_i-X_j)^T\mathbf{\Sigma}(X_i-X_j)}$, where $\mathbf{\Sigma}$ captures the variance-covariance structure of the data. In this work, our goal is to jointly learn h and a measurable function, $\varphi \in \mathcal{C} := \{\varphi : \mathcal{X} \to \mathbb{R}^d\}$, so that the resubstitution estimate of the error probability is minimized with $\rho_\varphi(X_i, X_j) := \|\varphi(X_i) - \varphi(X_j)\|_2$. Once h and φ are known, the kernel classification rule is completely specified by Eq. (2).

Devroye et al., (1996, Section 25.6) show that kernel rules of the form in Eq. (1) picked by minimizing $\widehat{L}(g_n)$ with smoothing factor $h > 0$ are generally inconsistent if X is nonatomic. The same argument can be extended to the multi-class rule given by Eq. (2). To learn φ, simply minimizing $\widehat{L}(g_n)$ without any smoothness conditions on φ can lead to kernel rules that overfit the training set. Such a φ can be constructed as follows. Let n_l be the number of points that belong to l^{th} class. Suppose $n_1 = n_2 = \cdots = n_L$. Then for any $h \geq 1$, choosing $\varphi(X) = Y_i$ when $X = X_i$ and $\varphi(X) = 0$ when $X \notin \{X_i\}_{i=1}^n$ clearly yields zero resubstitution error. However, such a choice of φ leads to a kernel rule that always assigns the unseen data to class 1, leading to very poor performance. Therefore, to avoid overfitting to the training set, the function class $\mathcal{C}$ should satisfy some smoothness properties so that highly non-smooth functions like the one we defined above are not chosen while minimizing $\widehat{L}(g_n)$. To this end, we introduce a penalty functional, $\Omega : \mathcal{C} \to \mathbb{R}_+$, which penalizes

[3]Apart from the resubstitution estimate, holdout and deleted estimates can also be used to estimate the error probability. These estimates are usually more reliable but more involved than the resubstitution estimate.

non-smooth functions in $\mathcal{C}$ so that they are not selected.[4] Therefore, our goal is to learn φ and h by minimizing the regularized error functional given as

$$L_{reg}(\varphi, h) = \frac{1}{n}\sum_{i=1}^{n} \mathbb{1}_{\{g_n(X_i)\neq Y_i\}} + \lambda' \, \Omega[\varphi], \qquad (3)$$

where $\varphi \in \mathcal{C}$, $h > 0$ and the regularization parameter, $\lambda' > 0$. g_n in Eq. (3) is given by Eq. (2), with ρ replaced by ρ_φ. Minimizing $L_{reg}(\varphi, h)$ is equivalent to minimizing the number of training instances for which $g_n(X) \neq Y$, over the function class, $\{\varphi : \Omega[\varphi] \leq s\}$, for some appropriately chosen s.

Consider $g_n(x)$ defined in Eq. (2). Suppose $Y_i = k$ for some X_i. Then $g_n(X_i) = k$ if and only if

$$\sum_{\{j:Y_j=k\}} K^{\varphi}_{X_j,h}(X_i) \geq \max_{\substack{l\in[L]\\ l\neq k}} \sum_{\{j:Y_j=l\}} K^{\varphi}_{X_j,h}(X_i), \qquad (4)$$

where the superscript φ is used to indicate the dependence of K on φ.[5] Since the right hand side of Eq. (4) involves the max function which is not differentiable, we use the inequality $\max\{a_1, \ldots, a_m\} \leq \sum_{i=1}^{m} a_i$ to upper bound[6] it with $\sum_{\substack{l\in[L]\\ l\neq k}} \sum_{j=1}^{n} \mathbb{1}_{\{Y_j=l\}} K_{X_j}(X_i)$. Thus, to maximize $\sum_{i=1}^{n} \mathbb{1}_{\{g_n(X_i)=Y_i\}}$, we maximize its lower bound given by $\sum_{i=1}^{n} \mathbb{1}_{\left\{\sum_{\substack{j=1\\ j\neq i}}^{n} \mathbb{1}_{\{Y_j=Y_i\}} K_{X_j}(X_i) \geq \sum_{j=1}^{n} \mathbb{1}_{\{Y_j\neq Y_i\}} K_{X_j}(X_i)\right\}}$, resulting in a conservative rule.[7] In the above bound, we use $j \neq i$ just to make sure that $\varphi(X_i)$ is not the only point within its neighborhood of radius h. Define $\tau_{ij} := 2\delta_{Y_i,Y_j} - 1$ where δ represents the Kronecker delta. Then, the problem of learning φ and h by minimizing $L_{reg}(\varphi, h)$ in Eq. (3) reduces to solving the following optimization problem,

$$\min_{\varphi,\, h} \Big\{ \sum_{i=1}^{n} \psi_i(\varphi, h) + \lambda \, \Omega[\varphi] \; : \; \varphi \in \mathcal{C},\, h > 0 \Big\}, \qquad (5)$$

where $\lambda = n\lambda'$ and $\psi_i(\varphi, h)$ given by

$$\mathbb{1}_{\left\{\sum_{\substack{j=1\\ j\neq i}}^{n} \mathbb{1}_{\{\tau_{ij}=1\}} K_{X_j}(X_i) < \sum_{j=1}^{n} \mathbb{1}_{\{\tau_{ij}=-1\}} K_{X_j}(X_i)\right\}}$$

is an upper bound on $\mathbb{1}_{\{g_n(X_i)\neq Y_i\}}$ for $i \in [n]$. Solving the above non-convex optimization problem is NP-hard. The gradient optimization is difficult because the gradients are zero almost everywhere. In addition to the computational hardness, the problem in Eq. (5) is not theoretically solvable unless some assumptions about $\mathcal{C}$ are made. In the following section, we assume $\mathcal{C}$ to be an RKHS with the reproducing kernel $\mathfrak{K}$ and provide a representation for the optimum φ that minimizes Eq. (5). We remind the reader that K is a smoothing kernel which is not required to be a positive definite function but takes on positive values, while $\mathfrak{K}$ is a reproducing kernel which is positive definite and can take negative values.

3. Regularization in Reproducing Kernel Hilbert Space

Many machine learning algorithms like SVMs, regularization networks, and logistic regression can be derived within the framework of regularization in RKHS by choosing an appropriate empirical risk functional with the penalizer being the squared RKHS norm (see Evgeniou et al. (2000)). In Eq. (5), we have extended this framework to kernel classification rules, wherein we compute the $\varphi \in \mathcal{C}$ and $h > 0$ that minimize an upper bound on the resubstitution estimate of the error probability. To this end, we choose $\mathcal{C}$ to be an RKHS with the penalty functional being the squared RKHS norm,[8] i.e., $\Omega[\varphi] = \|\varphi\|^2_{\mathcal{C}}$. By fixing h, the objective function $\sum_{i=1}^{n} \psi_i(\varphi, h)$ in Eq. (5) depends on φ only through $\{\|\varphi(X_i) - \varphi(X_j)\|_2\}_{i,j=1}^{n}$. By letting $\sum_{i=1}^{n} \psi_i(\varphi, h) = \theta_h\left(\{\|\varphi(X_i) - \varphi(X_j)\|_2\}_{i,j=1}^{n}\right)$ where $\theta_h : \mathbb{R}^{n^2} \to \mathbb{R}_+$, Eq. (5) can be written as

$$\min_{h>0} \min_{\varphi\in\mathcal{C}} \; \theta_h\left(\{\|\varphi(X_i) - \varphi(X_j)\|_2\}_{i,j=1}^{n}\right) + \lambda \, \|\varphi\|^2_{\mathcal{C}}. \qquad (6)$$

The following result provides a representation for the minimizer of Eq. (6), and is proved in Appendix A. We remind the reader that φ is a vector-valued mapping from $\mathcal{X}$ to $\mathbb{R}^d$.

Theorem 1 (Multi-output regularization)**.** *Suppose $\mathcal{C} = \{\varphi : \mathcal{X} \to \mathbb{R}^d\} = \mathcal{H}_1 \times \ldots \times \mathcal{H}_d$ where $\mathcal{H}_i$ is an RKHS with reproducing kernel $\mathfrak{K}_i : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ and $\varphi = (\varphi_1, \ldots, \varphi_d)$ with $\mathcal{H}_i \ni \varphi_i : \mathcal{X} \to \mathbb{R}$. Then each minimizer $\varphi \in \mathcal{C}$ of Eq. (6) admits a representation of the form*

$$\varphi_j = \sum_{i=1}^{n} c_{ij} \mathfrak{K}_j(., X_i), \;\; \forall \, j \in [d] \qquad (7)$$

where $c_{ij} \in \mathbb{R}$ and $\sum_{i=1}^{n} c_{ij} = 0$, $\forall \, i \in [n]$, $\forall \, j \in [d]$.

[4] This is equivalent to restricting the size of the function class $\mathcal{C}$ from which φ has to be selected.

[5] To simplify the notation, from now onwards, we write $K^{\varphi}_{X_j,h}(X_i)$ as $K_{X_j}(X_i)$ where the dependence of K on φ and h is implicit.

[6] Another upper bound that can be used for the max function is $\max\{a_1, \ldots, a_m\} \leq \log\left(\sum_{i=1}^{m} e^{a_i}\right)$.

[7] Using the upper bound of max function in Eq. (4) makes the resulting kernel rule conservative as there can be samples from the training set that do not satisfy this inequality but get correctly classified according to Eq. (2).

[8] Another choice for $\mathcal{C}$ could be the space of bounded Lipschitz functions with the penalty functional, $\Omega[\varphi] = \|\varphi\|_L$, where $\|\varphi\|_L$ is the Lipschitz semi-norm of φ. With this choice of $\mathcal{C}$ and Ω, von Luxburg and Bousquet (2004) studied large margin classification in metric spaces. One more interesting choice for $\mathcal{C}$ could be the space of Mercer kernel maps. It can be shown that solving for φ in Eq. (5) with such a choice for $\mathcal{C}$ is equivalent to learning the kernel matrix associated with φ and $\{X_i\}_{i=1}^{n}$. However, this approach is not useful as it does not allow for an out-of-sample extension.

Remark 2. *(a) By Eq. (7), φ is completely determined by $\{c_{ij} : i \in [n], j \in [d]\}$. Therefore, the problem of learning φ reduces to learning $n \cdot d$ scalars, $\{c_{ij} : \sum_{i=1}^{n} c_{ij} = 0\}$.*

(b) θ_h in Eq. (6) depends on φ through $\|\varphi(.) - \varphi(.)\|_2$. Therefore, for any $z, w \in \mathcal{X}$, we have $\|\varphi(z) - \varphi(w)\|_2^2 = \sum_{m=1}^{d} \left[\mathbf{c}_m^T (\mathbf{k}_m^z - \mathbf{k}_m^w)\right]^2 = \sum_{m=1}^{d} tr(\mathbf{\Sigma}_m (\mathbf{k}_m^z - \mathbf{k}_m^w)(\mathbf{k}_m^z - \mathbf{k}_m^w)^T)$ where $\mathbf{c}_m := (c_{1m}, \ldots, c_{nm})^T$, $\mathbf{k}_m^z := (\mathfrak{K}_m(z, X_1), \ldots, \mathfrak{K}_m(z, X_n))^T$, $\mathbf{\Sigma}_m := \mathbf{c}_m \mathbf{c}_m^T$, $\forall\, m \in [d]$ and tr(.) represents the trace.

(c) The regularizer, $\|\varphi\|_{\mathcal{C}}^2$ in Eq. (6) is given by $\|\varphi\|_{\mathcal{C}}^2 = \sum_{m=1}^{d} \|\varphi_m\|_{\mathcal{H}_m}^2 = \sum_{m=1}^{d} \sum_{i,j=1}^{n} c_{im} c_{jm} \mathfrak{K}_m(X_i, X_j) = \sum_{m=1}^{d} \mathbf{c}_m^T \mathbf{K}_m \mathbf{c}_m = \sum_{m=1}^{d} tr(\mathbf{K}_m \mathbf{\Sigma}_m)$ where $\mathbf{K}_m := (\mathbf{k}_m^{X_1}, \ldots, \mathbf{k}_m^{X_n})$.

(d) Since φ appears in the form of ρ_φ and $\|\varphi\|_{\mathcal{C}}^2$ in Eq. (6), learning φ is equivalent to learning $\{\mathbf{\Sigma}_m \succeq 0 : rank(\mathbf{\Sigma}_m) = 1, \mathbf{1}^T \mathbf{\Sigma}_m \mathbf{1} = 0\}_{m=1}^{d}$.

In the above remark, we have shown that θ_h and $\|\varphi\|_{\mathcal{C}}$ in Eq. (6) depend only on the entries in d kernel matrices (associated with d kernel functions) and $n \cdot d$ scalars, $\{c_{ij}\}$. In addition, we also reduced the representation of φ from $\{\mathbf{c}_m\}_{m=1}^{d}$ to $\{\mathbf{\Sigma}_m\}_{m=1}^{d}$. It can be seen that ρ_φ^2 and $\|\varphi\|_{\mathcal{C}}^2$ are convex quadratic functions of $\{\mathbf{c}_m\}_{m=1}^{d}$, while they are linear functions of $\{\mathbf{\Sigma}_m\}_{m=1}^{d}$. Depending on the nature of K, one representation would be more useful than the other.

Corollary 3. *Suppose $\mathfrak{K}_1 = \ldots = \mathfrak{K}_d = \mathfrak{K}$. Then, for any $z, w \in \mathcal{X}$, $\rho_\varphi^2(z, w)$ is the Mahalanobis distance between $\mathbf{k}^z$ and $\mathbf{k}^w$, with $\sum_{m=1}^{d} \mathbf{\Sigma}_m$ as its metric.*

Proof. By Remark 2, we have $\rho_\varphi^2(z, w) = \|\varphi(z) - \varphi(w)\|_2^2 = \sum_{m=1}^{d} (\mathbf{k}_m^z - \mathbf{k}_m^w)^T \mathbf{\Sigma}_m (\mathbf{k}_m^z - \mathbf{k}_m^w)$. Since $\mathfrak{K}_1 = \ldots = \mathfrak{K}_d = \mathfrak{K}$, we have $\mathbf{k}_1^z = \ldots = \mathbf{k}_d^z = \mathbf{k}^z$. Therefore, $\rho_\varphi^2(z, w) = (\mathbf{k}^z - \mathbf{k}^w)^T \mathbf{\Sigma} (\mathbf{k}^z - \mathbf{k}^w)$ where $\mathbf{\Sigma} := \sum_{m=1}^{d} \mathbf{\Sigma}_m$. □

The above result reduces the problem of learning φ to learning a matrix, $\mathbf{\Sigma} \succeq 0$, such that $\text{rank}(\mathbf{\Sigma}) \leq d$ and $\mathbf{1}^T \mathbf{\Sigma} \mathbf{1} = 0$. We now study the above result for linear kernels. The following corollary shows that applying a linear kernel is equivalent to assuming the underlying distance metric in $\mathcal{X}$ to be the Mahalanobis distance.

Corollary 4 (Linear kernel)**.** *Let $\mathcal{X} = \mathbb{R}^D$ and $z, w \in \mathcal{X}$. If $\mathfrak{K}(z, w) = \langle z, w \rangle_2 = z^T w$, then $\varphi(z) = \mathbf{L} z \in \mathbb{R}^d$ and $\|\varphi(z) - \varphi(w)\|_2^2 = (z - w)^T \mathbf{A} (z - w)$ with $\mathbf{A} := \mathbf{L}^T \mathbf{L}$.*

Proof. By Remark 2 and Corollary 3, we have $\varphi_m(z) = \sum_{i=1}^{n} c_{im} \mathfrak{K}(z, X_i) = \left(\sum_{i=1}^{n} c_{im} X_i\right)^T z =: \boldsymbol{\ell}_m^T z$. Therefore, $\varphi(z) = \mathbf{L} z$, where $\mathbf{L} := (\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_d)^T$. In addition, $\|\varphi(z) - \varphi(w)\|_2^2 = (z - w)^T \mathbf{A} (z - w)$ with $\mathbf{A} := \mathbf{L}^T \mathbf{L}$. □

In the following section, we use these results to derive an algorithm that jointly learns φ and h by solving Eq. (5).

4. Convex Relaxations & Semidefinite Program

Having addressed the theoretical issue of making assumptions about $\mathcal{C}$ to solve Eq. (5), we return to address the computational issue pointed out in §2. The program in Eq. (5) is NP-hard because of the nature of $\{\psi_i\}_{i=1}^{n}$. This issue can be alleviated by minimizing a convex upper bound of ψ_i, instead of ψ_i. Some of the convex upper bounds for the function $\psi(x) = \mathbb{1}_{\{x > 0\}}$ are $\Psi(x) = \max(0, 1 + x) := [1 + x]_+$, $\Psi(x) = \log(1 + e^x)$ etc. Replacing ψ_i by Ψ_i in Eq. (5) results in the following program,

$$\min_{\substack{\varphi \in \mathcal{C} \\ h > 0}} \sum_{i=1}^{n} \Psi_i \left(\gamma_i^-(\varphi, h) - \gamma_i^+(\varphi, h)\right) + \lambda \|\varphi\|_{\mathcal{C}}^2, \qquad (8)$$

where $\gamma_i^+(\varphi, h) := \sum_{\substack{j \neq i \\ \tau_{ij} = 1}} K_{X_j}(X_i)$ and $\gamma_i^-(\varphi, h) := \sum_{\{j : \tau_{ij} = -1\}} K_{X_j}(X_i)$. Eq. (8) can still be computationally hard to solve depending on the choice of the smoothing kernel, K. Even if we choose K such that γ^+ and γ^- are jointly convex in φ and h for some representation of φ (see Remark 2), Eq. (8) is still non-convex as the argument of Ψ_i is a difference of two convex functions.[9] In addition, if $\Psi(x) = [1 + x]_+$, then Eq. (8) is a d.c. (difference of convex functions) program (Horst & Thoai, 1999), which is NP-hard to solve. So, even for the nicest of cases, one has to resort to local optimization methods or computationally intensive global optimization methods. Nevertheless, if one does not worry about this disadvantage, then solving Eq. (8) yields φ (in terms of $\{\mathbf{c}_m\}_{m=1}^{d}$ or $\{\mathbf{\Sigma}_m\}_{m=1}^{d}$, depending on the chosen representation) and h that can be used in Eq. (2) to classify unseen data. However, in the following, we show that Eq. (8) can be turned into a convex program for the naïve kernel. As mentioned in §1, this choice of kernel leads to a classification rule that is similar in principle to the k-NN rule.

4.1. Naïve kernel: Semidefinite relaxation

The naïve kernel, $K_{x_0}(x) = \mathbb{1}_{\{\rho_\varphi(x, x_0) \leq h\}}$, indicates that the points, $\varphi(x)$, that lie within a ball of radius h centered at $\varphi(x_0)$ have a weighting factor of 1, while the remaining points have zero weight. Using this in Eq. (8), we have $\gamma_i^-(\varphi, h) - \gamma_i^+(\varphi, h) = \sum_{\{j : \tau_{ij} = -1\}} \mathbb{1}_{\{\rho_\varphi(X_i, X_j) \leq h\}} - \sum_{\{j : \tau_{ij} = 1\}} \mathbb{1}_{\{\rho_\varphi(X_i, X_j) \leq h\}} + 1$, which represents the difference between number of points with label different from Y_i that lie within the ball of radius of h centered at $\varphi(X_i)$ and the number of points with the same label as X_i (excluding X_i) that lie within the same ball. If this difference is

[9] For example, let K be a Gaussian kernel, $K_y(x) = \exp(-\rho_\varphi^2(x, y)/h)$. Using the $\{\mathbf{\Sigma}_m\}_{m=1}^{d}$ representation for φ, we have $\rho_\varphi^2(x, y)$ is linear in $\{\mathbf{\Sigma}_m\}_{m=1}^{d}$ and therefore, $K_y(x)$ is convex in $\{\mathbf{\Sigma}_m\}_{m=1}^{d}$. Here, we assume h to be fixed. This means γ_i^+ and γ_i^- are convex in φ.

positive, then the classification rule in Eq. (2) makes an error in classifying X_i. Therefore, φ and h should be chosen such that this misclassification rate is minimized. Suppose that $\{\varphi(X_i)\}_{i=1}^n$ is given. Then, h determines the misclassification rate like k in k-NN. It can be seen that the kernel classification rule and k-NN rule are similar when K is a naïve kernel. In the case of k-NN, the number of nearest neighbors are fixed for any point, whereas with the kernel rule, it varies for every point. On the other hand, the radius of the ball containing the nearest neighbors of a point varies with every point in the k-NN setting while it is the same for every point in the kernel rule.

$\gamma_i^-(\varphi,h) - \gamma_i^+(\varphi,h)$ can be further reduced to a more amenable form by the following algebra. Using $\sum_{\{j:\tau_{ij}=1\}} \mathbb{1}_{\{\rho_\varphi(X_i,X_j)\le h\}} = \sum_{j=1}^n \mathbb{1}_{\{\tau_{ij}=1\}} - \sum_{\{j:\tau_{ij}=1\}} \mathbb{1}_{\{\rho_\varphi(X_i,X_j)>h\}}$, we get $\gamma_i^-(\varphi,h) - \gamma_i^+(\varphi,h) = 1 - n_i^+ + \sum_{j=1}^n \mathbb{1}_{\{\tau_{ij}\rho_\varphi^2(X_i,X_j)>\tau_{ij}\tilde{h}\}}$ where $n_i^+ := \sum_{j=1}^n \mathbb{1}_{\{\tau_{ij}=1\}}$ and $\tilde{h} := h^2$. Note that we have neglected the set $\{j : \tau_{ij} = -1; \rho_\varphi(X_i,X_j) = h\}$ in the above calculation for simplicity. Using $\Psi(x) = [1+x]_+$, the first half of the objective function in Eq. (8) reduces to $\sum_{i=1}^n \Big[2 - n_i^+ + \sum_{j=1}^n \mathbb{1}_{\{\tau_{ij}\rho_\varphi^2(X_i,X_j)>\tau_{ij}\tilde{h}\}}\Big]_+$. Applying the convex relaxation one more time to the step function, we get $\sum_{i=1}^n \Big[2 - n_i^+ + \sum_{j=1}^n \Big[1 + \tau_{ij}\rho_\varphi^2(X_i,X_j) - \tau_{ij}\tilde{h}\Big]_+\Big]_+$ as an upper bound on the first half of the objective function in Eq. (8). Since ρ_φ^2 is a quadratic function of $\{\mathbf{c}_m\}_{m=1}^d$, it can be shown that representing φ in terms of $\{\mathbf{c}_m\}_{m=1}^d$ results in a d.c. program, whereas its representation in terms of $\{\mathbf{\Sigma}_m\}_{m=1}^d$ results in a semidefinite program (SDP) (except for the rank constraints), since ρ_φ^2 is linear in $\{\mathbf{\Sigma}_m\}_{m=1}^d$. Assuming for simplicity that $\mathfrak{K}_1 = \ldots = \mathfrak{K}_d = \mathfrak{K}$ and neglecting the constraint $\text{rank}(\mathbf{\Sigma}) \le d$, we obtain the following SDP,

$$\begin{aligned} \min_{\mathbf{\Sigma},\tilde{h}} \quad & \sum_{i=1}^n \Big[2 - n_i^+ + \sum_{j=1}^n \Big[1 + \tau_{ij}\text{tr}(\mathbf{M}_{ij}\mathbf{\Sigma}) - \tau_{ij}\tilde{h}\Big]_+\Big]_+ \\ & + \lambda\,\text{tr}(\mathbf{K}\mathbf{\Sigma}) \\ \text{s.t.} \quad & \mathbf{\Sigma} \succeq 0,\ \mathbf{1}^T\mathbf{\Sigma}\mathbf{1} = 0,\ \tilde{h} > 0, \end{aligned} \tag{9}$$

where $\mathbf{M}_{ij} := (\mathbf{k}^{X_i} - \mathbf{k}^{X_j})(\mathbf{k}^{X_i} - \mathbf{k}^{X_j})^T$. For notational details, refer to Remark 2 and Corollary 3. Since one does not usually know the optimal embedding dimension, d, the $\mathbf{\Sigma}$ representation is advantageous as it is independent of d (as we neglected the rank constraint) and depends only on n. On the other hand, it is a disadvantage as the algorithm does not scale well to large datasets.

Although the program in Eq. (9) is convex, solving it by general purpose solvers that use interior point methods scales as $O(n^6)$, which is prohibitive. Instead, following the ideas of Weinberger et al. (2006), we used a first order gradient method (which scales as $O(n^2)$ per iteration) and an alternating projections method (which scales as $O(n^3)$ per iteration). At each iteration, we take a small step in the direction of the negative gradient of the objective function, followed by a projection onto the set $\mathcal{N} = \{\mathbf{\Sigma} : \mathbf{\Sigma} \succeq 0,\ \mathbf{1}^T\mathbf{\Sigma}\mathbf{1} = 0\}$ and $\{\tilde{h} > 0\}$. The projection onto $\mathcal{N}$ is performed by an alternating projections method which involves projecting a symmetric matrix alternately between the convex sets, $\mathcal{A} = \{\mathbf{\Sigma} : \mathbf{\Sigma} \succeq 0\}$ and $\mathcal{B} = \{\mathbf{\Sigma} : \mathbf{1}^T\mathbf{\Sigma}\mathbf{1} = 0\}$. Since $\mathcal{A} \cap \mathcal{B} \neq \emptyset$, this alternating projections method is guaranteed to find a point in $\mathcal{A} \cap \mathcal{B}$. Given any $\mathbf{A}_0 \in \mathcal{A}$, the alternating projections algorithm computes $\mathbf{B}_m = P_{\mathcal{B}}(\mathbf{A}_m) \in \mathcal{B}$, $\mathbf{A}_{m+1} = P_{\mathcal{A}}(\mathbf{B}_m) \in \mathcal{A}$, $m = 0, 1, 2, \ldots$, where $P_{\mathcal{A}}$ and $P_{\mathcal{B}}$ are the projection on $\mathcal{A}$ and $\mathcal{B}$, respectively. In summary, the update rule can be given as $\mathbf{B}_m = \mathbf{A}_m - \frac{\mathbf{1}^T\mathbf{A}_m\mathbf{1}}{n^2}\mathbf{1}\mathbf{1}^T$ and $\mathbf{A}_{m+1} = \sum_{i=1}^n [\lambda_i]_+ \mathbf{u}_i\mathbf{u}_i^T$ where $\{\mathbf{u}_i\}_{i=1}^n$ and $\{\lambda_i\}_{i=1}^n$ are the eigenvectors and eigenvalues of $\mathbf{B}_m$.[10] A pseudocode of the gradient projection algorithm to solve Eq. (9) is shown in Algorithm 1.

Algorithm 1 Gradient Projection Algorithm

Require: $\{\mathbf{M}_{ij}\}_{i,j=1}^n$, $\mathbf{K}$, $\{\tau_{ij}\}_{i,j=1}^n$, $\{n_i^+\}_{i=1}^n$, $\lambda > 0$, $\epsilon > 0$ and $\{\alpha_i,\ \beta_i\} > 0$ (see Eq. (9))

Set $t = 0$. Choose $\mathbf{\Sigma}_0 \in \mathcal{A}$ and $\tilde{h}_0 > 0$.
repeat
  $A_t = \{i : \sum_{j=1}^n \Big[1 + \tau_{ij}\text{tr}(\mathbf{M}_{ij}\mathbf{\Sigma}_t) - \tau_{ij}\tilde{h}_t\Big]_+ + 2 \le n_i^+\} \times \{j : j \in [n]\}$
  $B_t = \{(i,j) : 1 + \tau_{ij}\text{tr}(\mathbf{M}_{ij}\mathbf{\Sigma}_t) > \tau_{ij}\tilde{h}_t\}$
  $N_t = B_t \backslash A_t$
  $\mathbf{\Sigma}_{t+1} = P_{\mathcal{N}}(\mathbf{\Sigma}_t - \alpha_t \sum_{(i,j)\in N_t} \tau_{ij}\mathbf{M}_{ij} - \alpha_t\lambda\mathbf{K})$
  $\tilde{h}_{t+1} = \max(\epsilon, \tilde{h}_t + \beta_t \sum_{(i,j)\in N_t} \tau_{ij})$
  $t = t + 1$
until convergence
return $\mathbf{\Sigma}_t$, $\tilde{h}_t$

Having computed $\mathbf{\Sigma}$ and $\tilde{h}$ that minimize Eq. (9), a test point, $x \in \mathcal{X}$, can be classified by using the kernel rule in Eq. (2), where $K_{X_i}(x) = \mathbb{1}_{\{\rho_\varphi(x,X_i)\le h\}}$ with $\rho_\varphi^2(x,X_i) = (\mathbf{k}^x - \mathbf{k}^{X_i})^T\mathbf{\Sigma}(\mathbf{k}^x - \mathbf{k}^{X_i})$. Therefore, $\mathbf{\Sigma}$ and h completely specify the classification rule.

5. Experiments & Results

In this section, we compare the performance of our method (referred to as kernel classification rule (KCR)) to several metric learning algorithms on a supervised classification task in terms of the training and test errors. The training phase of KCR involves solving the SDP in Eq. (9) to learn optimal $\mathbf{\Sigma}$ and h from the data, which are then used in Eq. (2) to classify the test data. Note that the SDP in Eq. (9)

[10] Given $\mathbf{A}_m \in \mathcal{A}$, $\mathbf{B}_m$ is obtained by solving $\min\{\|\mathbf{B}_m - \mathbf{A}_m\|_F^2 : \mathbf{1}^T\mathbf{B}_m\mathbf{1} = 0\}$. Similarly, for a given $\mathbf{B}_m \in \mathcal{B}$, $\mathbf{A}_{m+1}$ is obtained by solving $\min\{\|\mathbf{A}_{m+1} - \mathbf{B}_m\|_F^2 : \mathbf{A}_{m+1} \succeq 0\}$.

Table 1. k-NN classification accuracy on UCI datasets. The algorithms compared are k-NN (with Euclidean distance metric), LMNN (large margin NN by Weinberger et al. (2006)), *Kernel*-NN (see footnote 11), KMLCC (kernel version of metric learning by collapsing classes by Globerson and Roweis (2006)), KLMCA (kernel version of LMNN by Torresani and Lee (2007)), and KCR (proposed method). Mean (μ) and standard deviation (σ) of the train and test (generalization) errors (in $\%$) are reported.

is obtained by using the naïve kernel for K in Eq. (2). For other smoothing kernels, one has to solve the program in Eq. (8) to learn optimal $\mathbf{\Sigma}$ and h. Therefore, the results reported in this section under KCR refer to those obtained by using the naïve kernel.

The algorithms used in the comparative evaluation are:

- The k-NN rule with the Euclidean distance metric.
- The LMNN (large margin nearest neighbor) method proposed by Weinberger et al. (2006), which learns a Mahalanobis distance metric by minimizing the distance between predefined target neighbors and separating them by a large margin from the examples with non-matching labels.
- The *Kernel*-NN rule, which uses the empirical kernel maps[11] as training data and performs k-NN classification on this data using the Euclidean distance metric.
- The KMLCC (kernel version of metric learning by collapsing classes) method proposed by Globerson and Roweis (2006), which learns a Mahalanobis distance metric in the kernel space by trying to collapse all examples in the same class to a single point while pushing examples in other classes infinitely far away.
- The KLMCA (kernel version of large margin component analysis) method proposed by Torresani and Lee (2007), which is a non-convex, kernelized version of LMNN.

Four benchmark datasets from the UCI machine learning repository were considered for experimentation. Since the proposed method and KMLCC solve an SDP that scales poorly with n, we did not consider large problem sizes for experimentation.[12] The results shown in Table 1 are the average performance over 20 random splits of the data with 50% for training, 20% for validation and 30% for testing. The Gaussian kernel, $\mathfrak{K}(x, y) = e^{-\upsilon \|x-y\|_2^2}$ was used for the kernel based methods, i.e., *Kernel*-NN, KMLCC, KLMCA and KCR. The parameters υ and λ (only υ for *Kernel*-NN) were set with cross-validation by searching over $\upsilon \in \{2^i\}_{-4}^{4}$ and $\lambda \in \{10^i\}_{-3}^{3}$. While testing, KCR uses the rule in Eq. (2), whereas the k-NN rule was used for all the other methods.[13] It is clear from Table 1 that KCR almost always performs as well as or significantly better than all other methods. However, on the timing front (which we do not report here), KLMCA, which solves a non-convex program for $n \cdot d$ variables, is much faster than KMLCC and KCR, which solve SDPs involving n^2 variables. The role of empirical kernel maps is not clear as there is no consistent behavior between the performance accuracy achieved with k-NN and *Kernel*-NN.

KMLCC, KLMCA, and KCR learn the Mahalanobis distance metric in $\mathbb{R}^n$ which makes it difficult to visualize the class separability achieved by these methods. To visually appreciate their behavior, we generated a synthetic two dimensional dataset of 3 classes with each class being sampled from a Gaussian distribution with different mean and covariance. Figure 1(a) shows this dataset where the three classes are shown in different colors. Using this as training data, distance metrics were learned using KMLCC, KLMCA and KCR. If $\mathbf{\Sigma}$ is the learned metric, then the two dimensional projection of $x \in \mathbb{R}^n$ is obtained as $\widehat{x} = \mathbf{L}x$ where $\mathbf{L} = (\sqrt{\lambda_1}\mathbf{u}_1, \sqrt{\lambda_2}\mathbf{u}_2)^T$, with $\mathbf{\Sigma} = \sum_{i=1}^{n} \lambda_i \mathbf{u}_i \mathbf{u}_i^T$, and $\lambda_1 \geq \lambda_2 > \cdots \lambda_n$. Figure 1(b-d) show the two di-

[11] *Kernel*-NN is computed as follows. For each training point, X_i, the empirical map w.r.t. $\{X_j\}_{j=1}^{n}$ defined as $\mathbf{k}^{X_i} := (\mathfrak{K}(X_1, X_i), \ldots, \mathfrak{K}(X_n, X_i))^T$ is computed. Then, $\{\mathbf{k}^{X_i}\}_{i=1}^{n}$ is considered to be the training set for the NN classification of empirical maps of the test data using the Euclidean distance metric.

[12] To extend KCR to large datasets, one can represent φ in terms of $\{\mathbf{c}_m\}$, which leads to a non-convex program as in KLMCA.

[13] Although KCR, LMNN, and KMLCC solve SDPs to compute the optimal distance metric, KCR has fewer number of parameters to be tuned compared to these other methods. LMNN requires cross-validation over k (in k-NN) and the regularization parameter along with the knowledge about target neighbors. KMLCC requires cross-validation over k, the kernel parameter, υ and the regularization parameter. In KCR, we only need to cross-validate over υ and λ. In addition, if $\mathcal{X} = \mathbb{R}^D$ and $\mathfrak{K}$ is a linear kernel, then KCR only requires cross-validation over λ while computing the optimal Mahalanobis distance metric.

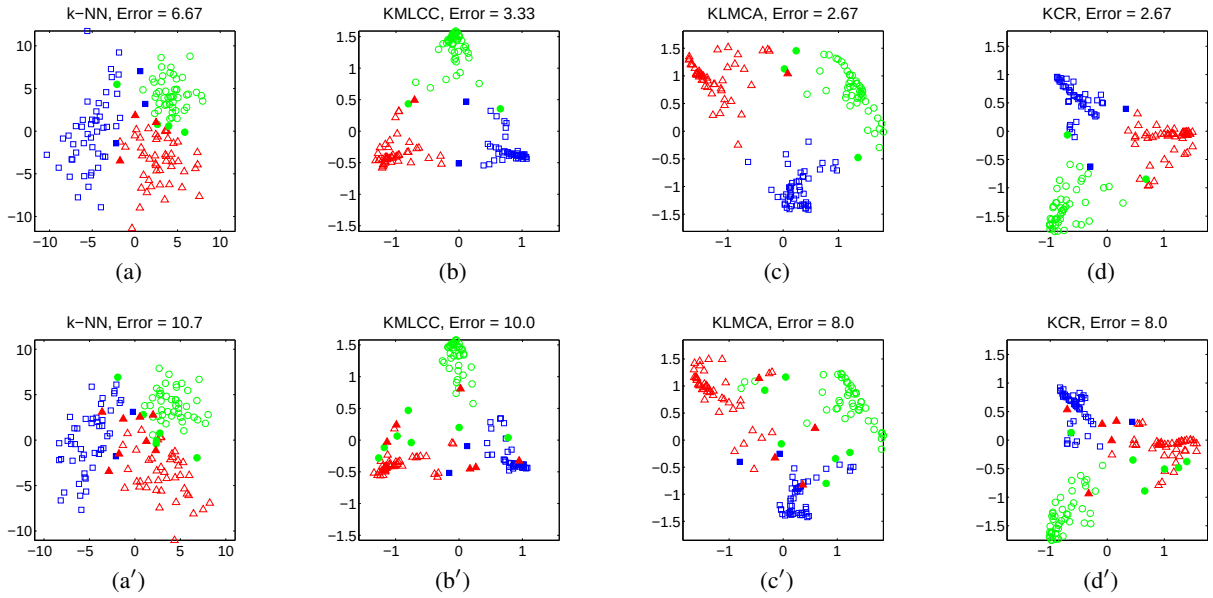

Figure 1. Dataset visualization results of k-NN, KMLCC, KLMCA and KCR applied to a two-dimensional synthetic dataset of three classes with each class being modeled as a Gaussian. (a,a′) denote two independent random draws from this distribution whereas (b-d, b′-d′) represent the two-dimensional projections of these data using the metric learned from KMLCC, KLMCA and KCR. The points in bold represent the misclassified points. It is interesting to note that KLMCA and KCR generate completely different embeddings but have similar error rates. See §5 for more details.

mensional projections of the training set using KMLCC, KLMCA and KCR. The projected points were classified using k-NN if $\mathbf{\Sigma}$ was obtained from KMLCC/KLMCA and using Eq. (2) if $\mathbf{\Sigma}$ was obtained from KCR. The misclassified points are shown in bold. Since the classification is done on the training points, one would expect better error rate and separability between the classes. To understand the generalization performance, a new data sample shown in Figure 1(a′) was generated from the same distribution as the training set. The learned $\mathbf{\Sigma}$ was used to obtain the two dimensional projections of the new data sample which are shown in Figure 1(b′-d′). It is interesting to note that KLMCA and KCR generate completely different projections but have similar error rates.

6. Related Work

We briefly review some relevant work and point out similarities and differences with our method. In our work, we have addressed the problem of extending kernel classification rules to arbitrary metric spaces by learning an embedding function that embeds data into Euclidean space while minimizing an upper bound on the resubstitution estimate of the error probability. The method that is closest in spirit (kernel rules) to ours is the recent work by Weinberger and Tesauro (2007) who learn a Mahalanobis distance metric for kernel regression estimates by minimizing the leave-one-out quadratic regression error of the training set. With the problem being non-convex, they resort to gradient descent techniques. Except for this work, we are not aware of any method related to kernel rules in the context of distance metric learning or learning the bandwidth of the kernel.

There has been lot of work in the area of distance metric learning for k-NN classification, some of which are briefly discussed in §5. The central idea in all these methods is that similarly labeled examples should cluster together and be far away from differently labeled examples. Shalev-Shwartz et al. (2004) proposed an online algorithm for learning a Mahalanobis distance metric with the constraint that any training example is closer to all the examples that share its label than to any other example of different label. In addition, examples from different classes are constrained to be separated by a large margin. Though Shalev-Shwartz et al. (2004) do not solve this as a batch optimization problem, it can be shown that it reduces to an SDP (after rank relaxation) and is in fact the same as Eq. (9) except for the outer $[.]_+$ function and the constraint $\mathbf{1}^T\mathbf{\Sigma}\mathbf{1} = 0$.

7. Concluding Remarks

In this paper, two questions related to the smoothing kernel based classification rule have been addressed. One is related to learning the bandwidth of the smoothing kernel, while the other is to extending the classification rule to arbitrary domains. We jointly addressed them by learning a function in a reproducing kernel Hilbert space while minimizing an upper bound on the resubstitution estimate of the error probability of the kernel rule. For a particular choice

of the smoothing kernel, called the naïve kernel, we showed that the resulting rule is related to the k-NN rule. Because of this relation, the kernel rule was compared to k-NN and its state-of-the-art distance metric learning algorithms on a supervised classification task and was shown to have comparable performance to these methods. In the future, we would like to develop some theoretical guarantees for the proposed method along with extending it to large-scale applications.

Appendix A. Proof of Theorem 1

We need the following result to prove Theorem 1.

Lemma 5. *Let $\mathcal{H} = \{f : \mathcal{X} \to \mathbb{R}\}$ be an RKHS with $\mathfrak{K} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ as its reproducing kernel. Let $\theta : \mathbb{R}^{n^2} \to \mathbb{R}$ be an arbitrary function. Then each minimizer $f \in \mathcal{H}$ of*

$$\theta\left(\{f(x_i) - f(x_j)\}_{i,j=1}^n\right) + \lambda\|f\|_{\mathcal{H}}^2 \tag{10}$$

admits a representation of the form $f = \sum_{i=1}^n c_i \mathfrak{K}(., x_i)$, where $\{c_i\}_{i=1}^n \in \mathbb{R}$ and $\sum_{i=1}^n c_i = 0$.

Proof. The proof follows the generalized representer theorem (Schölkopf et al., 2001, Theorem 4). Since $f \in \mathcal{H}$, $f(x) = \langle f, \mathfrak{K}(., x)\rangle_{\mathcal{H}}$. Therefore, the arguments of θ in Eq. (10) are of the form $\{\langle f, \mathfrak{K}(., x_i) - \mathfrak{K}(., x_j)\rangle_{\mathcal{H}}\}_{i,j=1}^n$. We decompose $f = f_{\|} + f_{\perp}$ so that $f_{\|} \in \text{span}\left(\{\mathfrak{K}(., x_i) - \mathfrak{K}(., x_j)\}_{i,j=1}^n\right)$ and $\langle f_{\perp}, \mathfrak{K}(., x_i) - \mathfrak{K}(., x_j)\rangle_{\mathcal{H}} = 0, \forall\, i, j \in [n]$. So, $f = \sum_{i,j=1}^n \alpha_{ij}(\mathfrak{K}(., x_i) - \mathfrak{K}(., x_j)) + f_{\perp}$ where $\{\alpha_{ij}\}_{i,j=1}^n \in \mathbb{R}$. Therefore, $f(x_i) - f(x_j) = \langle f, \mathfrak{K}(., x_i) - \mathfrak{K}(., x_j)\rangle_{\mathcal{H}} = \langle f_{\|}, \mathfrak{K}(., x_i) - \mathfrak{K}(., x_j)\rangle_{\mathcal{H}} = \sum_{p,m=1}^n \alpha_{pm}(\mathfrak{K}(x_i, x_p) - \mathfrak{K}(x_j, x_p) - \mathfrak{K}(x_i, x_m) + \mathfrak{K}(x_j, x_m))$. Now, consider the penalty functional, $\langle f, f\rangle_{\mathcal{H}}$. For all $f_{\perp}$, $\langle f, f\rangle_{\mathcal{H}} = ||f_{\|}||_{\mathcal{H}}^2 + ||f_{\perp}||_{\mathcal{H}}^2 \geq \|\sum_{i,j=1}^n \alpha_{ij}(\mathfrak{K}(., x_i) - \mathfrak{K}(., x_j))\|_{\mathcal{H}}^2$. Thus for any fixed $\alpha_{ij} \in \mathbb{R}$, Eq. (10) is minimized for $f_{\perp} = 0$. Therefore, the minimizer of Eq. (10) has the form $f = \sum_{i,j=1}^n \alpha_{ij}(\mathfrak{K}(., x_i) - \mathfrak{K}(., x_j))$, which is parameterized by n^2 parameters of $\{\alpha_{ij}\}_{i,j=1}^n$. By simple algebra, f reduces to $f = \sum_{i=1}^n c_i \mathfrak{K}(., x_i)$, where $c_i = \sum_{j=1}^n (\alpha_{ij} - \alpha_{ji})$ satisfies $\sum_{i=1}^n c_i = 0$. □

We are now ready to prove Theorem 1.

Proof of Theorem 1. The arguments of θ_h in Eq. (6) are of the form $\|\varphi(X_i) - \varphi(X_j)\|_2$. Consider $\|\varphi(X_i) - \varphi(X_j)\|_2^2 = \sum_{m=1}^d (\varphi_m(X_i) - \varphi_m(X_j))^2 = \sum_{m=1}^d (\langle \varphi_m, \mathfrak{K}_m(., X_i) - \mathfrak{K}_m(., X_j)\rangle_{\mathcal{H}_m})^2$. The penalizer in Eq. (6) reduces to $\|\varphi\|_{\mathcal{C}}^2 = \sum_{m=1}^d \|\varphi_m\|_{\mathcal{H}_m}^2$. Therefore, applying Lemma 5 to each φ_m, $m \in [d]$ proves the result. □

Abstract

Bayesian network classifiers have been widely used for classification problems. Given a fixed Bayesian network structure, parameters learning can take two different approaches: generative and discriminative learning. While generative parameter learning is more efficient, discriminative parameter learning is more effective. In this paper, we propose a simple, efficient, and effective discriminative parameter learning method, called *Discriminative Frequency Estimate* (DFE), which learns parameters by discriminatively computing frequencies from data. Empirical studies show that the DFE algorithm integrates the advantages of both generative and discriminative learning: it performs as well as the state-of-the-art discriminative parameter learning method ELR in accuracy, but is significantly more efficient.

1. Introduction

A Bayesian network (BN) (Pearl, 1988) consists of a directed acyclic graph G and a set P of probability distributions, where nodes and arcs in G represent random variables and direct correlations between variables respectively, and P is the set of local distributions for each node. A local distribution is typically specified by a conditional probability table (CPT). Thus, learning Bayesian networks from data has two elements: structure learning and parameter learning.

Bayesian networks are often used for classification problems, in which a learner attempts to construct a classifier from a given set of training instances with class labels. In learning Bayesian network classifiers, parameter learning often uses *Frequency Estimate* (FE), which determines parameters by computing the appropriate frequencies from data. The major advantage of FE is its efficiency: it only needs to count each data point (training instance) once. It is well-known that FE maximizes likelihood and thus is a typical generative learning method.

In classification, however, the objective is to maximize generalization accuracy, rather than likelihood. Thus, discriminative parameter learning that maximizes generalization accuracy or its alternative objective function, conditional likelihood, are more desirable. Unfortunately, there is no closed form for choosing the optimal parameters, because conditional likelihood does not decompose (Friedman et al., 1997). As a consequence, discriminative parameter learning for Bayesian networks often resorts to search methods, such as gradient descent.

Greiner and Zhou (2002) proposed a gradient descent based parameter learning method, called ELR, to discriminatively learn parameters for Bayesian network classifiers, and showed that ELR significantly outperforms the generative learning method FE. However, the application of ELR is limited due to its high computational cost. For example, Grossman and Domingos (2004) observed that ELR is computationally infeasible in structure learning. In fact, how to find an

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

efficient and effective discriminative parameter learning for Bayesian network classifiers is an open question.

In this paper, we propose a simple, efficient, and effective discriminative parameter learning method, called *Discriminative Frequency Estimate* (DFE). Our motivation is to turn the generative parameter learning method FE into a discriminative one by injecting a discriminative element into it. DFE discriminatively computes frequencies from data, and then estimates parameters based on the appropriate frequencies. Our empirical studies show that DFE inherits the advantages of both generative and discriminative learning.

2. Related Work

Greiner and Zhou (2002) showed that discriminative parameter learning for Bayesian networks is equivalent to a logistic regression problem under certain conditions. For many Bayesian network structures, they indicated that the conditional likelihood function may have only one global maximum, and thus can be maximized by local optimization methods. They also proposed a gradient descent based parameter learning method, called ELR. To make ELR work effectively, they modified the basic gradient descent method using FE to initialize parameters and cross tuning to prevent overfitting. Empirical studies showed that ELR significantly outperforms the generative learning approach.

Grossman and Domingos (2004) proposed a discriminative structure learning method for Bayesian network classifiers, and tried to combine discriminative structure learning with discriminative parameter learning. To overcome the efficiency problem of ELR, they reduced the fold of cross tuning, and used a small sample for parameter learning. They observed that the modified ELR still takes two orders of magnitude of learning time longer than FE in their experiments, and the performance of the combination of discriminative structure and parameter learning does not outperform the discriminative structure learning alone. Therefore, they suggested learning a structure by conditional likelihood, and setting parameters by the FE method.

To our knowledge, ELR is the state-of-the-art algorithm for discriminative parameter learning for Bayesian network classifiers. Unfortunately, its computational cost is quite high. In this paper, we propose a discriminative parameter learning algorithm that is as effective as ELR but much more efficient.

3. Frequency Estimate

We use capital letters X for a discrete random variable. The lower-case letters x is used for the value taken by variable X, and x_{ij} refers to the variable X_i taking on its j_{th} value. We use the boldface capital letters $\mathbf{X}$ for a set of variables, and the boldface lower case letters $\mathbf{x}$ for the values of variables in $\mathbf{X}$. The training data D consists of a set of finite number of training instances, and an instance e is represented by a vector $(\mathbf{x}, c)$, where c is the class label. In general, we use a "hat" to indicate parameter estimates.

A Bayesian network encodes a joint probability distribution $P(\mathbf{X}, C)$ by a set of local distributions P for each variable. By forcing the class variable C to be the parent of each variable X_i, we can compute the posterior probability $P(C|\mathbf{X})$ as follows.

$$P(C|\mathbf{X}) = \alpha P(C) \prod_{i=1}^{n} P(X_i|\mathbf{U}_i), \tag{1}$$

where α is a normalization factor, and $\mathbf{U}_i$ denotes the set of parents of variable X_i. Note that the class variable C is always one parent of X_i. In naive Bayes, $\mathbf{U}_i$ only contains the class variable C. $P(C)$ is called the prior probability and $P(X_i|\mathbf{U}_i)$ is called the local probability distribution of X_i.

The local distribution $P(X_i|\mathbf{U}_i)$ is usually represented by a conditional probability table (CPT), which enumerates all the conditional probabilities for each assignment of values to X_i and its parents $\mathbf{U}_i$. Each conditional probability $P(x_{ij}|\mathbf{u}_{ik})$ in a CPT is often estimated using the corresponding frequencies obtained from the training data as follows.

$$\hat{P}(x_{ij}|\mathbf{u}_{ik}) = \frac{n_{ijk}}{n_{ik}}, \tag{2}$$

where n_{ijk} denotes the number of training instances in which variable X_i takes on the value x_{ij} and its parents $\mathbf{U}_i$ take on the values $\mathbf{u}_{ik}$. n_{ik} is equal to the sum of n_{ijk} over all j. The prior probability $P(C)$ is also estimated in the same way.

For the convenience in implementation, an entry θ_{ijk} in a CPT is the frequency n_{ijk}, instead of $P(x_{ij}|\mathbf{u}_{ik})$, which can be easily converted to $P(x_i|\mathbf{u}_i)$. To compute the frequencies from a given training data set, we go through each training instance, and increase the corresponding entries θ_{ijk} in CPTs by 1. By scanning the training data set once, we can obtain all the required frequencies and then compute the corresponding conditional probabilities. This parameter learning method is called *Frequency Estimate* (FE).

It is well-known that FE is a generative learning approach, because it maximizes likelihood (Friedman

et al., 1997). In classification, however, the parameter setting that maximizes generalization accuracy is desired. Theoretically, if the structure of a Bayesian network is correct, the parameters determined by FE also maximize generalization accuracy. In practice, however, this assumption is rarely true. Therefore, the parameter learning method that directly maximizes generalization accuracy is more desirable in classification.

4. Discriminative Frequency Estimate

We now introduce *Discriminative Frequency Estimate* (DFE), a discriminative parameter learning algorithm for Bayesian network classifiers.

Note that, when counting a training instance in FE, we simply increase the corresponding frequencies by 1. Consequently, we do not directly take the effect on classification into account in computing frequencies. In fact, at any step in this process, we actually have a classifier on hand: the classifier whose local probabilities are computed by Equation 2 using the current entries (frequencies) in CPTs.

Thus, when we count an instance, we can apply the current classifier to it, and then update the corresponding entries based on how well (bad) the current classifier predicts on the instance. Intuitively, if the instance can be classified perfectly, there is no need to change any entries. In general, given an instance e, we can compute the difference between the true probability $P(c|e)$ and the predicted probability $\hat{P}(c|e)$ generated by the current parameters, where c is the true class of e, and then update the corresponding entries based on the difference. Furthermore, the FE process can be generalized such that we can count each instance more than once (as many as needed) until an convergence occurs. This is the basic idea of DFE.

More precisely, the DFE parameter learning algorithm iterates through the training instances. For each instance e, DFE firstly computes the predicted probability $\hat{P}(c|e)$, and then updates the frequencies in corresponding CPTs using the difference between the true $P(c|e)$ and the predicted $\hat{P}(c|e)$. The detail of the algorithm is depicted as follows. Here M is a pre-defined maximum number of steps. $L(e)$ is the prediction loss for training instance e based on the current parameters Θ^t, defined as follows.

$$L(e) = P(c|e) - \hat{P}(c|e). \tag{3}$$

In general, $P(c|e)$ are difficult to know in classification task, because the information we have for c is only the class label. Thus, we assume that $P(c|e) = 1$ when e is in class c in our implementations. Note this assumption may not be held if data can not be separated completely, and thus may introduce bias to our probability estimation.

Algorithm 1 Discriminative Frequency Estimate

1. Initialize each CPT entry θ_{ijk} to 0
2. **For** t from 1 to M **Do**
   - Randomly draw a training instance e from the training data set D.
   - Compute the posterior probability $\hat{P}(c|e)$ using the current parameters Θ^t and Equation 2.
   - Compute the loss $L(e)$ using Equation 3.
   - **For** each corresponding frequency θ_{ijk} in CPTs
     - Let θ^{t+1}_{ijk}=θ^t_{ijk}+$L(e)$.

Note that, in the beginning, each CPT entry θ_{ijk} is 0, and thus the predicted $\hat{P}(c|e)$ is $\frac{1}{|C|}$ after the probability normalization. In each step, if the current parameters Θ^t cannot accurately predict $P(c|e)$ for an instance e, the corresponding entries θ_{ijk} are increased significantly. If the current parameter Θ^t can perfectly predict $P(c|e)$, there will be no change on any entry.

The following summarizes our understanding for DFE:

1. The generative element is Equation 2. If we set the additive updates $L(e)$ in Equation 3 as a constant, DFE will be a maximum likelihood estimator, which is exactly the same as in the traditional naive Bayes. Thus, the parameters learned by DFE are influenced by the likelihood information $P(x_{ij}|\mathbf{u}_{ik})$ through Equation 2.
2. The discriminative element is Equation 3. If we use each entry θ_{ijk} in CPTs as parameters rather than generating the parameters using Equation 2, DFE will be a typical perceptron algorithm in the sense of error-driven learning. Thus, the parameters learned by DFE are also influenced by the prediction error through Equation 3.
3. DFE is different from a perceptron algorithm because of Equation 2. As we explained above, if we set the additive updates $L(e)$ in Equation 3 as a constant, there is no difference between DFE and a traditional naive Bayes. However, if we set the additive updates in a standard perceptron algorithm as a constant, the perceptron algorithm will not learn a traditional naive Bayes.

In summary, DFE learns parameters by considering the likelihood information $P(x_{ij}|\mathbf{u}_{ik})$ and the prediction error $P(c|e) - \hat{P}(c|e)$, and thus can be considered as a combination of generative and discriminative learning. Moreover, the likelihood information $P(x_{ij}|\mathbf{u}_{ik})$ seems to be more important than $P(c|e) - \hat{P}(c|e)$. For example, a DFE algorithm without Equation 2 performs significantly worse than naive Bayes, while a DFE algorithm without Equation 3 can still learn a traditional naive Bayes.

5. An Example

Before presenting our experiments, it could be helpful to get some intuitive feeling on DFE through a simple example.

A1	A2	A3	C
1	1	1	-
1	1	1	-
0	0	0	+
0	0	0	-
0	0	0	-

Figure 1. A data set with duplicate variables

Figure 1 shows a learning problem consisting of 5 instances and 3 variables. The variables A_2 and A_3 are the two duplicates of A_1, and thus all variables are perfectly dependent. For an instance $e = \{A_1 = 0, A_2 = 0, A_3 = 0\}$, the true posterior probability ratio is:

$$\frac{p(C = +|A_1 = 0, A_2 = 0, A_3 = 0)}{p(C = -|A_1 = 0, A_2 = 0, A_3 = 0)} = \frac{1}{2} \qquad (4)$$

However, naive Bayes, which does not consider the dependencies between variables, gives the estimated posterior probability ratio:

$$\frac{\hat{p}(C = +)}{\hat{p}(C = -)}(\frac{\hat{p}(A_1 = 0|+)}{\hat{p}(A_1 = 0|-)})^3 = \frac{2}{1} \qquad (5)$$

Thus, naive Bayes misclassifies e. Moreover, the estimated posterior probability $\hat{p}(C = +|A_1 = 0, A_2 = 0, A_3 = 0)$ from naive Bayes is 0.66, while the true probability $p(C = +|A_1 = 0, A_2 = 0, A_3 = 0) = 0.33$. This mismatch is due to the two duplicates A_2 and A_3. Since $\frac{p(A_i=0|C=+)}{p(A_i=0|C=-)} = 2$, the duplication of A_1 results in overestimating the probability that e belongs to the positive class.

For DFE, the story is different. Figure 2 shows how the estimated probability $\hat{p}(C = +|A_1 = 0, A_2 = 0, A_3 = 0)$ in naive Bayes changes with FE and DFE respectively, as the number of instances used increases. Both algorithms take an instance in the order in Figure 1 at each step, and update the corresponding frequencies. With the increased number of instances used, the estimated probability $\hat{p}(C = +|A_1 = 0, A_2 = 0, A_3 = 0)$ from DFE converges to 0.4 approximately, which is close to the true probability and leads to a correct classification. However, FE converges to 0.66, even using the training instances more than once.

From this example, we can see that computing the frequencies in a discriminative way tends to yield more accurate probability estimation and give more accurate classification consequently. Also, both DFE and FE tend to converge with the increased training effort.

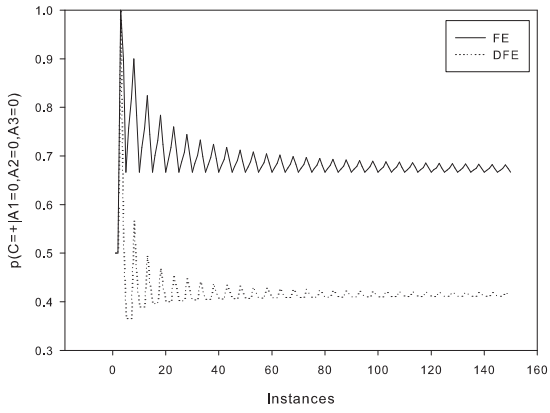

Figure 2. The y-axis is the predicted probability. The x-axis is the t_{th} instance fed into the algorithms.

6. Experiments

6.1. Experimental Setup

We conduct our experiments under the framework of WEKA (Witten & Frank, 2000). All experiments are performed on a Pentium 4 with 2.8GHZ CPU and 1G RAM. In our experiments, we use the 33 UCI data sets, selected by WEKA, which represent a wide range of domains and data characteristics. The smallest training data set "labor" has 51 training instances, and the largest data set "mushroom" has 7311 training instances. Numeric variables are discretized using the unsupervised ten-bin discretization implemented in WEKA. Missing values are replaced with the mean values from the training data. The multi-class data sets are transformed into binary ones by taking the two largest classes. The performance of an algorithm on each data set is observed via 10 runs of 10-fold stratified cross validation.

• worse, and ○ better, comparing with NB-DFE.

Two Bayesian network classifiers, naive Bayes (NB) and HGC (Heckerman et al., 1995), are used to compare the performance of different parameter learning methods. HGC is a hill-climbing structure search algorithm. In our experiments with HGC, we limit the number of parents of each node to 2.

In general, we use NB+X and HGC+X to indicate that NB and HGC with a specific parameter learning method X respectively: X is one of FE, DFE, ELR and Ada (Freund & Schapire, 1996). Note that, for HGC+DEF, we use HGC to learn the structure first, and then apply DFE to learn parameters. We do not use DFE in the structure learning of HGC. The following summarizes the parameter learning algorithms used in our experiments.

FE: the *generative parameter learning* method. Note the term "one iteration" in this paper indicates that we count all training instances exactly once.

DFE: the *discriminative parameter learning* method, depicted in Section 4. In our implementation, we simply go through the whole training data four times (iterations), instead of randomly choosing instances.

ELR: the *gradient descent based discriminative parameter learning* method, proposed in (Greiner & Zhou, 2002).

Ada: *Adaboost M1* is used as an ensemble method that combines the outputs of base classifiers to produce a better prediction (Freund & Schapire, 1996). The number of classifiers is 20.

In our experiments, we use the implementation of ELR from the authors (Greiner & Zhou, 2002) and the implementation of HGC and Ada in WEKA, and implement DFE in WEKA.

Table 2. Summary of the experimental results on accuracy.

	NB+FE	NB+ELR	NB+Ada	HGC+FE	HGC+DFE
NB+DFE	12/21/0	1/31/1	9/24/0	5/28/0	3/28/2
NB+FE		0/22/11	9/19/5	0/22/11	1/22/10
NB+ELR			4/29/0	4/27/2	2/28/3
NB+Ada				2/26/5	0/28/5
HGC+FE					0/30/3

6.2. Accuracy and Training Time

Table 1 gives the detailed experimental results on accuracy. To better understand the effect of training data size on the algorithm performance, we sort the data sets by their sizes. Table 2 shows the results of the paired t-test with significance level 0.05, in which each entry $w/t/l$ means that the learner in the corresponding row wins in w data sets, ties in t data sets, and loses in l data sets, compared to the learning algorithm in the corresponding column. The following is the highlight of our observations.

1. The two discriminative parameter learning methods ELR and DFE have the similar performance

Table 3. Experimental results on training time

○ slower, and • faster comparing with NB-DFE The training time unit is second

in terms of accuracy. NB+DFE performs better than NB+ELR in 1 data set and loses in 1 data set.

2. For naive Bayes, the discriminative parameter learning methods significantly improve the performance of the generative parameter learning method FE. NB+ELR and NB+DFE outperform NB+FE in 11 and 12 data sets without a loss respectively. In our experiments, NB+Ada loses to NB in 9 data sets and wins in 5 data sets. This means that using boosting as a discriminative parameter learning method is not effective according to our experiments.

3. NB+DFE outperforms HGC+FE in 5 data sets without a loss. Note that there is no structure learning in NB+DFE at all. Thus, we could expect that discriminative parameter learning can significantly reduce the effort for structure learning.

4. DFE improves the general Bayesian network learning algorithm HGC. HGC+DFE outperforms HGC+FE in 3 data sets without a loss. This improvement is not as significant as in naive Bayes. However, it is consistent with previous research results: while the structure of a Bayesian network is closer to the "true" one, discriminative parameter learning is less helpful (Greiner & Zhou, 2002; Grossman & Domingos, 2004).

5. HGC+FE outperforms NB+FE in 11 data sets without a loss. This results show that many data sets in our experiments contains strong dependencies. The structure learning in HGC relaxes the independence assumption in naive Bayes, and thus improves the performance significantly.

We have also observed the training time for each algorithm. Table 3 shows the average training time of each algorithm from 10 runs of 10-fold stratified cross validation. From Table 3, we can see that DFE is approximately 250,000 times faster than ELR. Recall that their performance in classification accuracy is similar. Certainly, FE is still the most efficient algorithm: 7 times faster than DFE, 70 faster than NB+Ada, and 1,800,000 times faster than ELR approximately.

6.3. Convergence, Overfitting and Learning Curves

In our experiments, we have investigated the convergence of the DFE algorithm. We have observed the relation between the number of iterations and the accuracy of NB+DFE on the 8 largest data sets, shown in Figure 3. Again, an iteration means counting all instances once. Each point in the curves corresponds to the number of iterations that a parameter learning method performs over the training data and the average accuracy from 10-fold cross validation.

Figure 3 shows that NB+DFE converges quickly. We

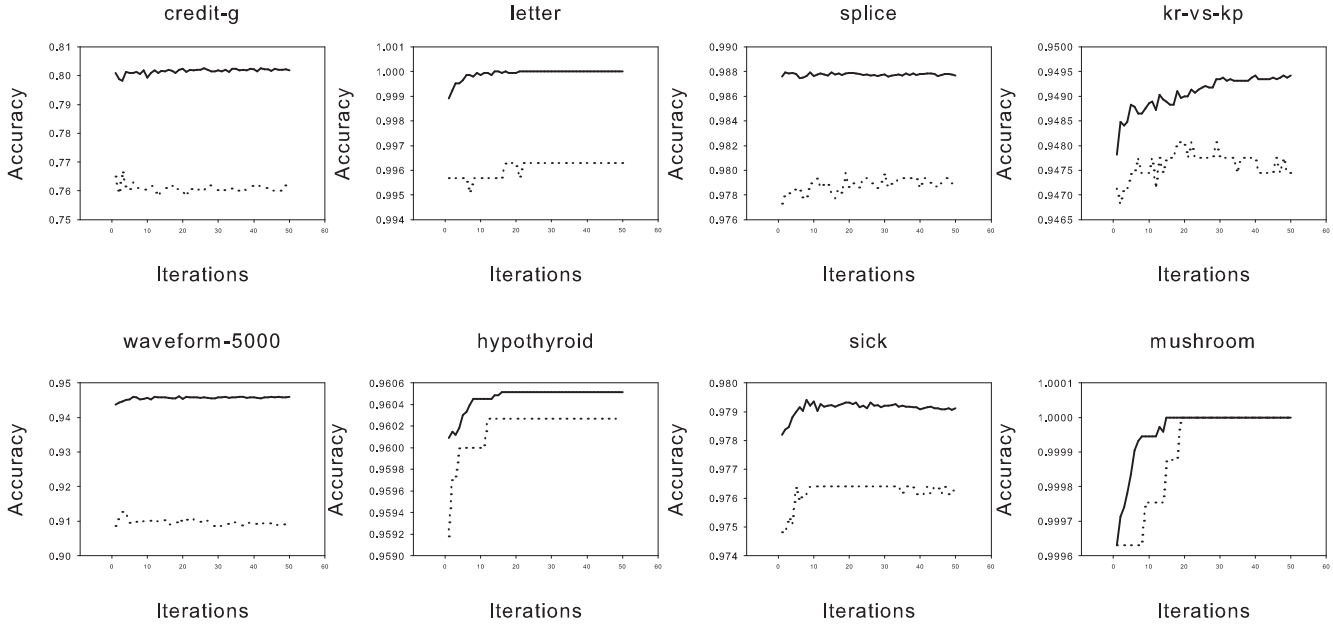

Figure 3. Relation between accuracies and the number of iterations over training and testing data. Solid lines represent training accuracy, and dotted lines represent testing accuracy.

can see that NB+DFE approaches its highest accuracy just after one iteration. As the number of iterations increases after that, there is no significant difference. For example, in all the 8 data sets, the differences between NB+DFE with one iteration and with more iterations are only around 0.005. In our experiments, in fact, we have tried different iteration numbers (1 to 2048) for DFE, and the accuracies of NB+DFE and HGC+DFE do not significantly change.

In the 33 data sets, there is only one data set "Vowel", in which NB+DFE needs more than one iteration to reach the asymptotic accuracy. NB+DFE achieves 90.00% after one iteration, and approaches 95.89% after 4 iterations. The "Vowel" data set has been observed to contain strong variable dependencies (Su & Zhang, 2005), and is small (contains only 180 training instances). However, when the sample size is not small, such as in "Kr-vs-kp" and "Mushroom", one iteration is still enough for DFE to reach its asymptotic accuracy, even though there are strong dependencies in these data sets.

From Figure 3, we can also observe that NB+DFE does not suffer from overfitting. With the increased iterations, the accuracies on test data, shown by the dotted lines, remain the same. That means, once NB+DFE reaches its asymptotic accuracy, the more learning effort does not influence the model. Consequently, no stopping criterion is required for DFE. In contrast, the discriminative learning algorithm ELR requires a stopping criterion to prevent overfitting. Greiner and Zhou (2002) showed that the accuracy of ELR may decrease with an increased training effort.

We have also studied the learning curves of NB+DFE. Ng and Jordan (2001) showed that discriminative learning may have disadvantage comparing to generative learning when sample size is small. Thus, we are interested in how our discriminative parameter learning algorithm DFE performs in this scenario.

Figure 4 shows the learning curves for NB+FE, NB+ELR, and NB+DFE on the same 8 UCI data sets. Since we are interested in the performance in a small sample size, we only observe the performance of each algorithm using up to 50 instances. The accuracy in the learning curves is the average accuracy, obtained on the data that is not used for training with a total of 30 runs. The learning curves show how the accuracy changes as more labeled data are used.

From Figure 4, we can see that NB+FE dominates NB+DFE and NB+ELR only on data sets "Credit-g" and "Hypothyroid" in terms of accuracy. On data sets "Kr-vs-kp" and "Mushroom", however, both discriminative learning algorithms NB+ELR and NB+DFE outperform NB+FE. On all other data sets, the results are mixed. It means that generative learning has actually no obvious advantage over discriminative learning even when the size of training data is small. In fact, our observations agree with the analysis in (Greiner & Zhou, 2002).

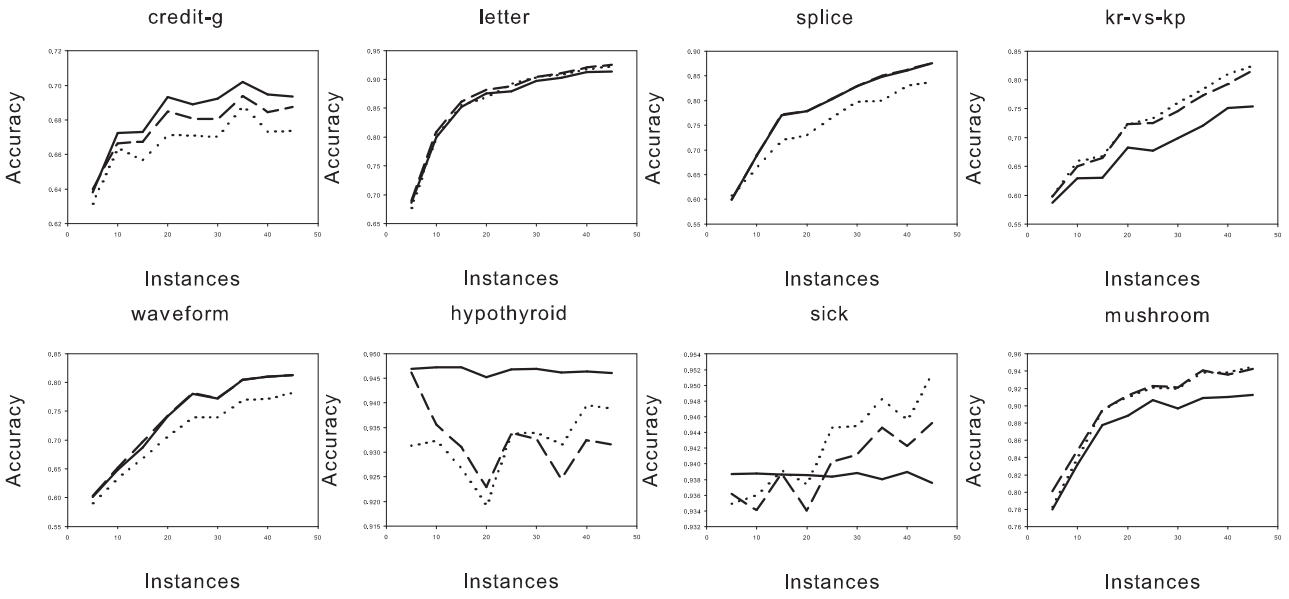

Figure 4. Relation between accuracies and training data sizes. Solid, dotted, and dashed lines correspond to NB+FE, NB+DFE, and NB+ELR respectively.

7. Conclusion

In this paper, we propose a novel discriminative parameter learning method for Bayesian network classifiers. DFE can be viewed as a discriminative version of frequency estimate. Our experiments show that the DFE algorithm combines the advantages of generative and discriminative learning: it is computationally efficient, converges quickly, does not suffer from the overfitting problem, and performs competitively with the state-of-the-art discriminative parameter learning algorithm ELR in accuracy.

This paper mainly studies the empirical side of DFE. Its theoretical nature remains unknown. Moreover, because of the efficiency of DFE, we would expect that DFE could be applied in general structure learning, leading to more accurate Bayesian network classifiers. In our future work, we will study DFE from theoretical perspective and embed DFE into the structure search process of HGC and other structure learning algorithms.

Abstract

Canonical Correlation Analysis (CCA) is a well-known technique for finding the correlations between two sets of multi-dimensional variables. It projects both sets of variables into a lower-dimensional space in which they are maximally correlated. CCA is commonly applied for supervised dimensionality reduction, in which one of the multi-dimensional variables is derived from the class label. It has been shown that CCA can be formulated as a least squares problem in the binary-class case. However, their relationship in the more general setting remains unclear. In this paper, we show that, under a mild condition which tends to hold for high-dimensional data, CCA in multi-label classifications can be formulated as a least squares problem. Based on this equivalence relationship, we propose several CCA extensions including sparse CCA using 1-norm regularization. Experiments on multi-label data sets confirm the established equivalence relationship. Results also demonstrate the effectiveness of the proposed CCA extensions.

1. Introduction

Canonical Correlation Analysis (CCA) (Hotelling, 1936) is commonly used for finding the correlations between two sets of multi-dimensional variables. It makes use of two views of the same set of objects and projects them into a lower-dimensional space in which they are maximally correlated. CCA has been applied successfully in various applications (Hardoon et al., 2004; Vert & Kanehisa, 2003). One popular use of CCA is for supervised learning, in which one view is derived from the data and another view is derived from the class labels. In this setting, the data can be projected into a lower-dimensional space directed by the label information. Such formulation is particularly appealing in the context of dimensionality reduction for multi-label data (Yu et al., 2006).

Multivariate linear regression (MLR) that minimizes the sum-of-squares cost function is a well-studied technique for regression problems. It can also be applied for classification with an appropriate class indicator matrix (Bishop, 2006; Hastie et al., 2001). The solution to least squares problems can be obtained by solving a linear system of equations. A number of algorithms, including the conjugate gradient algorithm, can be applied to solve it efficiently (Golub & Loan, 1996). Furthermore, the least squares formulation can be readily extended using the regularization technique. For example, 1-norm regularization can be incorporated into the least squares formulation to control model complexity and improve sparseness (Tibshirani, 1996). Sparseness often leads to easy interpretation and a good generalization ability. It has been used successfully in PCA (d'Aspremont et al., 2004) and SVM (Zhu et al., 2003).

In contrast to least squares, CCA involves a generalized eigenvalue problem, which is computationally more expensive to solve. Furthermore, it is challenging to derive sparse CCA, as it involves a difficult sparse generalized eigenvalue problem. Convex relaxation of sparse CCA has been studied in (Sriperumbudur et al., 2007), where the exact sparse CCA formulation has been relaxed in several steps. On the other hand, interesting connection between least squares and CCA has been established in the literature. In particular, CCA has been shown to be equivalent to Fisher Linear Discriminant Analysis (LDA) for binary-class problems (Hastie et al., 1995). Meanwhile, it is well-known that LDA is equivalent to least squares in this case (Bishop, 2006; Hastie et al., 2001). Thus CCA can be formulated as a least squares problem for binary-class

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

problems. In practice, the multi-class and multi-label problems are more prevalent. It is therefore tempting to investigate the relationship between least squares and CCA in the more general setting.

In this paper, we study the relationship between CCA and least squares for multi-label problems. We show that, under a mild condition which tends to hold for high-dimensional data, CCA can be formulated as a least squares problem by constructing a specific class indictor matrix. Based on this equivalence relationship, we propose several CCA extensions including sparse CCA using the 1-norm regularization. Furthermore, the entire solution path for sparse CCA can be readily computed by the Least Angle Regression algorithm (LARS) (Efron et al., 2004). We evaluate the established theoretical results using a collection of multi-label data sets. Our experiments confirm the equivalence relationship between these two models under the given assumption. Results also show that, even when the assumption does not hold, they achieve very similar performance. Our experiments also demonstrate the effectiveness of the proposed CCA extensions.

Notations The number of training samples, the data dimensionality, and the number of labels are denoted by n, d, and k, respectively. $x_i \in \mathbb{R}^d$ denotes the ith observation and $y_i \in \mathbb{R}^k$ encodes the corresponding label information. Let $X = [x_1, \cdots, x_n] \in \mathbb{R}^{d\times n}$ be the data matrix and $Y = [y_1, \cdots, y_n] \in \mathbb{R}^{k\times n}$ be the class label matrix. We assume that both $\{x_i\}_1^n$ and $\{y_i\}_1^n$ are centered, i.e., $\sum_{i=1}^n x_i = 0$, and $\sum_{i=1}^n y_i = 0$.

2. Background and Related Work

In this section we give a brief overview of CCA and least squares as well as several other related work.

2.1. Canonical Correlation Analysis

In CCA two different representations of the same set of objects are given, and a projection is computed for each representation such that they are maximally correlated in the dimensionality-reduced space. For $X \in \mathbb{R}^{d\times n}$ and $Y \in \mathbb{R}^{k\times n}$, CCA computes two projection vectors, $w_x \in \mathbb{R}^d$ and $w_y \in \mathbb{R}^k$, such that the following correlation coefficient:

$$\rho = \frac{w_x^T XY^T w_y}{\sqrt{(w_x^T XX^T w_x)(w_y^T YY^T w_y)}} \tag{1}$$

is maximized. Since ρ is invariant to the scaling of w_x and w_y, CCA can be formulated equivalently as

$$\begin{aligned} \max_{w_x, w_y} \quad & w_x^T XY^T w_y \\ \text{subject to} \quad & w_x^T XX^T w_x = 1, \;\; w_y^T YY^T w_y = 1. \end{aligned} \tag{2}$$

We assume that YY^T is nonsingular. It can be shown that w_x can be obtained by solving the following optimization problem:

$$\begin{aligned} \max_{w_x} \quad & w_x^T XY^T \left(YY^T\right)^{-1} YX^T w_x \\ \text{subject to} \quad & w_x^T XX^T w_x = 1. \end{aligned} \tag{3}$$

Both formulations in Eqs. (2) and (3) attempt to find the eigenvectors corresponding to top eigenvalues of the following generalized eigenvalue problem:

$$XY^T(YY^T)^{-1}YX^T w_x = \eta XX^T w_x, \tag{4}$$

where η is the eigenvalue corresponding to the eigenvector w_x. Multiple projection vectors under certain orthonormality constraints can be computed simultaneously by solving the following optimization problem (Hardoon et al., 2004):

$$\begin{aligned} \max_{W} \quad & \mathrm{trace}(W^T XY^T (YY^T)^{-1} YX^T W) \\ \text{subject to} \quad & W^T XX^T W = I, \end{aligned} \tag{5}$$

where $W \in \mathbb{R}^{d\times \ell}$ is the projection matrix, ℓ is the number of projection vectors, and I is the identity matrix. The solution to the optimization problem in Eq. (5) consists of the top ℓ eigenvectors of the generalized eigenvalue problem in Eq. (4).

In regularized CCA (rCCA), a regularization term λI with $\lambda > 0$ is added to XX^T in Eq. (5) to prevent the overfitting and avoid the singularity of XX^T (Bach & Jordan, 2003). Specifically, rCCA solves the following generalized eigenvalue problem:

$$XY^T(YY^T)^{-1}YX^T w_x = \eta(XX^T + \lambda I)w_x. \tag{6}$$

2.2. Least Squares for Regression and Classification

In regression, we are given a training set $\{(x_i, t_i)\}_{i=1}^n$, where $x_i \in \mathbb{R}^d$ is the observation and $t_i \in \mathbb{R}^k$ is the corresponding target. We assume that both the observations and the targets are centered. Thus the bias term can be ignored. In this case, the projection matrix W can be computed by minimizing the following sum-of-squares cost function:

$$\min_W \sum_{i=1}^n \|W^T x_i - t_i\|_2^2 = \|W^T X - T\|_F^2, \tag{7}$$

where $T = [t_1, \cdots, t_n]$. It is well known that the optimal projection matrix is given by

$$W_{LS} = (XX^T)^\dagger XT^T, \tag{8}$$

where the pseudo-inverse is used in case XX^T is singular. To improve the generality ability of the model, a penalty term based on 2-norm or 1-norm regularization is commonly applied (Hastie et al., 2001).

Least squares is also commonly applied for classification. In the general multi-class case, we are given a data set consisting of n samples $\{(x_i, y_i)\}_{i=1}^n$, where $x_i \in \mathbb{R}^d$, and $y_i \in \{1, 2, \cdots, k\}$ denotes the class label of the i-th sample, and $k > 2$. To apply the least squares formulation to the multi-class case, the 1-of-k binary coding scheme is usually employed to apply a vector-valued class code to each data point (Bishop, 2006). The solution to the least squares problem depends on the choice of class indicator matrix. Several class indicator matrices have been proposed in the literature (Hastie et al., 2001).

2.3. Related Work

The inherent relationship between least squares and several other models has been established in the past. In particular, LDA for binary-class problems can be formulated as a least squares problem (Duda et al., 2000; Bishop, 2006). Moreover, this equivalence relationship can be extended to the multi-class case using a specific class indicator matrix (Ye, 2007). CCA has been shown to be equivalent to LDA for multi-class problems (Hastie et al., 1995). Thus, CCA is closely related to least squares in the multi-class case. We show in the next section that, under a mild condition, CCA can be formulated as a least squares problem for multi-label classifications when one of the views used in CCA is derived from the labels.

3. Relationship between CCA and Least Squares

In this section we investigate the relationship between CCA and least squares in the multi-label case. We first define four matrices essential for our derivation:

$$\begin{aligned} H &= Y^T(YY^T)^{-\frac{1}{2}} \in \mathbb{R}^{n\times k}, && (9)\\ C_{XX} &= XX^T \in \mathbb{R}^{d\times d}, && (10)\\ C_{HH} &= XHH^TX^T \in \mathbb{R}^{d\times d}, && (11)\\ C_{DD} &= C_{XX} - C_{HH} \in \mathbb{R}^{d\times d}. && (12) \end{aligned}$$

Note that we assume $n \gg k$ and $\mathrm{rank}(Y) = k$ for multi-label problems. Thus, $(YY^T)^{-\frac{1}{2}}$ is well-defined. It follows from the definition above that the solution to CCA can be expressed as the eigenvectors corresponding to top eigenvalues of the matrix $C_{XX}^{\dagger}C_{HH}$.

3.1. Basic Matrix Properties

In this subsection, we study the basic properties of the matrices involved in the following discussion. Following the definition of H in Eq. (9), we have:

Lemma 1. *Let H be defined as in Eq. (9) and let $\{y_i\}_1^n$ be centered, i.e., $\sum_{i=1}^n y_i = 0$. Then we have*

(1). H has orthonormal columns, i.e., $H^TH = I_k$;

(2). $H^Te = 0$.

Given $H \in \mathbb{R}^{n\times k}$ with orthonormal columns, there exists $D \in \mathbb{R}^{n\times(n-k)}$ such that $[H, D] \in \mathbb{R}^{n\times n}$ is an orthogonal matrix (Golub & Loan, 1996), that is

$$I_n = [H, D][H, D]^T = HH^T + DD^T.$$

It follows that

$$C_{DD} = C_{XX} - C_{HH} = XDD^TX^T. \qquad (13)$$

It can be verified from Eqs. (10), (11), and (13) that the matrices C_{XX}, C_{HH}, and C_{DD} are all positive semidefinite.

Let the Singular Value Decomposition (SVD) of X be

$$\begin{aligned} X &= U\Sigma V^T = [U_1, U_2]\ \mathrm{diag}(\Sigma_r, 0)\ [V_1, V_2]^T \\ &= U_1\Sigma_r V_1^T, && (14) \end{aligned}$$

where $r = \mathrm{rank}(X)$, U and V are orthogonal matrices, $\Sigma \in \mathbb{R}^{d\times n}$, $U_1 \in \mathbb{R}^{d\times r}$, $U_2 \in \mathbb{R}^{d\times(d-r)}$, $V_1 \in \mathbb{R}^{n\times r}$, $V_2 \in \mathbb{R}^{n\times(n-r)}$, and $\Sigma_r \in \mathbb{R}^{r\times r}$.

Since U_2 lies in the null space X^T, we have:

Lemma 2. *Let H, X, U_2, and D be defined as above. Then $H^TX^TU_2 = 0$ and $D^TX^TU_2 = 0$.*

3.2. Computing CCA via Eigendecomposition

Recall that the solution to CCA consists of the top ℓ eigenvectors of the matrix $C_{XX}^{\dagger}C_{HH}$. We next show how to compute the eigenvectors of $C_{XX}^{\dagger}C_{HH}$. Define the matrix $A \in \mathbb{R}^{r\times k}$ by

$$A = \Sigma_r^{-1}U_1^TXH. \qquad (15)$$

Let the SVD of A be $A = P\Sigma_A Q^T$, where $P \in \mathbb{R}^{r\times r}$ and $Q \in \mathbb{R}^{k\times k}$ are orthogonal, and $\Sigma_A \in \mathbb{R}^{r\times k}$ is diagonal. Then

$$AA^T = P\Sigma_A\Sigma_A^TP^T. \qquad (16)$$

The matrix $C_{XX}^{\dagger}C_{HH}$ can be diagonalized as follows:

$$\begin{aligned}
C_{XX}^{\dagger}C_{HH} &= U_1\Sigma_r^{-2}U_1^T XHH^TX^T \\
&= U_1\Sigma_r^{-1}AH^TX^TUU^T \\
&= U\begin{bmatrix} I_r \\ 0 \end{bmatrix}\Sigma_r^{-1}A[H^TX^TU_1, H^TX^TU_2]U^T \\
&= U\begin{bmatrix} \Sigma_r^{-1}AA^T\Sigma_r & 0 \\ 0 & 0 \end{bmatrix}U^T \\
&= U\begin{bmatrix} \Sigma_r^{-1}P & 0 \\ 0 & I \end{bmatrix}\begin{bmatrix} \Sigma_A\Sigma_A^T & 0 \\ 0 & 0 \end{bmatrix}\begin{bmatrix} P^T\Sigma_r & 0 \\ 0 & I \end{bmatrix}U^T
\end{aligned}$$

where the second equality follows since U is orthogonal, the fourth equality follows since $H^TX^TU_2 = 0$ as shown in Lemma 2, and the last equality follows from Eq. (16). Thus the solution to CCA, which consists of the top ℓ eigenvectors of matrix $C_{XX}^{\dagger}C_{HH}$, is given by

$$W_{CCA} = U_1\Sigma_r^{-1}P_l, \tag{17}$$

where P_ℓ contains the first ℓ columns of P.

3.3. Equivalence of CCA and Least Squares

Recall from Eq. (8) that for a given class indicator matrix T, the solution to the least squares problem is given by

$$(XX^T)^{\dagger}XT^T.$$

We define the class indicator matrix $\tilde{T}$ as follows:

$$\tilde{T} = (YY^T)^{-\frac{1}{2}}Y = H^T. \tag{18}$$

In this case, the solution to the least squares problem is given by

$$\begin{aligned}
W_{LS} &= (XX^T)^{\dagger}XH = U_1\Sigma_r^{-2}U_1^TXH \\
&= U_1\Sigma_r^{-1}A = U_1\Sigma_r^{-1}P\Sigma_AQ^T.
\end{aligned} \tag{19}$$

It is clear from Eqs. (17) and (19) that the difference between CCA and least squares lies in Σ_A and Q^T.

We next show that all diagonal elements of Σ_A are one under a mild condition, that is, $\mathrm{rank}(X) = n-1$ and $\mathrm{rank}(Y) = k$. Note that the first condition is equivalent to requiring that the original data points are linearly independent before centering, which tends to hold for high-dimensional data.

Before presenting the main result summarized in Theorem 1 below, we have the following lemma:

Lemma 3. *Assume*

$$\mathit{rank}(C_{XX}) + s = \mathit{rank}(C_{HH}) + \mathit{rank}(C_{DD}),$$

for some non-negative integer s. Then for the matrix $\hat{\Sigma}_A = \Sigma_A\Sigma_A^T = \mathit{diag}(a_1, a_2, \cdots, a_r) \in \mathbb{R}^{r\times r}$, we have

$$1 = \cdots = a_{f-s} > a_{f-s+1} \geqslant \cdots \geqslant a_f > a_{f+1} = \cdots = 0.$$

where $f = \mathit{rank}(\Sigma_A)$.

Proof. Define the matrix $J \in \mathbb{R}^{d\times d}$ as follows:

$$J = U\begin{bmatrix} \Sigma_r^{-1}P & 0 \\ 0 & I_{d-r} \end{bmatrix}. \tag{20}$$

It follows from the definition of C_{XX}, C_{HH}, and C_{DD} in Eqs. (10)-(12) that

$$\begin{aligned}
J^TC_{XX}J &= \mathrm{diag}(I_r, 0), \\
J^TC_{HH}J &= \mathrm{diag}(\Sigma_A\Sigma_A^T, 0) \\
&= \mathrm{diag}(a_1, \cdots, a_r, 0, \cdots, 0), \\
J^TC_{DD}J &= J^TC_{XX}J - J^TC_{HH}J \\
&= \mathrm{diag}(b_1, \cdots, b_r, 0, \cdots, 0),
\end{aligned} \tag{21}$$

where $b_i = 1 - a_i$, for $i = 1, \cdots, r$. Note that since J is nonsingular, we have

$$\mathrm{rank}(C_{XX}) = \mathrm{rank}(J^TC_{XX}J) = r.$$

It follows from our assumption that

$$\mathrm{rank}(J^TC_{HH}J) + \mathrm{rank}(J^TC_{DD}J) = r + s. \tag{22}$$

Since both $J^TC_{HH}J$ and $J^TC_{DD}J$ are diagonal, there are a total of $r+s$ nonzero elements in $J^TC_{HH}J$ and $J^TC_{DD}J$. Note that $f = \mathrm{rank}(\Sigma_A) = \mathrm{rank}(\hat{\Sigma}_A)$, thus $a_1 \geqslant \cdots \geqslant a_f > 0 = a_{f+1} = \cdots = a_r$. It follows from Eq. (21) that

$$a_i + b_i = 1, \text{ for } 1 \leqslant i \leqslant r, \quad b_r \geqslant \cdots \geqslant b_1 \geqslant 0. \tag{23}$$

This implies that at least one of a_i or b_i is positive for $1 \leqslant i \leqslant r$. To satisfy the rank equality in Eq. (22), we therefore must have

$$\begin{aligned}
1 &= a_1 = a_2 = \cdots = a_{f-s} > a_{f-s+1} \geqslant \cdots \geqslant a_f \\
&> a_{f+1} = \cdots = a_r = 0, \\
0 &= b_1 = b_2 = \cdots = b_{f-s} < b_{f-s+1} \leqslant \cdots \leqslant b_f \\
&< b_{f+1} = \cdots = b_r = 1.
\end{aligned}$$

This completes the proof of the lemma. □

Theorem 1. *Assume that $\mathit{rank}(X) = n-1$ and $\mathit{rank}(Y) = k$ for multi-label problems. Then we have*

$$\mathit{rank}(C_{XX}) = n-1, \tag{24}$$
$$\mathit{rank}(C_{HH}) = k, \tag{25}$$
$$\mathit{rank}(C_{DD}) = n-k-1. \tag{26}$$

Thus $s = 0$, where s is defined in Lemma 3, and

$$1 = a_1 = \cdots = a_k > a_{k+1} = \cdots = a_r = 0.$$

This implies that all diagonal elements of Σ_A are ones.

Proof. Denote $e^T = [1, 1, \cdots, 1] \in \mathbb{R}^{1\times n}$, $H = [h_1, \cdots, h_k]$, and $D = [h_{k+1}, \cdots, h_n]$. Note that X is column centered, i.e., $\sum_{i=1}^n x_i = 0$. It follows from Lemma 1 that $H^T e = 0$, that is,

$$h_i^T e = 0, \text{ for } 1 \leqslant i \leqslant k. \tag{27}$$

Since $[H, D]$ is an orthogonal matrix, $\{h_1, \cdots, h_n\}$ form a basis for $\mathbb{R}^n$. Thus we can represent $e \in \mathbb{R}^n$ as

$$e = \sum_{i=1}^n \alpha_i h_i, \text{ where } \alpha_i \in \mathbb{R}. \tag{28}$$

It follows from the orthogonality of $[H, D]$ and Eq. (27) that e can be expressed as $e = \sum_{i=k+1}^n \alpha_i h_i$, and

$$0 = Xe = X\left(\sum_{i=k+1}^n \alpha_i h_i\right) = \sum_{i=k+1}^n \alpha_i (Xh_i). \tag{29}$$

Since not all α_i's are zero, the $n-k$ columns of XD are linearly dependent, thus $\text{rank}(XD) \leqslant n-k-1$. According to the property of matrix rank, we have

$$\begin{aligned} &\text{rank}(XD) \geqslant \text{rank}(X) + \text{rank}(D) - n \\ &= (n-1) + (n-k) - n = n-k-1. \end{aligned} \tag{30}$$

Thus, $\text{rank}(XD) = n-k-1$ holds.

For matrix XH, we have

$$\begin{aligned} &\text{rank}(X) = \text{rank}(X[H, D]) \leqslant \text{rank}(XH) + \text{rank}(XD) \\ &\Leftrightarrow n-1 \leqslant \text{rank}(XH) + n - k - 1 \\ &\Leftrightarrow \text{rank}(XH) \geqslant k. \end{aligned}$$

On the other hand, since $XH \in \mathbb{R}^{d\times k}$, $\text{rank}(XH) \leqslant k$. Thus we have $\text{rank}(XH) = k$ and

$$\begin{aligned} \text{rank}(C_{XX}) &= \text{rank}(X) = n-1, \\ \text{rank}(C_{HH}) &= \text{rank}(XH) = k, \\ \text{rank}(C_{DD}) &= \text{rank}(XD) = n-k-1. \end{aligned}$$

It follows that $s = 0$. On the other hand,

$$f = \text{rank}(A) = \text{rank}(\Sigma_r^{-1} U_1^T XH) = \text{rank}(XH) = k.$$

Hence,

$$1 = a_1 = a_2 = \cdots = a_k > 0 = a_{k+1} = \cdots = a_r,$$

and all diagonal elements of Σ_A are ones. This completes the proof of the theorem. □

Since $\text{rank}(\Sigma_A) = k$, $C_{XX}^\dagger C_{HH}$ contains k nonzero eigenvalues. If we choose $\ell = k$, then

$$W_{CCA} = U_1 \Sigma_r^{-1} P_k. \tag{31}$$

The only difference between W_{LS} and W_{CCA} lies in the orthogonal matrix Q^T in W_{LS}.

In practice, we can use both W_{CCA} and W_{LS} to project the original data onto a lower-dimensional space before classification. For any classifiers based on Euclidean distance, the orthogonal transformation Q^T will not affect the classification performance since the Euclidean distance is invariant of any orthogonal transformations. Some well-known algorithms with this property include the K-Nearest-Neighbor (KNN) algorithm (Duda et al., 2000) based on the Euclidean distance and the linear Support Vector Machines (SVM) (Schölkopf & Smola, 2002). In the following, the least squares CCA formulation is called "LS-CCA".

4. Extensions of CCA

Based on the equivalence relationship established in the last section, the classical CCA formulation can be extended using the regularization technique.

Regularization is commonly used to control the complexity of the model and improve the generalization performance. Linear regression using the 2-norm regularization, called ridge regression (Hoerl & Kennard, 1970), minimizes the penalized sum-of-squares cost function. By using the class indicator matrix $\tilde{T}$ in Eq. (18), we obtain the 2-norm regularized least squares CCA formulation (called "LS-CCA$_2$") by minimizing the following objective function:

$$L_2(W, \lambda) = \sum_{j=1}^k \left(\sum_{i=1}^n (x_i^T w_j - \tilde{T}_{ij})^2 + \lambda \|w_j\|_2^2 \right),$$

where $W = [w_1, \cdots, w_k]$, and $\lambda > 0$ is the regularization parameter.

In mathematical programming, it is known that sparseness can often be achieved by penalizing the L_1-norm of the variables (Donoho, 2006; Tibshirani, 1996). It has been introduced into the least squares formulation and the resulting model is called lasso (Tibshirani, 1996). Based on the established equivalence relationship between CCA and least squares, we derive the 1-norm least squares CCA formulation (called "LS-CCA$_1$") by minimizing the following objective function:

$$L_1(W, \lambda) = \sum_{j=1}^k \left(\sum_{i=1}^n (x_i^T w_j - \tilde{T}_{ij})^2 + \lambda \|w_j\|_1 \right).$$

The optimal w_j^*, for $1 \leq j \leq k$, is given by

$$w_j^* = \arg\min_{w_j} \left(\sum_{i=1}^n (x_i^T w_j - \tilde{T}_{ij})^2 + \lambda \|w_j\|_1 \right), \tag{32}$$

which can be reformulated as:

$$w_j^* = \arg \min_{\|w_j\|_1 \leq \tau} \sum_{i=1}^{n} (x_i^T w_j - \tilde{T}_{ij})^2, \qquad (33)$$

for some tuning parameter $\tau > 0$ (Tibshirani, 1996). Furthermore, the solution can be readily computed by the Least Angle Regression algorithm (Efron et al., 2004). One key feature of LARS is that it computes the entire solution path for all values of τ, with essentially the same computational cost as fitting the model with a single τ value.

If the value of τ is large enough, the constraint in Eq. (33) is not effective, resulting in an unconstrained optimization problem. We can thus consider τ from a finite range $[0, \hat{\tau}]$, for some $\hat{\tau} > 0$. Define $\gamma = \tau/\hat{\tau}$ so that $\tau = \hat{\tau}\gamma$ with $0 \leq \gamma \leq 1$. The estimation of τ is equivalent to the estimation of γ. Cross-validation is commonly used to estimate the optimal value from a large candidate set $S = \{\gamma_1, \gamma_2, \cdots, \gamma_{|S|}\}$, where $|S|$ denotes the size of S. If the value of γ is sufficiently small, many of the coefficients in W will become exactly zero, which leads to a sparse CCA model. We thus call γ the "sparseness coefficient".

5. Experiments

We use a collection of multi-label data sets to experimentally verify the equivalence relationship established in this paper. We also evaluate the performance of various CCA extensions.

5.1. Experimental Setup

We use two types of data in the experiment. The gene expression pattern image data[1] describe the gene expression patterns of *Drosophila* during development (Tomancak & *et al.*, 2002). Each image is annotated with a variable number of textual terms (labels) from a controlled vocabulary. We apply Gabor filters to extract a 384-dimensional feature vector from each image. We use five data sets with different numbers of terms (class labels). We also use the scene data set (Boutell et al., 2004) which contains 2407 samples of 294-dimension and 6 labels. In all the experiments, ten random splittings of data into training and test sets are generated and the averaged performance is reported.

In the experiment, five methods including CCA and its regularized version rCCA in Eq. (6), as well as LS-CCA and its regularization versions LS-CCA$_2$ and LS-CCA$_1$ are compared. These CCA methods are used to project the data into a lower-dimensional space in which a linear SVM is applied for classification for each label. The Receiver Operating Characteristic (ROC) score is computed for each label and the averaged performance over all labels is reported.

[1]All images were extracted from the FlyExpress database at http://www.flyexpress.net.

5.2. Gene Expression Pattern Image Data

In this experiment we first evaluate the equivalence relationship between CCA and least squares. For all cases, we set the data dimensionality d larger than the sample size n, i.e., $d/n > 1$. The condition in Theorem 1 holds in all cases. We observe that for all splittings of all of the five data sets, $\text{rank}(C_{XX})$ equals $\text{rank}(C_{HH}) + \text{rank}(C_{DD})$), and the ratio of the maximal to the minimal diagonal element of Σ_A is 1, which implies that all diagonal elements of Σ_A are the same, i.e., ones. Our experimental evidences are consistent with the theoretical results presented in Section 3.3.

5.2.1. Performance Comparison

In Table 1, we report the mean ROC scores over all terms and all splittings for each data set. The main observations include: (1) CCA and LS-CCA achieve the same performance for all data sets, which is consistent with our theoretical results; (2) The regularized CCA extensions including rCCA, LS-CCA$_2$, and LS-CCA$_1$ perform much better than their counterparts CCA and LS-CCA without the regularization; and (3) LS-CCA$_2$ is comparable to rCCA in all data sets, while LS-CCA$_1$ achieves the best performance in all cases. These further justify the use of the proposed least squares CCA formulations for multi-label classifications.

Table 1. Comparison of different CCA methods in terms of mean ROC scores. n_{tot} denotes the total number of images in the data set, and k denotes the number of terms (labels). Ten different splittings of the data into training (of size n) and test (of size $n_{tot} - n$) sets are applied for each data set. For the regularized algorithms, the value of the parameter is chosen via cross-validation. The proposed sparse CCA model (LS-CCA$_1$) performs the best for this data set.

n_{tot}	k	CCA	LS-CCA	rCCA	LS-CCA$_2$	LS-CCA$_1$
863	10	0.542	0.542	0.617	0.619	**0.722**
1041	15	0.534	0.534	0.602	0.603	**0.707**
1138	20	0.538	0.538	0.609	0.610	**0.714**
1222	25	0.540	0.540	0.603	0.605	**0.704**
1349	30	0.548	0.548	0.606	0.608	**0.709**

5.2.2. Sensitivity Study

In this experiment, we investigate the performance of LS-CCA and its variants in comparison with CCA when the condition in Theorem 1 does not hold, which

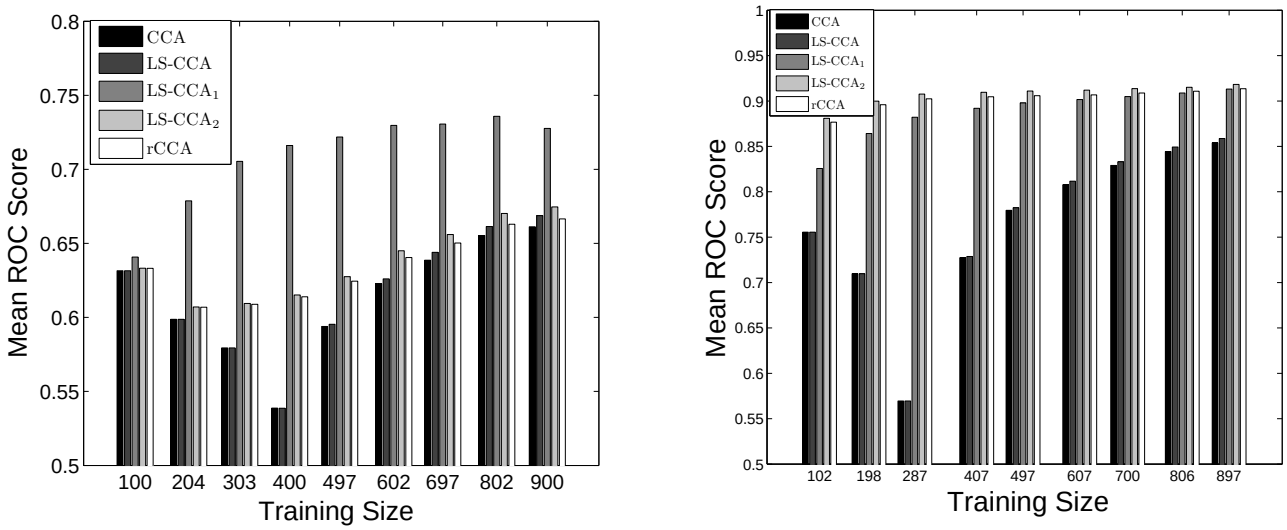

Figure 1. Comparison of all algorithms on gene data set (left) and scene data set (right) in terms of mean ROC scores.

is the case in many applications. Specifically, we use a gene data set with the dimensionality fixed at $d = 384$, while the size of the training set varies from 100 to 900 with a step size about 100.

The performance of different algorithms as the size of training set increases is presented in Figure 1 (left graph). We can observe that in general, the performance of all algorithms increases as the training size increases. When n is small, the condition in Theorem 1 holds, thus CCA and LS-CCA are equivalent, and they achieve the same performance. When n further increases, CCA and LS-CCA achieve different ROC scores, although the difference is always very small in our experiment. Similar to the last experiment, we can observe from the figure that the regularized methods perform much better than CCA and LS-CCA, and LS-CCA$_2$ is comparable to rCCA. The sparse formulation LS-CCA$_1$ performs the best for this data set.

5.3. Scene Data Set

We conduct a similar set of experiments on the scene data. As in the gene data set, the equivalence relationship holds when the condition in Theorem 1 holds.

For the performance comparison and sensitivity study, we generate a sequence of training sets with the size n ranging from 100 to 900 with a step size around 100. The results are summarized in Figure 1 (right graph). Similar to the gene data set, CCA and LS-CCA achieve the same performance when n is small, and they differ slightly when n is large. We can also observe from the figure that the regularized algorithms including rCCA, and LS-CCA$_2$, and LS-CCA$_1$ perform much better than CCA and LS-CCA without regularization, and LS-CCA$_2$ performs slightly better than others in this data set.

5.4. The Entire CCA Solution Path

In this experiment, we investigate the sparse CCA model, i.e., LS-CCA$_1$ using the scene data set. Recall that the sparseness of the weight vectors w_i's depends on the sparseness coefficient γ between 0 and 1.

Figure 2 shows the entire collection of solution paths for a subset of the coefficients from the first weight vector w_1. The x-axis denotes the sparseness coefficient γ, and the y-axis denotes the value of the coefficients. The vertical lines denote (a subset of) the turning point of the path, as the solution path for each of the coefficients is piecewise linear (Efron et al., 2004). We can observe from Figure 2 that when $\gamma = 1$, most of the coefficients are non-zero, i.e., the model is dense. When the value of the sparseness coefficient γ decreases (from the right to the left side along the x-axis), more and more coefficients become exactly zero. All coefficients become zero when $\gamma = 0$.

6. Conclusion and Future Work

In this paper we show that CCA for multi-label classifications can be formulated as a least squares problem under a mild condition, which tends to hold for high-dimensional data. Based on the equivalence relationship established in this paper, we propose several CCA extensions including sparse CCA. We have conducted experiments on a collection of multi-label data

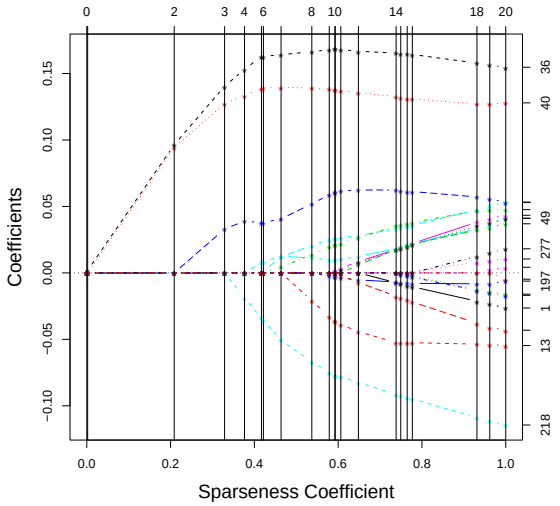

Figure 2. The entire collection of solution paths for a subset of the coefficients from the first weight vector w_1 on the scene data set. The x-axis denotes the sparseness coefficient γ, and the y-axis denotes the value of the coefficients.

sets to validate the proposed equivalence relationship. Our experimental results show that the performance of the proposed least squares formulation and CCA is very close even when the condition does not hold. Results also demonstrate the effectiveness of the proposed CCA extensions.

The proposed least squares formulation facilitates the incorporation of the unlabeled data into the CCA framework through the graph Laplacian, which captures the local geometry of the data (Belkin et al., 2006). We plan to examine the effectiveness of this semi-supervised CCA model for learning from both labeled and unlabeled data. The proposed sparse CCA performs well for the gene data set. We plan to analyze the biological relevance of the features extracted via the sparse CCA model.

Abstract

In apprenticeship learning, the goal is to learn a policy in a Markov decision process that is at least as good as a policy demonstrated by an expert. The difficulty arises in that the MDP's true reward function is assumed to be unknown. We show how to frame apprenticeship learning as a linear programming problem, and show that using an off-the-shelf LP solver to solve this problem results in a substantial improvement in running time over existing methods — up to two orders of magnitude faster in our experiments. Additionally, our approach produces stationary policies, while all existing methods for apprenticeship learning output policies that are "mixed", i.e. randomized combinations of stationary policies. The technique used is general enough to convert any mixed policy to a stationary policy.

1. Introduction

In apprenticeship learning, as with policy learning for Markov decision processes (MDPs), the objective is to find a good policy for an autonomous agent, called the "apprentice", in a stochastic environment. While the setup of an apprenticeship learning problem is almost identical to that of policy learning in an MDP, there are a few key differences. In apprenticeship learning the true reward function is unknown to the apprentice, but is assumed to be a weighted combination of several known functions. The apprentice is also assumed to have access to demonstrations from another agent, called the "expert", executing a policy in the same environment. The goal of the apprentice is to find a policy that is at least as good as the expert's policy with respect to the true reward function. This is distinct from policy learning, where the goal is to find an optimal policy with respect to the true reward function (which cannot be done in this case because it is unknown).

The apprenticeship learning framework, introduced by Abbeel & Ng (2004), is motivated by a couple of observations about real applications. The first is that reward functions are often difficult to describe exactly, and yet at the same time it is usually easy to specify what the rewards must depend on. A typical example, investigated by Abbeel & Ng (2004), is driving a car. When a person drives a car, it is plausible that her behavior can be viewed as maximizing some reward function, and that this reward function depends on just a few key properties of each environment state: the speed of the car, the position of other cars, the terrain, etc. The second observation is that demonstrations of good policies by experts are often plentiful. This is certainly true in the car driving example, as it is in many other applications.

Abbeel & Ng (2004) assumed that the true reward function could be written as a linear combination of k known functions, and described an iterative algorithm that, given a small set of demonstrations of the expert policy, output an apprentice policy within $O(k \log k)$ iterations that was nearly as good as the expert's policy. Syed & Schapire (2008) gave an algorithm that achieved the same guarantee in $O(\log k)$ iterations. They also showed that by assuming that the linear combination is also a convex one, their algorithm can sometimes find an apprentice policy that is substantially better than the expert's policy. Essentially, the assumption of positive weights implies that the apprentice has some prior knowledge about which policies are better than others, and their algorithm leverages this knowledge.

Existing algorithms for apprenticeship learning share a couple of properties. One is that they each use an algorithm for finding an MDP's optimal policy (e.g. value iteration or policy iteration) as a subroutine. Another is that they output apprentice policies that are "mixtures", i.e. randomized combinations of stationary policies. A stationary policy is a function of just the current environment state.

Our first contribution in this paper is to show that, if one uses the linear programming approach for finding an

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

MDP's optimal policy (Puterman, 1994) as a subroutine, then one can modify Syed & Schapire's (2008) algorithm so that it outputs a stationary policy instead of a mixed policy. Stationary policies are desirable for a number of reasons, e.g. they are simpler to describe, and are more natural and intuitive in terms of the behavior that they prescribe. Moreover, this technique can be straightforwardly applied to any mixed policy, such as the ones output by Abbeel & Ng's (2004) algorithms, to convert it to a stationary policy that earns the same expected cumulative reward.

Our technique leads naturally to the second contribution of this paper, which is the formulation of the apprenticeship learning problem as a linear program. We prove that the solution to this LP corresponds to an apprentice policy that has the same performance guarantees as those produced by existing algorithms, and that the efficiency of modern LP solvers results in a very substantial improvement in running time compared to Syed & Schapire's (2008) algorithm — up to two orders of magnitude in our experiments.

In work closely related to apprenticeship learning, Ratliff, Bagnell & Zinkevich (2006) described an algorithm for learning the true reward function by assuming that the expert's policy is not very different from the optimal policy. They took this approach because they wanted to learn policies that were similar to the expert's policy. In apprenticeship learning, by contrast, the learned apprentice policy can be very different from the expert's policy.

2. Preliminaries

Formally, an *apprenticeship learning problem* $\left(\mathcal{S}, \mathcal{A}, \theta, \alpha, \gamma, R^1 \ldots R^k, \mathcal{D}\right)$ closely resembles a Markov decision process. At each time step t, an autonomous agent occupies a state s_t from a finite set $\mathcal{S}$, and can take an action a_t from a finite set $\mathcal{A}$. When the agent is in state s, taking action a leads to state s' with transition probability $\theta_{sas'} \triangleq \Pr(s_{t+1} = s' \mid s_t = s, a_t = a)$. Initial state probabilities are given by $\alpha_s \triangleq \Pr(s_0 = s)$. The agent decides which actions to take based on its policy π, where $\pi_{sa} \triangleq \Pr(a_t = a \mid s_t = s)$. The value of a policy π is given by

$$V(\pi) \triangleq E\left[\sum_{t=0}^{\infty} \gamma^t R_{s_t a_t} \;\middle|\; \alpha, \pi, \theta\right]$$

where $R_{sa} \in [-1, 1]$ is the reward associated with the state-action pair (s, a), and $\gamma \in [0, 1)$ is a discount factor. An optimal policy π^* is one that satisfies $\pi^* = \arg\max_\pi V(\pi)$. We say a policy π is *ϵ-optimal* if $V(\pi^*) - V(\pi) \leq \epsilon$.

A policy π has *occupancy measure* x^π if

$$x^\pi_{sa} = E\left[\sum_{t=0}^{\infty} \gamma^t \mathbf{1}_{(s_t = s \wedge a_t = a)} \;\middle|\; \alpha, \pi, \theta\right] \qquad (1)$$

for all s, a. In other words, x^π_{sa} is the expected (discounted) number of visits to state-action pair (s, a) when following policy π.

Unlike an MDP, in apprenticeship learning the true reward function R is unknown. Instead, we are given *basis reward functions*[1] $R^1 \ldots R^k$, where R^i_{sa} is the reward of state-action pair (s, a) with respect to the ith basis reward function. We assume that the true reward function R is an unknown convex combination w^* of the basis reward functions, i.e., for all s, a

$$R_{sa} = \sum_i w^*_i R^i_{sa}$$

where the unknown weights satisfy $w^*_i \geq 0$ and $\sum_i w^*_i = 1$. Each basis reward function R^i has a corresponding *basis value function* $V^i(\pi)$ given by

$$V^i(\pi) \triangleq E\left[\sum_{t=0}^{\infty} \gamma^t R^i_{s_t a_t} \;\middle|\; \alpha, \pi, \theta\right].$$

Given the assumption of positive weights, the value of k can be viewed as a measure of how much the apprentice knows about the true reward function. If $k = 1$, the (only) basis value of a policy is equal to its true value, and the situation reduces to a traditional MDP. At the other extreme, if the ith basis reward function is just an indicator function for the ith state-action pair, then $k = |\mathcal{SA}|$, and the basis values of a policy are equal to its occupancy measure. In this situation, the apprentice knows essentially nothing about which policies are better than others.

The positive weight assumption also implies that if for state-action pairs (s, a) and (s', a') we have $R^i_{sa} \geq R^i_{s'a'}$ for all i, then $R_{sa} \geq R_{s'a'}$. So the basis rewards themselves can encode prior knowledge about the true rewards. If we wish not to assert any such prior knowledge, we can simply add the negative of each basis reward function to the original set, thereby at most doubling the number of basis reward functions.

We also assume that we are given a data set $\mathcal{D}$ of M i.i.d. sample trajectories from an *expert policy* π^E executing in the environment, where the mth trajectory is a sequence of state-action pairs visited by the expert, i.e., $(s^m_0, a^m_0, s^m_1, a^m_1, \ldots, s^m_H, a^m_H)$. For simplicity, we assume that all sample trajectories are truncated to the same length H.

The goal of apprenticeship learning (Abbeel & Ng, 2004) is to find an *apprentice policy* π^A such that

$$V(\pi^A) \geq V(\pi^E) \qquad (2)$$

even though the true value function $V(\pi)$ is unknown (since the true reward function is unknown).

2.1. A More Refined Goal

By our assumptions about the reward functions (and the linearity of expectation), we have

$$V(\pi) = \sum_i w^*_i V^i(\pi).$$

[1] In (Abbeel & Ng, 2004) and (Syed & Schapire, 2008) these functions were called *features*, but we believe that the present terminology is better suited for conveying these functions' role.

Consequently, for any policy π, the smallest possible difference between $V(\pi)$ and $V(\pi^E)$ is $\min_i V^i(\pi) - V^i(\pi^E)$, because in the worst-case, $w_i^* = 1$ for the minimizing i. Based on this observation, Syed & Schapire (2008) proposed finding an apprentice policy π^A that solves the maximin objective

$$v^* = \max_{\pi} \min_i V^i(\pi) - V^i(\pi^E). \tag{3}$$

Note that if π^A is a solution to (3), then $V(\pi^A) \geq V(\pi^E) + v^*$ (because $v^* = \min_i V^i(\pi^A) - V^i(\pi^E) \leq V(\pi^A) - V(\pi^E)$). We also have $v^* \geq 0$ (because $\pi = \pi^E$ is available in (3)). Therefore π^A satisfies the goal of apprenticeship learning given in (2).

Syed & Schapire (2008) showed that in some cases where $V(\pi^E)$ is small, v^* is large, and so adding v^* to the lower bound in (2) serves as a kind of insurance against bad experts. Our algorithms also produce apprentice policies that achieve this more refined goal.

2.2. Estimating the Expert Policy's Values

Our algorithms require knowledge of the basis values of the expert's policy. From the expert's sample trajectories $\mathcal{D}$, we can form an estimate $\widehat{V}^{i,E}$ of $V^i(\pi^E)$ as follows:

$$V^i(\pi^E) \approx \frac{1}{M} \sum_{m=1}^{M} \sum_{t=0}^{H} \gamma^t R^i_{s_t^m a_t^m} \triangleq \widehat{V}^{i,E}.$$

Clearly, as the number of sample trajectories M and the truncation length H increase, the error of this estimate will decrease. Thus the issue of accurately estimating $V^i(\pi^E)$ is related to *sample* complexity, while in this work we are primarily concerned with *computational* complexity. To make our presentation cleaner, we will assume that $\mathcal{D}$ is large enough to yield an estimate $\widehat{V}^{i,E}$ of $V^i(\pi^E)$ such that $|\widehat{V}^{i,E} - V^i(\pi^E)| \leq \epsilon$, for all i. We call such an estimate ϵ-*good*. The sample complexity of apprenticeship learning is treated in (Syed & Schapire, 2008).

2.3. Policy Types

Unless otherwise noted, a policy π is presumed to be stationary, i.e., π_{sa} is the probability of taking action a in state s. One exception is a *mixed policy*. A mixed policy $\tilde{\pi}$ is defined by a set of ordered pairs $\{(\pi^j, \lambda^j)\}_{j=1}^N$. The policy $\tilde{\pi}$ is followed by choosing at time 0 one of the stationary policies π^j, each with probability λ^j, and then following that policy exclusively thereafter. The value of a mixed policy is the expected value of the stationary policies it comprises, i.e.,

$$V(\tilde{\pi}) = E\left[V(\pi^j)\right] = \sum_{j=1}^{N} \lambda^j V(\pi^j), \text{ and}$$

$$V^i(\tilde{\pi}) = E\left[V^i(\pi^j)\right] = \sum_{j=1}^{N} \lambda^j V^i(\pi^j).$$

3. Multiplicative Weights Algorithm for Apprenticeship Learning

Syed & Schapire (2008) observed that solving the objective in (3) is equivalent to finding an optimal strategy in a certain two-player zero-sum game. Because the size of this game's matrix is exponential in the number of states $|\mathcal{S}|$, they adapted a multiplicative weights method for solving extremely large games. The resulting MWAL (Multiplicative Weights Apprenticeship Learning) algorithm is described in Algorithm 1 below.

Algorithm 1 MWAL algorithm

1: **Given:** $\mathcal{S}, \mathcal{A}, \theta, \alpha, \gamma, R^1 \ldots R^k, \mathcal{D}$.
2: Using the expert's sample trajectories $\mathcal{D}$, compute an ϵ-good estimate $\widehat{V}^{i,E}$ of $V^i(\pi^E)$, for all i.
3: Let $\beta = \left(1 + \sqrt{\frac{2 \log k}{T}}\right)^{-1} \in (0, 1]$.
4: Initialize $w_i^1 = \frac{1}{k}$, for $i = 1 \ldots k$.
5: **for** $t = 1 \ldots T$ **do**
6: Compute ϵ-optimal policy π^t for reward function $R_{sa} = \sum_i w_i^t R^i_{sa}$.
7: Compute ϵ-good estimate $\widehat{V}^{i,t}$ of $V^i(\pi^t)$, for $i = 1 \ldots k$.
8: Let $w_i^{t+1} = w_i^t \beta^{\widehat{V}^{i,t} - \widehat{V}^{i,E}}$, for $i = 1 \ldots k$.
9: Renormalize w.
10: **end for**
11: **Return:** Let apprentice policy π^A be the mixed policy defined by $\{(\pi^t, \frac{1}{T})\}_{t=1}^T$.

In each iteration of the MWAL algorithm, an optimal policy π^t is computed with respect to the current weight vector w^t. Then the weights are updated so that w_i is increased/decreased if π^t is a bad/good policy (relative to π^E) with respect to the ith basis reward function.

The next theorem bounds the number of iterations T required for the MWAL algorithm to produce a good apprentice policy. The computational complexity of each iteration is discussed in Section 3.1.

Theorem 1 (Syed & Schapire (2008)). *Let π^A be the mixed policy returned by the MWAL algorithm. If*

$$T \geq O\left(\frac{\log k}{(\epsilon(1-\gamma))^2}\right)$$

then

$$V(\pi^A) \geq V(\pi^E) + v^* - O(\epsilon)$$

where $v^* = \max_\pi \min_i V^i(\pi) - V^i(\pi^E)$.

3.1. MWAL-VI and MWAL-PI

The specification of the MWAL algorithm is somewhat open-ended. Step 6 requires finding an ϵ-optimal policy in an MDP, and Step 7 requires computing ϵ-good estimates of the basis values of that policy. There are several procedures available for accomplishing each of these steps, with each option leading to a different variant of the basic algorithm.

We briefly describe some natural options, and remark on their implications for the overall computational complexity of the MWAL algorithm.

In Step 6, we can find the optimal policy using value iteration (Puterman, 1994), which has a worst-case running time of $O\left(\log_\gamma\left(1/\epsilon(1-\gamma)\right)|\mathcal{S}|^2|\mathcal{A}|\right)$. We can also use value iteration to compute the k basis values in Step 7 (this is sometimes called "policy evaluation"), which implies a worst-case running time of $O\left(k\log_\gamma\left(1/\epsilon(1-\gamma)\right)|\mathcal{S}|^2\right)$. We call this variant the MWAL-VI algorithm.

Another choice for Step 6 is to find the optimal policy using policy iteration (Puterman, 1994). No polynomial time bound for policy iteration is known; however, in practice it has often been observed to be faster than value iteration. We call this variant the MWAL-PI algorithm. In Section 8, we present experiments comparing these algorithms to the ones described later in the paper.

4. Dual Methods for MDPs

As we previously observed, the MWAL algorithm must repeatedly find the optimal policy in an MDP, and this task is usually accomplished via classic iterative techniques such as value iteration and policy iteration. However, there are other techniques available for solving MDPs, and in this work we show that they can lead to better algorithms for apprenticeship learning. Consider the following linear program:

$$\max_x \sum_{s,a} R_{sa}x_{sa} \tag{4}$$

such that

$$\sum_a x_{sa} = \alpha_s + \gamma\sum_{s',a} x_{s'a}\theta_{s'as} \tag{5}$$

$$x_{sa} \geq 0 \tag{6}$$

It is well-known (Puterman, 1994) that if x^* is a solution to (4) - (6), then $\pi^*_{sa} = \frac{x^*_{sa}}{\sum_a x^*_{sa}}$ is an optimal policy, and x^* is the occupancy measure of π^*. Often (5) - (6) are called the *Bellman flow constraints*.

The linear program in (4) - (6) is actually the dual of the linear program that is typically used to find an optimal policy in an MDP. Accordingly, solving (4) - (6) is often called the *Dual LP* method of solving MDPs .

Having found an optimal policy by the Dual LP method, computing its values is straightforward. The next lemma follows immediately from the definitions of the occupancy measure and value of a policy.

Lemma 1. *If policy π has occupancy measure x^π, then $V(\pi) = \sum_{s,a} R_{sa}x^\pi_{sa}$ and $V^i(\pi) = \sum_{s,a} R^i_{sa}x^\pi_{sa}$.*

5. Main Theoretical Tools

Recall that the MWAL algorithm produces mixed policies. In Sections 6 and 7, we will present algorithms that achieve the same theoretical guarantees as the MWAL algorithm, but produce stationary policies (and are also faster). To prove the correctness of these algorithms, we need to show that every mixed policy has an equivalent stationary policy.

In Section 4, we said that the Dual LP method of solving an MDP outputs the occupancy measure of an optimal policy. In fact, *all* x that satisfy the Bellman flow constraints (5) - (6) are the occupancy measure of some stationary policy, as the next theorem shows.

Theorem 2. *Let x satisfy the Bellman flow constraints* (5) - (6)*, and let $\pi_{sa} = \frac{x_{sa}}{\sum_a x_{sa}}$ be a stationary policy. Then x is the occupancy measure for π. Conversely, if π is a stationary policy such that x is its occupancy measure, then $\pi_{sa} = \frac{x_{sa}}{\sum_a x_{sa}}$ and x satisfies the Bellman flow constraints.*

An equivalent result as Theorem 2 is given in (Feinberg & Schwartz, 2002), p. 178. For completeness, a simple and direct proof is contained in the Appendix.

The Bellman flow constraints make it very easy to show that, for every mixed policy, there is a stationary policy that has the same value.

Theorem 3. *Let $\tilde{\pi}$ be a mixed policy defined by $\{(\pi^j, \lambda^j)\}_{j=1}^N$, and let x^j be the occupancy measure of π^j, for all j. Let $\hat{\pi}$ be a stationary policy where*

$$\hat{\pi}_{sa} = \frac{\sum_j \lambda^j x^j_{sa}}{\sum_a \sum_j \lambda^j x^j_{sa}}.$$

Then $V(\hat{\pi}) = V(\tilde{\pi})$.

Proof. By Theorem 2, x^j satisfies the Bellman flow constraints (5) - (6) for all j. Let $\hat{x}_{sa} = \sum_j \lambda^j x^j_{sa}$. By linearity, $\hat{x}$ also satisfies the Bellman flow constraints. Hence, by Theorem 2, the stationary policy $\hat{\pi}$ defined by $\hat{\pi}_{sa} = \frac{\hat{x}_{sa}}{\sum_a \hat{x}_{sa}}$ has occupancy measure $\hat{x}$. Therefore,

$$V(\hat{\pi}) = \sum_{s,a} R_{sa}\hat{x}_{sa} = \sum_j \lambda^j \sum_{s,a} R_{sa}x^j_{sa} = \sum_j \lambda^j V(\pi^j)$$
$$= V(\tilde{\pi}).$$

where these equalities use, in order: Lemma 1; the definition of $\hat{x}$; Lemma 1; the definition of a mixed policy. □

6. MWAL-Dual Algorithm

In this section, we will make a minor modification to the MWAL algorithm so that it outputs a stationary policy instead of a mixed policy.

Recall that the MWAL algorithm requires, in Steps 6 and 7, a way to compute an optimal policy and its basis values, but that no particular methods are prescribed. Our proposal is to use the Dual LP method in Step 6 to find the occupancy measure x_t of a policy π_t that is ϵ-optimal for reward function $R_{sa} = \sum_i w^t_i R^i_{sa}$. Then in Step 7 we let

$\widehat{V}^{i,t} = \sum_{s,a} R^i_{sa} x^t_{sa}$, for $i = 1 \ldots k$. Note that Lemma 1 implies $\widehat{V}^{i,t} = V^i(\pi^t)$.

Now we can apply Theorem 3 to combine all the policies computed during the MWAL algorithm into a single stationary apprentice policy. This amounts to changing Step 11 to the following:

> **Return:** Let apprentice policy π^A be the stationary policy defined by
>
> $$\pi^A_{sa} = \frac{\frac{1}{T}\sum_t x^t_{sa}}{\sum_a \frac{1}{T}\sum_t x^t_{sa}}.$$

We call this modified algorithm the MWAL-Dual algorithm, after the method it uses to compute optimal policies.

It is straightforward to show that these changes to the MWAL algorithm do not affect its performance guarantee.

Theorem 4. *Let π^A be the stationary policy returned by the MWAL-Dual algorithm. If*

$$T \geq O\left(\frac{\log k}{(\epsilon(1-\gamma))^2}\right)$$

then

$$V(\pi^A) \geq V(\pi^E) + v^* - O(\epsilon)$$

where $v^* = \max_\pi \min_i V^i(\pi) - V^i(\pi^E)$.

Proof. By Theorem 3, the stationary policy returned by the MWAL-Dual algorithm has the same value as the mixed policy returned by the original MWAL algorithm. Hence the guarantee in Theorem 1 applies to the MWAL-Dual algorithm as well. □

Of course, the trick used here to convert a mixed policy to a stationary one is completely general, provided that the occupancy measures of the component policies can be computed. For example, this technique could be applied to the mixed policy output by the algorithms due to Abbeel & Ng (2004).

Let $T(n)$ be the worst-case running time of an LP solver on a problem with at most n constraints and variables.[2] For a typical LP solver, $T(n) = O(n^{3.5})$ (Shu-Cherng & Puthenpura, 1993), although they tend to be much faster in practice. Using this notation, we can bound the running time of Steps 6 and 7 in the MWAL-Dual algorithm. Finding an optimal policy using the Dual LP method takes $T(|\mathcal{S}||\mathcal{A}|)$ time. And by Lemma 1, given the occupancy measure of a policy, we can compute its basis values in $O(k|\mathcal{S}||\mathcal{A}|)$ time.

7. LPAL Algorithm

We now describe a way to use the Bellman flow constraints to find a good apprentice policy in a much more direct fashion than the MWAL algorithm. Recall the objective function proposed in (Syed & Schapire, 2008) for solving apprenticeship learning:

$$v^* = \max_\pi \min_i V^i(\pi) - V^i(\pi^E) \tag{7}$$

We observed earlier that, if π^A is a solution to (7), then $V(\pi^A) \geq V(\pi^E) + v^*$, and that $v^* \geq 0$. In this section, we describe a linear program that solves (7). In Section 8, we describe experiments that show that this approach is much faster than the MWAL algorithm, although it does have some disadvantages, which we also illustrate in Section 8.

Our LPAL (Linear Programming Apprenticeship Learning) algorithm is given in Algorithm 2. The basic idea is to use the Bellman flow constraints (5) - (6) and Lemma 1 to define a feasible set containing all (occupancy measures of) stationary policies whose basis values are above a certain lower bound, and then maximize this bound.

Algorithm 2 LPAL algorithm

1: **Given:** $\mathcal{S}, \mathcal{A}, \theta, \alpha, \gamma, R^1 \ldots R^k, \mathcal{D}$.
2: Using the expert's sample trajectories $\mathcal{D}$, compute an ϵ-good estimate $\widehat{V}^{i,E}$ of $V^i(\pi^E)$, for all i.
3: Find a solution (B^*, x^*) to this linear program:

$$\max_{B,x} \quad B \tag{8}$$

such that

$$B \leq \sum_{s,a} R^i_{sa} x_{sa} - \widehat{V}^{i,E} \tag{9}$$

$$\sum_a x_{sa} = \alpha_s + \gamma \sum_{s',a} x_{s'a}\theta_{s'as} \tag{10}$$

$$x_{sa} \geq 0 \tag{11}$$

4: **Return:** Let apprentice policy π^A be the stationary policy defined by

$$\pi^A_{sa} = \frac{x^*_{sa}}{\sum_a x^*_{sa}}.$$

Theorem 5. *Let π^A be the stationary policy returned by the LPAL algorithm. Then*

$$V(\pi^A) \geq V(\pi^E) + v^* - O(\epsilon)$$

where $v^* = \max_\pi \min_i V^i(\pi) - V^i(\pi^E)$.

Proof. By Theorem 2, the Bellman flow constraints (10) - (11) imply that all feasible x correspond to the occupancy measure of some stationary policy π. Using this fact and Lemma 1, we conclude that solving the linear program is equivalent to finding (B^*, π^A) such that

$$B^* = \min_i V^i(\pi^A) - \widehat{V}^{i,E}$$

and B^* is as large as possible. Since $|\widehat{V}^{i,E} - V^i(\pi^E)| \leq \epsilon$ for all i, we know that $B^* \geq v^* - \epsilon$. Together with (9) and

[2] Technically, the time complexity of a typical LP solver also depends on the number of bits in the problem representation.

Lemma 1 this implies

$$V^i(\pi^A) = \sum_{s,a} R^i_{sa} x^*_{sa} \geq \widehat{V}^{i,E} + B^* \geq V^i(\pi^E) + v^* - 2\epsilon.$$

□

Note that the *overall* worst-case running time of the LPAL algorithm is $T(|\mathcal{S}||\mathcal{A}| + k)$, where $T(n)$ is the complexity of an LP solver.

8. Experiments

8.1. Gridworld

We tested each algorithm in gridworld environments that closely resemble those in the experiments of Abbeel & Ng (2004). Each gridworld is an $N \times N$ square of states. Movement is possible in the four compass directions, and each action has a 30% chance of causing a transition to a random state. Each gridworld is partitioned into several square regions, each of size $M \times M$. We always choose M so that it evenly divides N, so that each gridworld has $k = (\frac{N}{M})^2$ regions. Each gridworld also has k basis reward functions, where the ith basis reward function R^i is a 0-1 indicator function for the ith region.

For each gridworld, in each trial, we randomly chose a sparse weight vector w^*. Recall that the true reward function has the form $R(s) = \sum_i w^*_i R^i(s)$, so in these experiments the true reward function just encodes that some regions are more desirable than others. In each trial, we let the expert policy π^E be the optimal policy with respect to R, and then supplied the basis values $V^i(\pi^E)$, for all i, to the MWAL-VI, MWAL-PI, MWAL-Dual and LPAL algorithms.[3]

Our experiments were run on an ordinary desktop computer. We used the Matlab-based `CVX` package (Grant & Boyd, 2008) for our LP solver. Each of the values in the tables below is the time, in seconds, that the algorithm took to find an apprentice policy π^A such that $V(\pi^A) \geq 0.95V(\pi^E)$. Each running time is the average of 10 trials.

Table 1. Time (sec) to find π^A s. t. $V(\pi^A) \geq 0.95V(\pi^E)$

Gridworld Size	MWAL-VI (sec)	MWAL-PI (sec)	MWAL-Dual (sec)	LPAL (sec)
16×16	6.43	5.78	46.99	1.46
24×24	14.45	10.27	90.16	1.55
32×32	27.23	15.04	247.38	2.76
48×48	61.37	35.33	791.61	8.62
64×64	114.12	85.26	3651.70	30.52
128×128	406.24	307.58	4952.74	80.21
256×256	1873.93	1469.56	29988.85	588.60

[3]Typically in practice, π_E will be unknown, and so the basis values would need to be estimated from the data set of expert sample trajectories $\mathcal{D}$. However, since we are primarily concerned with computational complexity in this work, and not sample complexity, we sidestep this issue and just compute each $V^i(\pi^E)$ directly.

Table 2. Time (sec) to find π^A s. t. $V(\pi^A) \geq 0.95V(\pi^E)$

Gridworld Size	Number of Regions	MWAL-VI (sec)	MWAL-PI (sec)	MWAL-Dual (sec)	LPAL (sec)

In the first set of experiments (Table 1), we tested the algorithms in gridworlds of varying sizes, while keeping the number of regions in each gridworld fixed (64 regions). Recall that the number of regions is equal to the number of basis reward functions. In the next set of experiments (Table 2), we varied the number of regions while keeping the size of the gridworld fixed.

Several remarks about these results are in order. For every gridworld size and every number of regions, the LPAL algorithm is substantially faster than the other algorithms — in some cases two orders of magnitude faster. As we previously noted, LP solvers are often much more efficient than their theoretical guarantees. Interestingly, in Table 2, the running time for LPAL eventually decreases as the number of regions increases. This may be because the number of constraints in the linear program increases with the number of regions, and more constraints often make a linear program problem easier to solve.

Also, the MWAL-Dual algorithm is much slower than the other algorithms. We suspect this is only because the MWAL-Dual algorithm calls the LP solver in each iteration (unlike the LPAL algorithm, which calls it just once), and there is substantial overhead to doing this. Modifying MWAL-Dual so that it uses the LP solver as less of a black-box may be a way to alleviate this problem.

8.2. Car driving

In light of the results from the previous section, one might reasonably wonder whether there is any argument for using an algorithm other than LPAL. Recall that, in those experiments, the expert's policy was an optimal policy for the unknown reward function. In this section we explore the behavior of each algorithm when this is not the case, and find that MWAL produces better apprentice policies than LPAL. Our experiments were run in a car driving simulator modeled after the environments in (Abbeel & Ng, 2004) and (Syed & Schapire, 2008).

The task in our driving simulator is to navigate a car on a busy three-lane highway. The available actions are to move left, move right, drive faster, or drive slower. There are three basis reward functions that map each environment state to a numerical reward: collision (0 if contact with an-

other car, and 1/2 otherwise), off-road (0 if on the grass, and 1/2 otherwise), and speed (1/2, 3/4 and 1 for each of the three possible speeds, with higher values corresponding to higher speeds). The true reward function is assumed to be some unknown weighted combination w^* of the basis reward functions. Since the weights are assumed to be positive, by examining the basis reward functions we see that the true reward function assigns higher reward to states that are intuitively "better".

We designed three experts for these experiments, described in Table 3. Each expert is optimal for one of the basis reward functions, and mediocre for the other two. Therefore each expert policy π^E is an optimal policy if $w^* = w^E$, where w^E is the weight vector that places all weight on the basis reward function for which π^E is optimal. At the same time, each π^E is very likely to be suboptimal for a randomly chosen w^*.

We used the MWAL and LPAL algorithms to learn apprentice policies from each of these experts.[4] The results are presented in Table 4. We let $\gamma = 0.9$, so the maximum value of the basis value function corresponding to speed was 10, and for the others it was 5. Each of the reported policy values for randomly chosen w^* was averaged over 10,000 uniformly sampled w^*'s. Notice that for each expert, when w^* is chosen randomly, MWAL outputs better apprentice policies than LPAL.

Table 3. Expert types

	Speed	Collisions (per sec)	Off-roads (per sec)
"Fast" expert	Fast	1.1	10
"Avoid" expert	Slow	0	10
"Road" expert	Slow	1.1	0

Table 4. Driving simulator experiments.

Expert type	Algorithm used	$w^* = w^E$		w^* chosen randomly	
		$V(\pi^A)$	$V(\pi^E)$	$V(\pi^A)$	$V(\pi^E)$
"Fast"	MWAL	10	10	9.83	8.25
	LPAL	10	10	8.84	8.25
"Avoid"	MWAL	5	5	8.76	6.32
	LPAL	5	5	7.26	6.32
"Road"	MWAL	5	5	9.74	7.49
	LPAL	5	5	8.12	7.49

9. Conclusion and Future Work

Each of the algorithms for apprenticeship learning presented here have advantages and disadvantages that make them each better suited to different situations. As our experiments showed, the LPAL algorithm is much faster than any of the MWAL variants, and so is most appropriate for problems with large state spaces or many basis reward functions. And unlike the original MWAL algorithm, it produces a stationary policy, which make it a good choice whenever a simple and easily interpretable apprentice policy is desired. On the other hand, we also presented evidence that LPAL performs poorly when the expert policy is far from an optimal policy for the true reward function. If one suspects in advance that this may be the case, then one of the MWAL variants would be a better choice for a learning algorithm. Among these variants, only MWAL-Dual produces a stationary policy, although it has the drawback of being the slowest algorithm that we tested.

Although the theoretical performance guarantees of both the MWAL and LPAL algorithm are identical, the results in Table 4 suggest that the two algorithms are not equally effective. It seems possible that the current theoretical guarantees for the MWAL algorithm are not as strong as they could be. Investigation of this possibility is ongoing work.

One way to describe the poor performance of the LPAL algorithm versus MWAL is to say that, when there are several policies that are better than the expert's policy, the LPAL algorithm fails to optimally break these "ties". This characterization suggests that recent techniques for computing robust strategies in games (Johanson et al., 2008) may be an avenue for improving the LPAL algorithm.

It would also be interesting to examine practically and theoretically how apprenticeship learning can be combined with MDP approximation techniques. In particular, the dual linear programming approach in this work might combine nicely with recent work on stable MDP approximation techniques based on the dual form (Wang et al., 2008).

[4] Each of the MWAL variants behaved in exactly the same way in this experiment. The results presented are for the MWAL-PI variant.

10. Appendix

This is a proof of Theorem 2. Before proceeding, we introduce another linear system. For any stationary policy π, the *π-specific Bellman flow constraints* are given by the following linear system in which the x_{sa} variables are unknown:

$$x_{sa} = \pi_{sa}\alpha_s + \pi_{sa}\gamma \sum_{s',a'} x_{s'a'}\theta_{s'a's} \tag{12}$$

$$x_{sa} \geq 0 \tag{13}$$

The next lemma shows that π-specific Bellman flow constraints have a solution.

Lemma 2. *For any stationary policy π, the occupancy measure x^π of π satisfies the π-specific Bellman flow constraints* (12) - (13).

Proof. Clearly, x^π_{sa} is non-negative for all s, a, and so (13) is satisfied. As for (12), we simply plug in the definition of x^π_{sa} from (1). (In the following derivation, all the expectations and probabilities are conditioned on α, θ, and π. They have been omitted from the notation for brevity.)

$$\begin{aligned}
x^\pi_{sa} &= E\left[\sum_{t=0}^{\infty}\gamma^t \mathbf{1}_{(s_t=s\wedge a_t=a)}\right] \\
&= \sum_{t=0}^{\infty}\gamma^t \Pr(s_t=s, a_t=a) \\
&= \pi_{sa}\alpha_s + \sum_{t=0}^{\infty}\gamma^{t+1}\Pr(s_{t+1}=s, a_{t+1}=a) \\
&= \pi_{sa}\alpha_s \\
&\quad + \sum_{t=0}^{\infty}\gamma^{t+1}\sum_{s',a'}\Pr(s_t=s', a_t=a', s_{t+1}=s, a_{t+1}=a) \\
&= \pi_{sa}\alpha_s + \sum_{t=0}^{\infty}\gamma^{t+1}\sum_{s',a'}\Pr(s_t=s', a_t=a')\cdot\theta_{s'a's}\pi_{sa} \\
&= \pi_{sa}\alpha_s + \pi_{sa}\gamma\sum_{s',a'}E\left[\sum_{t=0}^{\infty}\gamma^t\mathbf{1}_{(s_t=s'\wedge a_t=a')}\right]\theta_{s'a's} \\
&= \pi_{sa}\alpha_s + \pi_{sa}\gamma\sum_{s',a'}x^\pi_{s'a'}\theta_{s'a's}
\end{aligned}$$

□

Now we show that the solution to the π-specific Bellman flow constraints given by Lemma 2 is unique.

Lemma 3. *For any stationary policy π, the π-specific Bellman flow constraints* (12) - (13) *have at most one solution.*

Proof. Define the matrix

$$A_{(sa,s'a')} \triangleq \begin{cases} 1-\gamma\theta_{s'a's}\pi_{sa} & \text{if } (s,a)=(s',a') \\ -\gamma\theta_{s'a's}\pi_{sa} & \text{otherwise.}\end{cases}$$

and the vector $b_{sa} \triangleq \pi_{sa}\alpha_s$. (Note that A and b are indexed by state-action pairs.) We can re-write (12) - (13) equivalently as

$$Ax = b \tag{14}$$

$$x \geq 0 \tag{15}$$

The matrix A is column-wise strictly diagonally dominant. This is because $\sum_{s'}\theta_{sas'} = 1$, $\sum_a \pi_{sa} = 1$ and $\gamma < 1$, so for all s', a'

$$\begin{aligned}
&\sum_{s,a}\gamma\theta_{s'a's}\pi_{sa} = \gamma < 1 \\
\Rightarrow\quad & 1-\gamma\theta_{s'a's'}\pi_{s'a'} > \sum_{(s,a)\neq(s',a')}\gamma\theta_{s'a's}\pi_{sa} \\
\Rightarrow\quad & |A_{(s'a',s'a')}| > \sum_{(s,a)\neq(s',a')}|A_{(sa,s'a')}|.
\end{aligned}$$

where the last line is the definition of column-wise strict diagonal dominance. This implies that A is non-singular (Horn & Johnson, 1985), so (14) - (15) has at most one solution. □

We are now ready to prove Theorem 2.

Proof of Theorem 2. For the first direction of the theorem, we assume that x satisfies the Bellman flow constraints (5) - (6), and that $\pi_{sa} = \dfrac{x_{sa}}{\sum_a x_{sa}}$. Therefore,

$$\pi_{sa} = \frac{x_{sa}}{\alpha_s + \gamma\sum_{s',a'}x_{s'a'}\theta_{s'a's}}. \tag{16}$$

Clearly x is a solution to the π-specific Bellman flow constraints (12) - (13), and Lemmas 2 and 3 imply that x is the occupancy measure of π.

For the other direction of the theorem, we assume that x is the occupancy measure of π. Lemmas 2 and 3 imply that x is the unique solution to the π-specific Bellman flow constraints (12) - (13). Therefore, π is given by (16). And since $\sum_a \pi_{sa} = 1$, we have

$$\frac{\sum_a x_{sa}}{\alpha_s + \gamma\sum_{s',a'}x_{s'a'}\theta_{s'a's}} = 1$$

which can be rearranged to show that x satisfies the Bellman flow constraints, and also combined with (16) to show that $\pi_{sa} = \dfrac{x_{sa}}{\sum_a x_{sa}}$. □

Composite Kernel Learning

Abstract

The Support Vector Machine (SVM) is an acknowledged powerful tool for building classifiers, but it lacks flexibility, in the sense that the kernel is chosen prior to learning. Multiple Kernel Learning (MKL) enables to learn the kernel, from an ensemble of basis kernels, whose combination is optimized in the learning process. Here, we propose Composite Kernel Learning to address the situation where distinct components give rise to a group structure among kernels. Our formulation of the learning problem encompasses several setups, putting more or less emphasis on the group structure. We characterize the convexity of the learning problem, and provide a general wrapper algorithm for computing solutions. Finally, we illustrate the behavior of our method on multi-channel data where groups correpond to channels.

1. Motivation

Kernel methods have been extensively used in learning problems (Schölkopf & Smola, 2001). In these models, the observations are implicitly mapped in a feature space via a mapping $\Phi : \mathcal{X} \to \mathcal{H}$, where $\mathcal{H}$ is a Reproducing Kernel Hilbert Space (RKHS) with reproducing kernel $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$.

We address the problem of learning the kernel in Support Vector Machines (SVM) and related methods. Indeed, the kernel is crucial in many respects, and its relevance is essential to the success of kernel methods. Formally, the primary role of K is to define the evaluation functional in $\mathcal{H}$: $\forall f \in \mathcal{H},\ f(\boldsymbol{x}) = \langle f, K(\boldsymbol{x}, \cdot)\rangle_{\mathcal{H}}$, but K also defines (i) $\mathcal{H}$ itself, since $\forall f \in \mathcal{H},\ f(\boldsymbol{x}) = \sum_{i=1}^{\infty} \alpha_i K(\boldsymbol{x}_i, \boldsymbol{x})$; (ii) a metric, and hence a smoothness functional in $\mathcal{H}$: $\|f\|_{\mathcal{H}}^2 = \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} \alpha_i\alpha_i K(\boldsymbol{x}_i, \boldsymbol{x}_j)$; (iii) a distance between observations: $\|\Phi(\boldsymbol{x}) - \Phi(\boldsymbol{x}')\|^2 = K(\boldsymbol{x}, \boldsymbol{x}) + K(\boldsymbol{x}', \boldsymbol{x}') - 2K(\boldsymbol{x}, \boldsymbol{x}')$.

In this paper, we devise Composite Kernel Learning (CKL), a framework where the kernel is learned in a way to favor the selection of variables or groups of variables. Section 2 motivates our approach while briefly reviewing the different means proposed to extend kernel methods beyond the predefined kernel setup. We then follow in Section 3 by considering some recent developments in variable selection that are relevant for our aims. Section 4 describes the CKL framework; the optimization algorithm is provided in Section 5, and experiments are reported in Section 6.

2. Flexible Kernel Methods

From now on, we restrict our discussion to classification, where, from a learning set $S = \{(\boldsymbol{x}_i, y_i)\}_{i=1}^n$ of pairs of observations and label $(\boldsymbol{x}_i, y_i)$, one aims at building a decision rule that predicts the class label y of any observation $\boldsymbol{x}$. We furthermore focus on the binary case, where $(\boldsymbol{x}_i, y_i) \in \mathcal{X} \times \{\pm 1\}$. However, it should be kept in mind that most of our observations carry on to other settings, such as multiclass classification, clustering or regression with kernel methods.

2.1. Support Vector Machines

A SVM builds the decision rule $\operatorname{sign}\left(f^\star(\boldsymbol{x}) + b^\star\right)$, where $f^\star$ and $b^\star$ are defined as the solution of

$$\begin{cases} \min\limits_{f,b,\boldsymbol{\xi}} & \frac{1}{2}\|f\|_{\mathcal{H}}^2 + C\sum\limits_{i=1}^{n}\xi_i \\ \text{s. t.} & y_i\big(f(\boldsymbol{x}_i) + b\big) \geq 1 - \xi_i \quad 1 \leq i \leq n \\ & \xi_i \geq 0 \qquad\qquad\qquad\quad 1 \leq i \leq n\ . \end{cases} \tag{1}$$

The regularization parameter C is the only adjustable parameter in this procedure. This is usually not flexible

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

enough to provide good results when the kernel is chosen prior to seeing data. Hence, most applications of SVM incorporate a mechanism for learning the kernel.

2.2. Learning the Kernel

Cross-validation is the most rudimentary, but also the most common way to learn the kernel. It consists in (i) defining a family of kernels (*e.g.* Gaussian), indexed by one or more parameters (*e.g.* bandwidth), the so-called kernel hyper-parameters, (ii) running the SVM algorithm on each hyper-parameter setting, and (iii) finally choosing the hyper-parameter minimizing a cross-validation score.

A thorough discussion of the pros and cons of cross-validation is out of the scope of this paper, but it is clear that this approach is inherently limited to one or two hyper-parameters and few trial values. This observation led to several proposals allowing for more flexibility.

2.2.1. Filters, Wrappers & Embedded Methods

Learning the kernel amounts to learn the feature mapping. It should thus be of no surprise that the approaches investigated bear some similarities with the ones developed for variable selection, where one encounters filters, wrappers and embedded methods (Guyon & Elisseeff, 2003). Some general frameworks do not belong to a single category but the distinction is appropriate in most cases.

In filter approaches, the kernel is adjusted before building the SVM, with no explicit relationship to the objective value of Problem (1). For example, the kernel target alignment of Cristianini et al. (2002) adapts the kernel to the available data without training any classifier.

In wrapper algorithms, the SVM solver is the inner loop of two nested optimizers, whose outer loop is dedicated to adjust the kernel. This tuning may be guided by various generalization bounds (Cristianini et al., 1999; Weston et al., 2001; Chapelle et al., 2002).

Kernel learning can also be embedded in Problem (1), with the SVM objective value minimized jointly with respect to the SVM parameters and the kernel hyper-parameters (Grandvalet & Canu, 2003). Our approach, which belongs to this family of methods, is based on the Multiple Kernel Learning (MKL) framework (Lanckriet et al., 2004).

2.2.2. Multiple Kernel Learning

MKL is a joint optimization problem of the coefficients of the SVM classifier and a convex combination of kernels that defines the actual SVM kernel

$$K(\boldsymbol{x}, \boldsymbol{x}') = \sum_{m=1}^{M} \sigma_m K_m(\boldsymbol{x}, \boldsymbol{x}') \ , \tag{2}$$

where each kernel K_m is associated to a RKHS $\mathcal{H}_m$ whose elements will be denoted f_m, and $\{\sigma_m\}_{m=1}^M$ are coefficients to be learned under the convex combination constraints

$$\sum_{m=1}^{M} \sigma_m = 1 \ , \ \ \sigma_m \geq 0 \ , 1 \leq m \leq M \ . \tag{3}$$

Bach et al. (2004) proposed the following formulation of MKL [1]:

$$\begin{cases} \min\limits_{\substack{f_1,\dots,f_M,\\ b,\boldsymbol{\xi}}} \frac{1}{2}\big(\sum\limits_m \|f_m\|_{\mathcal{H}_m}\big)^2 + C\sum\limits_i \xi_i \\ \quad \text{s. t.} \quad y_i\big(\sum\limits_m f_m(\boldsymbol{x}_i) + b\big) \geq 1 - \xi_i \quad 1 \leq i \leq n \\ \qquad\quad \xi_i \geq 0 \qquad\qquad\qquad\qquad 1 \leq i \leq n \,, \end{cases} \tag{4}$$

whose solution leads to a decision rule of the form $\operatorname{sign}\left(\sum_m f_m^\star(\boldsymbol{x}) + b^\star\right)$. This expression of the learning problem is remarkable in that it only deviates slightly from the original SVM problem (1). The squared RKHS norm in $\mathcal{H}$ is simply replaced by a mixed-norm, with the standard RKHS norm within each feature space $\mathcal{H}_m$, and an ℓ_1 norm in $\mathbb{R}^M$ on the vector built by concatenating these norms. This ℓ_1 norm encourages sparse solutions, that is, solutions where some functions f_m have zero norm. In this respect, the MKL problem may be seen as the kernelization of the group-LASSO (Yuan & Lin, 2006).

2.2.3. Composite Kernel Learning

When the individual kernels K_m represent a series, such as Gaussian kernels with different scale parameters, MKL may be used as an alternative to cross-validation. When the input data originates from M differents sources, and that each kernel is affiliated to one input variable, MKL can be used to select relevant input variables.

However, MKL is not meant to address problems where several kernels pertain to one input variable. In this situation, the sparseness mechanism of MKL does not favor solutions discarding all the kernels computed from an irrelevant input. Although most of the related coefficients should vanish in combination (2), spurious correlation may cause irrelevant input variables to participate to the solution.

The flat combination of kernels in MKL does not include a mechanism to cluster the kernels related to one input variable. In order to favor the selection of kernels within predefined groups, one has to define a group structure among kernels, which will guide the selection process through a structured kernel combination. This type of hierarchy among

[1] To lighten notations, the range of indexes is often omitted in summations, in which case: indexes i and j refer to examples and go from 1 to n; index m refers to kernels and goes from 1 to M; index ℓ refers to groups of kernels and goes from 1 to L.

variables has been investigated in linear models (Szafranski et al., 2008; Zhao et al., to appear). We briefly recapitulate the general framework in the following section, before discussing its adaptation to kernel learning in Section 4.

3. Grouped and Hierarchical Selection

The introduction of ℓ_1 penalties, with the seminal paper of Tibshirani (1996) on the LASSO, gave rise to many important theoretical and practical advances in the statistics and machine learning fields. As stated in Section 2.2.2, MKL itself belongs to the series of algorithms affiliated to the LASSO, through its relationship with group-LASSO. In this lineage, Zhao et al. (to appear) defined the very general Composite Absolute Penalties (CAP) family.

3.1. Composite Absolute Penalties

Consider a linear model with M parameters, $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_M)^\mathsf{t}$, and let $I = \{1, \ldots, M\}$ be a set of index on these parameters. A group structure on the parameters is defined by a series of L subsets $\{G_\ell\}_{\ell=1}^L$, where $G_\ell \subseteq I$. Additionally, let $\{\gamma_\ell\}_{\ell=0}^L$ be $L+1$ norm parameters. Then, the member of the CAP family for the chosen groups and norm parameters is

$$\Omega = \sum_\ell \Big(\sum_{m \in G_\ell} |\beta_m|^{\gamma_\ell} \Big)^{\gamma_0/\gamma_\ell} \quad . \tag{5}$$

Mixed-norms correspond to groups defined as a partition of the set of variables. A CAP may also rely on nested groups, $G_1 \subset G_2 \subset \ldots \subset G_L$, and $\gamma_0 = 1$, in which case it favors what Zhao et al. call hierarchical selection, that is, the selection of groups of variables in the predefined order $\{I \setminus G_L\}, \{G_L \setminus G_{L-1}\}, \ldots, \{G_2 \setminus G_1\}, G_1$. This example is provided here to stress that Zhao et al.'s notion of hierarchy differs from the one that follows.

3.2. Hierarchical Penalization

Hierarchical penalization uses shrinking coefficients to transform a ridge-like penalty into a sparse penalizer (Szafranski et al., 2008). The model parameterized by $\boldsymbol{\beta}$ is fitted by minimizing a differentiable loss function $J(\cdot)$, subject to a ridge penalty with adaptive coefficients that encourages sparseness among and within groups:

$$\begin{cases} \min\limits_{\boldsymbol{\beta}, \boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2} J(\boldsymbol{\beta}) + \lambda \sum\limits_\ell \sum\limits_{m \in G_\ell} \frac{\beta_m^2}{\sqrt{\sigma_{1,\ell}\, \sigma_{2,m}}} \\ \text{s. t. } \sum\limits_\ell d_\ell\, \sigma_{1,\ell} = 1\,, \;\; \sigma_{1,\ell} \geq 0 \qquad 1 \leq \ell \leq L \\ \qquad \sum\limits_m \sigma_{2,m} = 1 \quad , \; \sigma_{2,m} \geq 0 \quad 1 \leq m \leq M\,. \end{cases} \tag{6}$$

The Lagrange parameter λ controls the amount of shrinkage, and d_ℓ is the size of group ℓ. The constraints expressed on the two last lines encourage sparseness in $\sigma_{1,\ell}$ and $\sigma_{2,m}$, which induces sparseness in β_m.

Here, the groups G_ℓ form a partition of I, and the hierarchy refers to the tree-structure of the shrinking coefficients: $\sigma_{2,m}$ shrinks parameter β_m, while $\sigma_{1,\ell}$ shrinks the parameters for group G_ℓ. In the words of Zhao et al., the objective here is grouped variable selection.

The minimizer of Problem (6) is the minimizer of

$$\min_{\boldsymbol{\beta}} J(\boldsymbol{\beta}) + \lambda \Big(\sum_\ell d_\ell^{1/4} \Big(\sum_{m \in G_\ell} |\beta_m|^{4/3} \Big)^{3/4} \Big)^2 \quad ,$$

which is essentially a CAP estimate, where parameter d_ℓ only accounts for the group sizes (Szafranski et al., 2008). The inner $\ell_{4/3}$ norm and the outer ℓ_1 norm form a mixed-norm penalty that will be denoted $\ell_{(4/3,1)}$. The overall penalizer favors sparse solutions at the group level, with few leading coefficients within the selected groups.

4. From Multiple to Composite Kernels

MKL has been formalized as a quadratically constrained program by Lanckriet et al. (2004), then as a second-order cone program by Bach et al. (2004). More recently, other formulations led to wrapper algorithms, where the optimization with respect to kernel hyper-parameters is still based on the SVM objective value, but is performed in an outer loop that wraps a standard SVM solver. The outer loop is cutting planes for Sonnenburg et al. (2006), and gradient descent for Rakotomamonjy et al. (2007). Wrapper algorithms have appealing features: (i) they benefit from the developments of solvers specifically tailored for the SVM problem in the inner loop; (ii) they allow to address large-scale problems; (iii) they are multipurpose, since the SVM inner loop may be replaced by another algorithm with little or no adjustments.

We chose to build on gradient-based MKL. First, it has been shown to be more efficient than the SILP approach of Sonnenburg et al. (2006), thanks to the stability of the updates performed in the outer loop, which induces good initializations for the inner loop solver (Rakotomamonjy et al., 2007). Second, and even more important for our purpose, gradient-based MKL is amenable to the extension to groups of kernels, thanks to the formulation of hierarchical penalization of Section 3.2.

4.1. Variational Multiple Kernel Learning

Problem (4) is not differentiable at $\|f_m\|_{\mathcal{H}_m} = 0$, a difficulty that causes a considerable algorithmic burden. The MKL formulation of Rakotomamonjy et al. (2007) can be viewed as a variational form of Problem (4), where M new variables $\sigma_1, \ldots, \sigma_M$ are introduced in order to avoid

these differentiability issues. The resulting problem, which is equivalent to Problem (4), is stated as:

$$\left\{\begin{array}{ll}\min\limits_{\substack{f_1,\dots,f_M,\\ b,\boldsymbol{\xi},\boldsymbol{\sigma}}} & \frac{1}{2}\sum\limits_m \frac{1}{\sigma_m}\|f_m\|^2_{\mathcal{H}_m} + C\sum\limits_i \xi_i \\ \text{s. t.} & y_i\big(\sum\limits_m f_m(\boldsymbol{x}_i)+b\big) \geq 1-\xi_i \quad 1\leq i\leq n \\ & \xi_i \geq 0 \qquad\qquad\qquad\qquad 1\leq i\leq n \\ & \sum\limits_m \sigma_m = 1 \quad ,\ \sigma_m \geq 0 \qquad 1\leq m\leq M\,. \end{array}\right. \tag{7}$$

Here and in what follows, u/v is defined by continuation at zero as $u/0=\infty$ if $u\neq 0$ and $0/0=0$.

The constraints expressed on the last line encourage sparseness in σ_m, which induces sparseness in f_m. As already mentioned in Section 2.2.2, the sparseness applies at the kernel level, ignoring the group structure. The latter is taken into account in the formulation proposed in the following section.

4.2. Variational Composite Kernel Learning

Here, we build on the variational form of the composite absolute penalties presented in Section 3.2 to take into account the group structure. Hierarchical penalization can deal with kernel methods if the ridge penalties are replaced by RKHS norms. We first generalize Problem (6) to obtain smooth variational formulations for arbitrary mixed-norm penalties, so that to address a wide variety of problems including MKL:

$$\left\{\begin{array}{ll}\min\limits_{\substack{f_1,\dots,f_M,\\ b,\boldsymbol{\xi},\boldsymbol{\sigma}_1,\boldsymbol{\sigma}_2}} & \frac{1}{2}\sum\limits_\ell \sigma_{1,\ell}^{-p}\sum\limits_{m\in G_\ell}\sigma_{2,m}^{-q}\|f_m\|^2_{\mathcal{H}_m} + C\sum\limits_i \xi_i \\ \text{s. t.} & y_i\big(\sum\limits_m f_m(\boldsymbol{x}_i)+b\big) \geq 1-\xi_i \quad 1\leq i\leq n \\ & \xi_i \geq 0 \qquad\qquad\qquad\qquad 1\leq i\leq n \\ & \sum\limits_\ell d_\ell\,\sigma_{1,\ell} = 1 \quad ,\ \sigma_{1,\ell}\geq 0 \quad 1\leq \ell\leq L \\ & \sum\limits_m \sigma_{2,m} = 1 \quad ,\ \sigma_{2,m}\geq 0 \quad 1\leq m\leq M, \end{array}\right. \tag{8}$$

where p and q are exponents to be set according to the problem at hand.

This formulation, which is difficult to optimize, is simplified by replacing the two shrinking coefficients $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_2$ by $\boldsymbol{\sigma}$, defined by $\sigma_m = \sigma_{1,\ell}^p\sigma_{2,m}^q$. In a first step, we consider the change of variable that maps $\boldsymbol{\sigma}_2$ to $\boldsymbol{\sigma}$. When $q\neq 0$, this mapping is one-to-one provided $\sigma_{1,\ell}\neq 0$. Furthermore, if $\sigma^\star_{1,\ell}$ and $\sigma^\star_{2,m}$ denote the optimal $\sigma_{1,\ell}$ and $\sigma_{2,m}$ values for Problem (8), we have that $\sigma^\star_{1,\ell}=0 \Rightarrow \sigma^\star_{2,m}=0$, hence Problem (8) is equivalent to

$$\left\{\begin{array}{ll}\min\limits_{\substack{f_1,\dots,f_M,\\ b,\boldsymbol{\xi},\boldsymbol{\sigma}_1,\boldsymbol{\sigma}}} & \frac{1}{2}\sum\limits_m \frac{1}{\sigma_m}\|f_m\|^2_{\mathcal{H}_m} + C\sum\limits_i \xi_i \\ \text{s. t.} & y_i\big(\sum\limits_m f_m(\boldsymbol{x}_i)+b\big) \geq 1-\xi_i \quad 1\leq i\leq n \\ & \xi_i \geq 0 \qquad\qquad\qquad\qquad 1\leq i\leq n \\ & \sum\limits_\ell d_\ell\,\sigma_{1,\ell} = 1 \quad ,\ \sigma_{1,\ell}\geq 0 \quad 1\leq \ell\leq L \\ & \sum\limits_\ell \sigma_{1,\ell}^{-p/q}\sum\limits_{m\in G_\ell}\sigma_m^{1/q} \leq 1 \\ & \sigma_m \geq 0 \qquad\qquad\qquad\qquad 1\leq m\leq M\,. \end{array}\right. \tag{9}$$

The new problem is simplified further by showing that $\boldsymbol{\sigma}_1$ can be dropped out from the optimization process, leading to the following formulation of Composite Kernel Learning (CKL):

$$\left\{\begin{array}{ll}\min\limits_{\substack{f_1,\dots,f_M,\\ b,\boldsymbol{\xi},\boldsymbol{\sigma}}} & \frac{1}{2}\sum\limits_m \frac{1}{\sigma_m}\|f_m\|^2_{\mathcal{H}_m} + C\sum\limits_i \xi_i \\ \text{s. t.} & y_i\big(\sum\limits_m f_m(\boldsymbol{x}_i)+b\big) \geq 1-\xi_i \quad 1\leq i\leq n \\ & \xi_i \geq 0 \qquad\qquad\qquad\qquad 1\leq i\leq n \\ & \sum\limits_\ell \Big(d_\ell^p\Big(\sum\limits_{m\in G_\ell}\sigma_m^{1/q}\Big)^q\Big)^{1/(p+q)} \leq 1 \\ & \sigma_m \geq 0 \qquad\qquad\qquad\qquad 1\leq m\leq M\,, \end{array}\right. \tag{10}$$

Before considering particular settings of interest, we state below two helpful propositions. The first one gives a more interpretable formulation of Problem (10); the second one presents the conditions for convexity of formulation (10), that will guaranty the convergence towards the global minimum for the algorithm described in Section 5.

Proposition 1. ***CAP Formulation:*** *Problem (10) is equivalent to the following MKL problem with a CAP-like penalty on the RKHS norms:*

$$\left\{\begin{array}{ll}\min\limits_{\substack{f_1,\dots,f_M,\\ b,\boldsymbol{\xi}}} & \frac{1}{2}\Big(\sum\limits_\ell d_\ell^{\gamma^*}\big(\sum\limits_{m\in G_\ell}\|f_m\|^\gamma_{\mathcal{H}_m}\big)^{\gamma_0/\gamma}\Big)^{2/\gamma_0} + C\sum\limits_i \xi_i \\ \text{s. t.} & y_i\big(\sum\limits_m f_m(\boldsymbol{x}_i)+b\big) \geq 1-\xi_i \quad 1\leq i\leq n \\ & \xi_i \geq 0 \qquad\qquad\qquad\qquad 1\leq i\leq n, \end{array}\right. \tag{11}$$

with $\gamma=\frac{2}{q+1}$, $\gamma_0=\frac{2}{p+q+1}$ *and* $\gamma^*=1-\frac{\gamma_0}{\gamma}$.

Sketch of proof. Let $\mathcal{L}$ be the Lagrangian of problem (10). The optimality conditions for σ_m are obtained from the first order optimality conditions for σ_m ($\frac{\partial\mathcal{L}}{\partial\sigma_m}=0$):

$$\sigma_m = \Big(\sum_\ell d_\ell^{\gamma^*} s_\ell^{\gamma_0/\gamma}\Big)^{(\gamma_0-2)/\gamma_0} d_\ell^{-\gamma^*} s_\ell^{\gamma^*}\|f_m\|^{2-\gamma}_{\mathcal{H}_m}\,, \tag{12}$$

where $s_\ell = \sum\limits_{m\in G_\ell}\|f_m\|^\gamma_{\mathcal{H}_m}$. Plugging this expression in Problem (10) yields the claimed result. □

Note that the outer exponent $\frac{2}{\gamma_0}$ only influences the strength of the penalty, not its type. Hence, the penalty in the objective function (11) differs from (5) in the RKHS norms $\|\cdot\|_{\mathcal{H}_m}$ and in the parameters d_ℓ that accommodate for group sizes.

Proposition 2. ***Conditions for Convexity:*** *Problem (10) is convex if and only if* $0 \leq q \leq 1$ *and* $0 \leq p+q \leq 1$.

Proof. A problem minimizing a convex criterion on a convex set is convex. The objective function of Problem (10) is convex (Boyd & Vandenberghe, 2004, p. 89). The first, second and fourth constraints define convex sets, and the third one also provided (i) $\left(\sum_{m\in G_\ell} \sigma_m^{1/q}\right)^q$ is a norm, that is $0 \leq q \leq 1$, and (ii) $\sum_\ell t_\ell^{1/(p+q)}$ is convex in t_ℓ, that is $0 \leq p+q \leq 1$. □

Within the values of p and q ensuring convexity, we pick the following particular cases of interest:

- $p = 0$, $q = 1$ yields a LASSO type penalty on the RKHS norms. It results in the generalization of the group-LASSO known as MKL, as formulated in (4);
- $p = 1$, $q = 0$ yields a group-LASSO type penalty on the RKHS norms. It results in another MKL, with L effective kernels $\overline{K}_\ell$, defined as $\overline{K}_\ell = \sum_{m\in G_\ell} K_m$;
- $p = q = \frac{1}{2}$ yields a hierarchical-penalization type penalty on the RKHS norms. It is a true CKL, where there are M effective kernels, and where the penalty favors sparse solutions at the group level, with few leading kernels within the selected groups.

Hence, when p goes from zero to one, with $q = 1-p$, the penalty gives more and more emphasis to the group structure. For most applications where convexity is a key issue, we recommend the balanced setup $p = q = \frac{1}{2}$.

Note however that convex penalties restrict the sparseness of the solution to either the group level or the kernel level. In Section 6, we will illustrate that giving up convexity may turn out to be an interesting option when considering interpretability issues.

5. Algorithm

Our approach to solve Problem (10) draws on the MKL algorithm of Rakotomamonjy et al. (2007). We use the wrapper scheme described below, where the outer loop is carried out by a projected gradient descent update.

5.1. A Gradient-Based Wrapper

The wrapper scheme considers the following constrained optimization problem:

$$\begin{cases} \min\limits_{\boldsymbol{\sigma}} J(\boldsymbol{\sigma}) \\ \text{s. t.} \sum\limits_\ell \left(d_\ell^p \left(\sum\limits_m \sigma_m^{1/q} \right)^q \right)^{1/(p+q)} & \leq 1 \\ \quad \sigma_m \geq 0, & 1 \leq m \leq M\,, \end{cases}$$

where $J(\boldsymbol{\sigma})$ is defined as the objective value of

$$\begin{cases} \min\limits_{f_1,\ldots,f_M,\, b,\boldsymbol{\xi}} \frac{1}{2}\sum\limits_\ell \sum\limits_{m\in G_\ell} \frac{1}{\sigma_m}\|f_m\|_{\mathcal{H}_m}^2 + C\sum\limits_i \xi_i \\ \text{s. t.} \;\; y_i\big(\sum\limits_m f_m(\boldsymbol{x}_i) + b\big) \geq 1-\xi_i\,,\; 1 \leq i \leq n \\ \qquad \xi_i \geq 0\,,\; 1 \leq i \leq n\;. \end{cases} \tag{13}$$

The global optimization problem consists thus of two nested problems. In the inner loop, the criterion is optimized with respect to $f_1, \ldots, f_M$, b and $\boldsymbol{\xi}$, considering that the coefficients $\boldsymbol{\sigma}$ are fixed. In the outer loop, $\boldsymbol{\sigma}$ is updated to decrease the criterion, with f_m, b and $\boldsymbol{\xi}$ being fixed.

Equation (12) may be used to update $\boldsymbol{\sigma}$ in closed form. However, this approach lacks convergence guarantees and may lead to numerical problems, in particular when some elements of $\boldsymbol{\sigma}$ approach zero. Hence, following Rakotomamonjy et al. (2007), we use that the objective function $J(\boldsymbol{\sigma})$ is actually an optimal SVM objective value to update $\boldsymbol{\sigma}$ by an efficient projected gradient descent scheme.

5.2. Computing the Gradient

The dual formulation offers a convenient means to compute the gradient $\nabla J(\boldsymbol{\sigma})$. The derivation of the Lagrangian of Problem (13), which is omitted here for brevity, shows that its dual formulation is identical to the one of a standard SVM using the aggregated kernel $\overline{K}_{\boldsymbol{\sigma}}$ defined in Equation (2). Hence, the dual problem takes the usual form

$$\begin{cases} \max\limits_{\alpha} -\frac{1}{2}\sum\limits_{i,j} \alpha_i\alpha_j y_i y_j \overline{K}_{\boldsymbol{\sigma}}(\boldsymbol{x}_i,\boldsymbol{x}_j) + \sum\limits_i \alpha_i \\ \text{s. t.} \sum\limits_i \alpha_i y_i = 0 \\ \quad C \geq \alpha_i \geq 0 \qquad\qquad 1 \leq i \leq n\;, \end{cases} \tag{14}$$

which can be solved by any SVM solver.

As $J(\boldsymbol{\sigma})$ is defined as the optimal objective value of the convex Problem (13) for which strong duality applies, $J(\boldsymbol{\sigma})$ is also the dual objective value:

$$J(\boldsymbol{\sigma}) = -\frac{1}{2}\sum_{i,j} \alpha_i^\star\alpha_j^\star y_i y_j \overline{K}_{\boldsymbol{\sigma}}(\boldsymbol{x}_i,\boldsymbol{x}_j) + \sum_i \alpha_i^\star\;, \tag{15}$$

where $\alpha^\star$ solves Problem (14).

The existence and computation of the derivatives of $J(\cdot)$ follow from general results on optimal values, such as Theorem 4.1 of Bonnans and Shapiro (1998), which, in a nutshell states that the differentiability of $J(\boldsymbol{\sigma})$ is ensured by the unicity of $\alpha^\star$, and by the differentiability of (15). [2] Furthermore, the derivatives of $J(\boldsymbol{\sigma})$ can be computed as if $\alpha^\star$ were not to depend on $\boldsymbol{\sigma}$. Thus, the gradient $\nabla J(\boldsymbol{\sigma})$ is simply

$$\frac{\partial J}{\partial \sigma_m} = -\frac{1}{2} \sum_{i,j} \alpha_i^\star \alpha_j^\star y_i y_j \sum_\ell \sum_{m \in G_\ell} K_m(\boldsymbol{x}_i, \boldsymbol{x}_j) \ .$$

5.3. CKL Algorithm

Now, we have all the ingredients to adapt the machinery developed for MKL by Rakotomamonjy et al. (2007). According to the process described in Section 5.1, we propose Algorithm 1.

Algorithm 1 Composite Kernel Learning

initialize $\boldsymbol{\sigma}$
solve the SVM problem $\rightarrow J(\boldsymbol{\sigma})$
repeat
  compute direction $d = -\nabla J(\boldsymbol{\sigma})$
  repeat
    compute d', the projection of d onto the tangent of the surface of the admissible set
    compute the smallest step that nullifies a component of $\boldsymbol{\sigma}$
      $\mathcal{S} = \left\{ j : d'_j < 0 \text{ and } \sigma_j \neq 0 \right\}$
      $\nu = \min_{j \in \mathcal{S}} -\frac{\sigma_j}{d'_j} \quad k = \arg\min_{j \in \mathcal{S}} -\frac{\sigma_j}{d'_j} \quad d_k = 0$
    $\boldsymbol{\sigma}^\dagger = \boldsymbol{\sigma} + \nu \, d'$
    project $\boldsymbol{\sigma}^\dagger$ onto the surface of the admissible set
    solve the SVM problem $\rightarrow J(\boldsymbol{\sigma}^\dagger)$
    if $J(\boldsymbol{\sigma}^\dagger) < J(\boldsymbol{\sigma})$ **then** $\boldsymbol{\sigma} = \boldsymbol{\sigma}^\dagger$
  until $J(\boldsymbol{\sigma}^\dagger) \geq J(\boldsymbol{\sigma})$
  compute $\nu^\star = \arg\min_\nu J(\boldsymbol{\sigma} + \nu \, d)$
  $\boldsymbol{\sigma} = \boldsymbol{\sigma} + \nu^\star \, d$
until convergence

The stopping criterion for assessing the convergence of the outer loop can be based on standard criteria for gradient-based algorithms or on the duality gap. In the following experiments, it is based on the stability of $\boldsymbol{\sigma}$ and $J(\boldsymbol{\sigma})$.

6. Channel Selection for BCI

This experiment deals with single trial classification of EEG signals coming from Brain-Computer Interface (BCI). Depending on each BCI paradigm, these EEG signals are recorded from specific electrode positions. However, as stated by Schröder et al. (2005), automated channel selection should be performed for each single subject since it leads to better performances or a substantial reduction of the number of useful channels. Reducing the number of channels involved in the decision function is of primary importance for BCI real-life applications, since it makes the acquisition system easier to use and to set-up.

We use here the dataset from the BCI 2003 competition for the task of interfacing the P300 Speller (Blankertz et al., 2004). The dataset consists in 7560 EEG signals paired with positive or negative stimuli responses. The signal, processed as in (Rakotomamonjy et al., 2005), leads to 7560 examples of dimension 896 (14 time frames for each of the 64 channels).

The experimental protocol is then the following: we have randomly picked 567 training examples from the datasets and used the remaining as testing examples. For each parameter, C has been selected by retaining a small part of the training set as a validation set, for selecting the parameter which the highest AUC. This overall procedure has been repeated 10 times. Using a small part of the examples for training can be justified by the use of ensemble of SVMs (that we do not consider here) on a latter stage of the EEG classification procedure (Rakotomamonjy et al., 2005), and the AUC performance measure is justified by how the EEG recognition is transformed into selected character in the P300.

The 896 features extracted from the EEG signals are not tranformed before classification: we do not use any kernelization. However, to unify the presentation, we will refer to these features as linear kernels. Hence, in this application where the kernels related to a given channel form a group of kernels, we have to learn $M = 896$ coefficients σ_m, divided into $L = 64$ groups.

CKL is well-suited to the classification objectives, since we aim at classifying the EEG trials with as few channels as possible. Furthermore, it is also likely that some time frames are irrelevant, so that variable selection may be carried out within each channel. To reach a sparse solution at the channel and the time frame levels, we test a non-convex parametrization of CKL that encourages sparseness within and between groups.

In the following, $\text{CKL}_{1/2}$ stands for a convex version of our algorithm, with $p = q = 1/2$ (a $\ell_{(4/3,1)}$ mixed-norm), CKL_1 is a non-convex version, with $p = q = 1$ (a $\ell_{(1,2/3)}$ (pseudo) mixed-norm). Note that MKL is also implemented by our algorithm, with $p = 0$ and $q = 1$.

Table 1 summarizes the average performance of SVM, MKL, and CKL, that is, for 4 different penalization terms: quadratic penalization for the classical SVM (which is

[2] The unicity of $\alpha^\star$ is ensured provided that the Gram matrix built from kernel $K_{\boldsymbol{\sigma}}$ is positive-definite. To enforce this property, a small ridge may be added to the diagonal.

trained with the mean of 896 kernels), ℓ_1 norm for MKL, and mixed-norms for the two versions of CKL: $\text{CKL}_{1/2}$ and CKL_1. The number of channels and kernels selected by these algorithms is also reported.

Table 1. Average Results for SVMs with 4 different penalization terms on the BCI datasets.

Algorithms	AUC	# Channels	# Kernels
SVM	83.87 ± 0.8	64	896
MKL	85.43 ± 0.9	62.2 ± 1	255.8 ± 15
$\text{CKL}_{1/2}$	85.49 ± 1.1	62.9 ± 1	835.7 ± 25
CKL_1	84.15 ± 0.8	24.0 ± 4	60.9 ± 10

The prediction performances of the 4 algorithms are similar, with a slight advantage for sparse methods. $\text{CKL}_{1/2}$ is much less sparse than MKL, which itself keeps about four times as much kernels compared to CKL_1. In the number of groups, MKL and $\text{CKL}_{1/2}$ behave similarly, with only one or two channels removed. CKL_1 is much sparser and removes about two thirds of the channels.

Figure 6 represents the median relevance of the electrodes over the 10 experiments. It displays which electrodes have been selected by the different kernel learning methods. For one experiment, the relevance for channel ℓ is computed by the relative contribution of group ℓ to the norm of the solution, that is

$$\frac{1}{Z} \sum_{m \in G_\ell} \frac{1}{\sigma_m^\star} \|f_m^\star\|_{\mathcal{H}_m}^2 \quad ,$$

where Z is a normalization factor that sets the sum of relevances to one.

The results for CKL_1 are particularly neat, with high relevances for the electrodes in the areas of the visual cortex (especially the lateral electrodes PO_7 and PO_8), and the primary motor and Somatosensory cortex ($\text{C}_\bullet$ and CP_Z). The scalp maps for MKL and $\text{CKL}_{1/2}$ are very similar and show the importance of the same regions. In addition they also highlight numerous frontal electrodes that are not likely to be relevant for the BCI P300 Speller paradigm.

7. Conclusion and Further Works

This paper is at the crossroad of kernel learning and variable selection. From the former viewpoint, we extended the multiple kernel learning problem to take into account the group structure among kernels. From the latter viewpoint, we generalized the hierarchical penalization framework to kernel classifiers by considering penalties in RKHS instead of parametric function spaces.

As a side contribution, we also provide a smooth variational formulation for arbitrary mixed-norm penalties, enabling to tackle a wide variety of problems. This formulation is not restricted to convex mixed-norm, a property that turns out to be of interest for reaching sparser, hence more interpretable solutions.

Our approach is embedded, in the sense that the kernel hyper-parameters are optimized jointly with the parameters of classifier to minimize the soft-margin criterion. It is however implemented by a simple wrapper algorithm, for which the inner and the outer subproblems have the same objective function, and where the inner loop is a standard SVM problem.

In particular, this implementation allows to use available solvers for kernel machines in the inner loop. Hence, although this paper considered binary classification problems, our approach can be readily extended to other learning problems, such as multiclass classification, clustering, regression or ranking.

The Many Faces of Optimism: a Unifying Approach

István Szita SZITYU@GMAIL.COM
András Lőrincz ANDRAS.LORINCZ@ELTE.HU
Eötvös Loránd University, 1117 Pázmány P. sétány 1/C, Budapest, Hungary

Abstract

The exploration-exploitation dilemma has been an intriguing and unsolved problem within the framework of reinforcement learning. "Optimism in the face of uncertainty" and model building play central roles in advanced exploration methods. Here, we integrate several concepts and obtain a fast and simple algorithm. We show that the proposed algorithm finds a near-optimal policy in polynomial time, and give experimental evidence that it is robust and efficient compared to its ascendants.

1. Introduction

Reinforcement learning (RL) is the art of maximizing long-term rewards in a stochastic, unknown environment. In the construction of RL algorithms, the choice of exploration strategy is of central significance.

We shall examine the problem of exploration in the Markov decision process (MDP) framework. While simple methods like ϵ-greedy and Boltzmann exploration are commonly used, it is known that their behavior can be extremely poor (Koenig & Simmons, 1993). Recently, a number of efficient exploration algorithms have been published, and for some of them, formal proofs of efficiency also exist. We review these methods in Section 2. By combining ideas from several sources, we construct a new algorithm for efficient exploration. The new algorithm, *optimistic initial model* (OIM), is described in Section 3. In Section 4, we show that many of the advanced algorithms, including ours, can be treated in a unified way. We use this fact to sketch a proof that OIM finds a near-optimal policy in polynomial time with high probability. Section 5 provides experimental comparison between OIM and a number of other methods on some benchmark problems. Our results are summarized in Section 6. In the rest of this section, we review the necessary preliminaries, Markov decision processes and the exploration task.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

1.1. Markov Decision Processes (MDPs)

Markov decision processes are the standard framework for RL, and the basis of numerous extensions (like continuous MDPs, partially observable MDPs or factored MDPs). An MDP is characterized by a quintuple $(X, A, \mathcal{R}, P, \gamma)$, where X is a finite set of states; A is a finite set of possible actions; $\mathcal{R} : X \times A \times X \to \mathcal{P}_{\mathbb{R}}$ is the reward distribution, $R(x, a, y)$ denotes the mean value of $\mathcal{R}(x, a, y)$, $P : X \times A \times X \to [0, 1]$ is the transition function; and finally, $\gamma \in [0, 1)$ is the discount rate on future rewards. We shall assume that all rewards are nonnegative and bounded from above by $R^0_{\max}$.

A (stationary) policy of the agent is a mapping $\pi : X \times A \to [0, 1]$. For any $x_0 \in X$, the policy of the agent and the parameters of the MDP determine a stochastic process experienced by the agent through the instantiation $x_0, a_0, r_0, x_1, a_1, r_1, \ldots, x_t, a_t, r_t, \ldots$

The goal is to find a policy that maximizes the expected value of the discounted total reward. Let us define the state-action value function (value function for short) of π as $Q^\pi(x, a) := E\Big(\sum_{t=0}^{\infty} \gamma^t r_t \;\Big|\; x = x_0, a = a_0\Big)$ and the optimal value function as

$$Q^*(x, a) := \max_\pi Q^\pi(x, a)$$

for each $(x, a) \in X \times A$. Let the greedy action at x w.r.t. value function Q be $a^Q_x := \arg\max_a Q(x, a)$. The greedy policy of Q deterministically takes the greedy action in each state. It is well-known that the greedy policy of Q^* is an optimal policy and Q^* satisfies the Bellman equations:

$$Q^*(x, a) = \sum_y P(x, a, y)\Big(R(x, a, y) + \gamma Q^*(y, a^{Q^*}_y)\Big).$$

1.2. The Exploration Problem

In the classical reinforcement learning setting, it is assumed that the environment can be modelled as an MDP, but its parameters (that is, P and R) are unknown to the agent, and she has to collect information by interacting with the environment. If too little time is spent with the exploration of the environment, the agent will get stuck with a suboptimal policy, without knowing that there exists a better one. On the other hand, the agent should not spend too much time visiting areas with low rewards and/or accurately known parameters.

What is the optimal balance between exploring and exploiting the acquired knowledge and how could the agent concentrate her exploration efforts? These questions are central for RL. It is known that the optimal exploration policy in an MDP is non-Markovian, and can be computed only for very simple tasks like k-armed bandit problems.

2. Related Literature

Here we give a short review about some of the most important exploration methods and their properties.

2.1. ϵ-greedy and Boltzmann Exploration

The most popular exploration method is ϵ-greedy action selection. The method works without a model, only an approximation of the action value function $Q(x, a)$ is needed. The agent in state x selects the greedy action a_x^Q or an explorative move with a random action with probabilities $1-\epsilon$ and ϵ, respectively. Sooner or later, all paths with nonzero probability will have been visited many times, so, a suitable learning algorithm can learn to choose the optimal path. It is known, for example, that Q-learning with nonzero exploration converges to the optimal value function with probability 1 (Littman & Szepesvári, 1996), and so does SARSA (Singh et al., 2000), if the exploration rate diminishes according to an appropriate schedule.

Boltzmann exploration selects actions as follows: the probability of choosing action a is $\frac{\exp\left(Q(s,a)/T\right)}{\sum_{a' \in A} \exp\left(Q(s,a')/T\right)}$, where 'temperature' $T\,(>0)$ regulates the amount of explorative actions. Convergence results of the ϵ-greedy method carry through to this case.

Unfortunately, for the ϵ-greedy and the Boltzmann method, exploration time may scale exponentially in the number of states (Koenig & Simmons, 1993).

2.2. Optimistic Initial Values (OIV)

One may boost exploration with a simple trick: the initial value of each state action pair can be set to some overwhelmingly high number. If a state x is visited often, then its estimated value will become more exact, and therefore, lower. Thus, the agent will try to reach the more rarely visited areas, where the estimated state values are still high. This method, called 'exploring starts' or 'optimistic initial values', is a popular exploration heuristic (Sutton & Barto, 1998), sometimes combined with others, e.g., the ϵ-greedy exploration method. Recently, Even-Dar and Mansour (2001) gave theoretical justification for the method: they proved that if the optimistic initial values are sufficiently high, Q-learning converges to a near-optimal solution. One apparent disadvantage of OIV is that if initial estimations are too high, then it takes a long to fix them.

2.3. Bayesian Methods

We may assume that the MDP (with the unknown values of P and R) is drawn from a parameterized distribution $\mathcal{M}_0$. From the collected experience and the prior distribution $\mathcal{M}_0$, we can calculate successive posterior distributions $\mathcal{M}_t, t = 1, 2, \ldots$ by Bayes' rule. Furthermore, we can calculate (at least in principle) the policy that minimizes the uncertainty of the parameters (Strens, 2000). Dearden (2000) approximates the distribution of state values directly. Exact computation of the optimal exploration policy is infeasible and Bayesian methods are computationally demanding even with simplifying assumptions about the distributions, e.g., the independencies of certain parameters.

2.4. Confidence Interval Estimation

Confidence interval estimation algorithms are between Bayesian exploration and OIV. It assumes that each state value is drawn from an independent Gaussian distribution and it computes the confidence interval of the state values. The agent chooses the action with the highest upper confidence bound. Initially, all confidence intervals are very wide, and shrink gradually towards the true state values. Therefore, the behavior of the technique is similar to OIV. The IEQL+ method of Meuleau and Bourgine (1999) directly estimates confidence intervals of Q-values, while Wiering and Schmidhuber (1998) calculate confidence intervals for P and R, and obtain Q-value bounds indirectly. Strehl and Littman (2006) improve the method and prove a polynomial-time convergence bound. Both algorithms are called *model-based interval estimation*. To avoid

confusion, we will refer to them as MBIE(WS) and MBIE(SL).

Auer and Ortner (2006) give a confidence interval-based algorithm, for which the online regret is only logarithmic in the number of steps taken.

2.5. Exploration Bonus Methods

The agent can be directed towards less-known parts of the state space by increasing the value of 'interesting' states artificially with bonuses. States can be interesting given their *frequency*, *recency*, *error*, etc. (Meuleau & Bourgine, 1999; Wiering & Schmidhuber, 1998).

The balance of exploration and exploitation is usually set by a scaling factor κ, so that the total immediate reward of the agent at time t is $r_t + \kappa \cdot b_t(x_t, a_t, x_{t+1})$, where b_t is one of the above listed bonuses. The bonuses are calculated by the agent and act as intrinsic motivating forces. Exploration bonuses for a state can vary swiftly and model-based algorithms (like prioritized sweeping or Dyna) are used for spreading the changes effectively. Alas, the weight of exploration κ needs to be annealed according to a suitable schedule.

Alternatively, the agent may learn *two* value functions separately: a regular one, Q_t^r which is based on the rewards r_t received from the environment, and an exploration value function Q_t^e which is based on the exploration bonuses. The agent's policy will be greedy with respect to their combination $Q_t^r + \kappa Q_t^e$. Then the exploration mechanism may remain the same, but several advantages appear. First of all, the changes in κ take effect *immediately*. As an example, we can immediately switch off exploration by setting κ to 0. Furthermore, Q_t^r may converge even if Q_t^e does not.

Confidence interval estimation can be phrased as an exploration bonus method: see IEQL+ (Meuleau & Bourgine, 1999) or MBIE-EB (Strehl & Littman, 2006). Even-Dar and Mansour (2001) have shown that ϵ-greedy and Boltzmann explorations can be formulated as exploration bonus methods although rewards are not propagated through the Bellman equations.

2.6. E^3 and R-max

The *Explicit explore or exploit* (E^3) algorithm of Kearns and Singh (1998) and its successor, R-max (Brafman & Tennenholtz, 2001) were the first algorithms that have polynomial time bounds for finding near-optimal policies. R-max collects statistics about transitions and rewards. When visits to a state enable high precision estimations of real transition probabilities and rewards then state is declared *known*. R-max also maintains an approximate model of the environment. Initially, the model assumes that all actions in all states lead to a (hypothetical) maximum-reward absorbing state. The model is updated each time when a state becomes known. The optimal policy of the model is either the near-optimal policy in the real environment or enters a not-yet-known state and collects new information.

3. Construction of the Algorithm

Our agent starts with a simple, but overly optimistic model. By collecting new experiences, she updates her model, which becomes more realistic. The value function is computed over the approximate model with (asynchronous) dynamic programming. The agent always chooses her action greedily w.r.t. her value function. Exploration is induced by the optimism of the model: unknown areas are believed to yield large rewards. Algorithmic components are detailed below.

Separate exploration values. Similarly to the approach of Meuleau and Bourgine (1999), we shall separate the 'true' state values from exploration values. Formally, the value function has the form

$$Q(x, a) = Q^r(x, a) + Q^e(x, a)$$

for all $(x, a) \in X \times A$, where Q^r and Q^e will summarize external and exploration rewards, respectively.

'Garden of Eden' state. Similarly to R-max, we introduce a new hypothetical 'garden of Eden' state x_E, and assume an extended state space $X' = X \cup \{x_E\}$. Once there, then, according to the inherited model, the agent remains in x_E indefinitely and receives $R_{\max}$ reward for every step, which may exceed $R^0_{\max} =: \max_{x,a,y} R(x, a, y)$, the maximal reward of the original environment.

Model approximation. The agent builds an approximate model of the environment. For each $x, y \in X$ and $a \in A$, let $N_t(x, a)$, $N_t(x, a, y)$, and $C_t(x, a, y)$ denote the number of times when a was selected in x up to step t, the number of times when transition $x \xrightarrow{a} y$ was experienced, and the sum of external rewards for $x \xrightarrow{a} y$ transitions, respectively. With these notations, the approximate model parameters are

$$\hat{P}_t(x, a, y) = \frac{N_t(x, a, y)}{N_t(x, a)} \text{ and } \hat{R}_t(x, a, y) = \frac{C_t(x, a, y)}{N_t(x, a, y)}.$$

Suitable initializations of $N_t(x, a)$, $N_t(x, a, y)$ and $C_t(x, a, y)$ will ensure that the ratios are well-defined everywhere. The exploration rewards are defined as

$$R^e(x, a, y) := \begin{cases} R_{\max}, & \text{if } y = x_E; \\ 0, & \text{if } y \neq x_E, \end{cases}$$

for each $x, y \in X \cup \{x_E\}$, $a \in A$, and are not modified during the course of learning.

Optimistic initial model. The initial model assumes that x_E has been reached once for each state-action pairs: for each $x \in X \cup \{x_E\}$, $y \in X$ and $a \in A$,

$$\begin{aligned} &N_0(x,a) = 1, \\ &N_0(x,a,y) = 0, \quad C_0(x,a,y) = 0. \\ &N_0(x,a,x_E) = 1, \quad C_0(x,a,x_E) = 0. \end{aligned}$$

Then, the optimal initial value function equals

$$Q_0(x,a) = Q_0^r(x,a) + Q_0^e(x,a) = 0 + \frac{1}{1-\gamma} R_{\max} := V_{\max}$$

for each $(x,a) \in X' \times A$, analogously to OIV.

Dynamic programming. Both value functions can be updated using the approximate model. For each $x \in X$, let a_x be the greedy action according to the combined value function, i.e.,

$$a_x := \arg\max_{a \in A} \big(Q^r(x,a) + Q^e(x,a)\big).$$

The dynamic programming equations for the value function components are

$$Q_{t+1}^r(x,a) := \sum_{y \in X} \hat{P}_t(x,a,y) \left(\hat{R}_t(x,a,y) + \gamma Q_t^r(y,a_y)\right)$$

$$\begin{aligned} Q_{t+1}^e(x,a) := \gamma &\sum_{y \in X} \hat{P}_t(x,a,y) Q_t^e(y,a_y) \\ &+ \hat{P}_t(x,a,x_E) V_{\max}. \end{aligned}$$

Episodic tasks can be handled as usual way; we introduce an absorbing final state with 0 external reward.

Asynchronous update. The algorithm can be online, if instead of full update sweeps over the state space updates are limited to state set L_t in the 'neighborhood' of the agent's current state. Neighborhood is restricted by computation time constraints; any asynchronous dynamic programming algorithm suffices. It is implicitly assumed that the current state is always updated, i.e., $x_t \in L_t$. In this paper, we used the improved prioritized sweeping algorithm of Wiering and Schmidhuber (1998).

Putting it all together. The method is summarized as Algorithm 1.

4. Analysis

In the first part of this section, we analyze the similarities and differences between various exploration methods, with an emphasis on OIM. Based on this analysis, we sketch the proof that OIM finds a near-optimal policy in polynomial time. Details of the proof can be found in (Szita & Lőrincz, 2008).

4.1. Relationship to Other Methods

'Optimism in the face of uncertainty' is a common point in exploration methods: the agent believes that she can obtain extra rewards by reaching the unexplored parts of the state space.

Note that as far as the combined value function Q is concerned, OIM is an asynchronous dynamic programming method augmented with model approximation.

Optimistic initial values. Apparently, OIM is the model-based extension of the OIV heuristic. Note however, that optimistic initialization of Q-values is not effective with a model: the more updates are made, the less effect the initialization has and it fully diminishes if value iteration is run until convergence. Therefore, naive combination of OIV and model construction is contradictory: the number of DP-updates should be kept low in order to save the initial boost, but it should be as high as possible in order to propagate the real rewards quickly.

OIM resolves this paradox by moving the optimism into the model. The optimal value function of the initial model is $Q_0 \equiv V_{\max}$, corresponding to OIV. However, DP updates can not, but only model updates may lower the exploration boost.

Note that we can set the initial model value as high as we like, but we do not have to wait until the initial boost diminishes, because Q^r and Q^e are separated.

R-max. The 'Garden of Eden' state x_E of OIM is identical to the fictitious max-reward absorbing state of R-MAX (and E^3). In both cases, the agent's model tells that all unexplored (x,a) pairs lead to x_E. R-MAX, however, updates the model only when the transition probabilities and rewards are known with high precision, which is only after many visits to (x,a). In contrast, OIM updates the model after each single visit, employing each bit of experience as soon as it is obtained. As a result, the approximate model can be used long before it becomes accurate.

Exploration bonus methods. The extra reward offered by the Garden of Eden state can be understood as an exploration bonus: for each visit of the pair (x,a), the agent gets the bonus $b_t(x,a) = \frac{1}{N_t(x,a)}\big(V_{\max} - Q_t(x,a)\big)$. It is insightful to contrast this formula with those of the other methods like the *frequency-based* bonus $b_t = -\alpha \cdot N_t(x,a)$ or the *error-based* bonus $b_t = \alpha \cdot \big|Q_{t+1}(x,a) - Q_t(x,a)\big|$.

Model-based interval exploration. The exploration bonus form of the MBIE method of Strehl and Littman (2005) sets $b_t = \frac{\alpha}{N_t(x,a)}$. MBIE-EB is not an ad-hoc method: the form of the bonus comes from

Algorithm 1 The Optimistic initial model algorithm

Input: $x_0 \in X$ initial state, $\epsilon > 0$ required precision, optimism parameter $R_{\max}$
Model initialization: $t := 0$; $\forall x, y \in X, \forall a \in A$:
$N(x,a,y) := 0$, $N(x,a,x_E) := 1$, $N(x,a) := 1$, $C(x,a,y) := 0$, $Q^r(x,a) := 0$, $Q^e(x,a) := R_{\max}/(1-\gamma)$;
repeat
  $a_t :=$ greedy action w.r.t. $Q^r + Q^e$; apply a_t and observe r_t and x_{t+1}
  $C(x_t,a_t,x_{t+1}) := C(x_t,a_t,x_{t+1}) + r_t$; $N(x_t,a_t,x_{t+1}) := N(x_t,a_t,x_{t+1}) + 1$; $N(x_t,a_t) := N(x_t,a_t) + 1$
  $L_t :=$ list of states to be updated
  for each $x \in L_t$ **do**
    $Q^r_{t+1}(x,a) := \sum_{y \in X} \hat{P}(x,a,y) \left(\hat{R}(x,a,y) + \gamma Q^r_t(y,a_y) \right)$
    $Q^e_{t+1}(x,a) := \hat{P}(x,a,x_E) R_{\max}/(1-\gamma) + \gamma \sum_{y \in X} \hat{P}(x,a,y) Q^e_t(y,a_y)$.
  end for
  $t := t + 1$
until Bellman-error$> \epsilon$

confidence interval estimations. The comparison to MBIE-EB will be especially valuable, as it converges in polynomial-time and the proof can be transported to OIM with slight modifications.

4.2. Polynomial-time Convergence

Theorem 4.1 *There exists a constant C so that for any $\epsilon > 0$, $\delta > 0$, $\epsilon_1 := \epsilon/4$, $\epsilon_2 := \epsilon_1(1-\gamma)$, $H := \frac{1}{1-\gamma} \ln \frac{R^0_{\max}}{\epsilon_1(1-\gamma)}$, $K := \left(\frac{2C|X|^5|A|H^4}{\delta \epsilon_1^4} \ln \frac{1}{\delta} \right)^{1/6}$, OIM converges almost surely to a near-optimal policy in polynomial time if started with $R_{\max} \geq \frac{3}{\epsilon_2(1-\gamma)} (R^0_{\max})^2 \ln(K R^0_{\max})$, that is, with probability $1-\delta$, the number of timesteps where $Q^{\pi^{OIM}}(x_t,a_t) > Q^*(x_t,a_t) - \epsilon$ does not hold, is $O\Big((\frac{|X|H}{\epsilon_1})^5 \frac{|A|(R^0_{\max})^7}{(1-\gamma)\epsilon_1^5} \ln^2 \frac{1}{\delta} \Big)$.*

For the sketch of the proof, we shall follow the technique of Kearns and Singh (2002) and Strehl and Littman (2006), and will use the shorthands [KS] and [SL] for referring to them. See (**?**) for the detailed proof with a slightly better polynomial bound.

A pair (x,a) is declared known, if it has been visited at least $m = C(\frac{|X|H}{\epsilon_1})^4 (R^0_{\max})^6 \ln \frac{1}{\delta}$ times, with a suitable constant C. OIM preserves the optimism of the value function:

Lemma 4.2 *Let Q_t be the sequence of Q-functions generated by* OIM. *Then, it holds with probability $1 - \delta/2$ that for any t, $Q_t(x,a) \geq Q^*(x,a) - \epsilon_1$.*

Proof: According to [SL], with probability $1 - \delta/2$,

$$\sum_y \hat{P}_t(x,a,y) \big(\hat{R}_t(x,a,y) + \gamma V^*(y) \big) - Q^*(x,a) \geq -\beta/\sqrt{N_t(x,a)}, \quad (1)$$

where $\beta := R^0_{\max}/(1-\gamma)\sqrt{\ln(2\,|X|\,|A|\,m/\delta)/2} = \frac{\sqrt{3}}{1-\gamma} R^0_{\max} \sqrt{\ln(K R^0_{\max})}$.

We will show that

$$R_{\max}/(N_t(x,a)(1-\gamma)) + \epsilon_2 \geq \beta/\sqrt{N_t(x,a)}. \quad (2)$$

For $N_t(x,a) \leq \frac{R_{\max}}{(1-\gamma)\epsilon_2}$, the first term dominates the l.h.s. and we can omit the second term (and prove the stricter inequality). If the relation is reversed, then the first term can be omitted. In both cases, we arrive at the requirement $R_{\max} \geq \frac{3}{\epsilon_2(1-\gamma)} (R^0_{\max})^2 \ln(K R^0_{\max})$, which holds by assumption.

At step t, a number of DP updates are carried out. We proceed by induction on the number of DP-updates. Initially, $Q^{(0)}(x,a) \geq Q^*(x,a) - \epsilon_1$, then
$\sum_y \hat{P}_t(x,a,y) \big(\hat{R}_t(x,a,y) + \gamma V^{(i)}(y) \big) + \frac{V_{\max}}{N_t(x,a)}$
$\geq \sum_y \hat{P}_t(x,a,y) \big(\hat{R}_t(x,a,y) + \gamma (V^*(y) - \epsilon_1) \big) + \frac{V_{\max}}{N_t(x,a)}$
$\geq Q^*(x,a) - \beta/\sqrt{N_t(x,a)} - \gamma\epsilon_1 + \frac{V_{\max}}{N_t(x,a)}$
$\geq Q^*(x,a) - \gamma\epsilon_1 - \epsilon_2 = Q^*(x,a) - \epsilon_1$,
where we applied (1), (2), the induction assumption and the definition of ϵ_2. □

Let M denote the true (and unknown) MDP, let $\hat{M}$ be the approximate model of OIM, and define $\bar{M}$ so that it is identical to M for known pairs, and equals $\hat{M}$ for unknown pairs. The parameters of $\hat{M}$ and $\bar{M}$ are nearly identical: if (x,a) becomes known, then the local values of $\hat{P}$ and $\hat{R}$ are $O(\frac{\epsilon}{|X|H R^0_{\max}})^2$-approximations of P and R with probability $1 - \delta/2$ (Lemma 5 of [KS]). Therefore, by Lemma 4 of [KS],

$$|Q^\pi_{\hat{M}}(x,a) - Q^\pi_{\bar{M}}(x,a)| < \epsilon_1. \quad (3)$$

Define the H-step truncated value function of policy π as $Q^\pi(x,a,H) := E\Big(\sum_{t=0}^H \gamma^t r_t \;\Big|\; x = x_0, a = a_0 \Big)$. According to [KS] Lemma 2, $H = \frac{1}{1-\gamma} \ln \frac{R^0_{\max}}{\epsilon_1(1-\gamma)}$ is an

ϵ_1-horizon time, i.e., $|Q^\pi_M(x,a,H) - Q^\pi_M(x,a)| < \epsilon_1$ for any (x,a), π and any MDP M with discount factor γ.

Consider a state-action pair (x_1,a_1) and a H-step long trajectory generated by π. Let A_M be the event that an unknown pair (x,a) is encountered along the trajectory. Then, by Lemma 3 of [SL],

$$Q^\pi_M(x_1,a_1) \geq Q^\pi_{\hat{M}}(x_1,a_1) - V_{\max} \Pr(A_M). \qquad (4)$$

To conclude the proof, we separate two cases (following the line of thoughts of Theorem 1 in [SL]). In the first case, an exploration step will occur with high probability: Let $V^0_{\max} := R^0_{\max}/(1-\gamma)$. Suppose that $\Pr(A_M) > \epsilon_1/V^0_{\max}$, that is, an unknown pair (x,a) is visited in H steps with high probability. This can happen at most $m|X||A|$ times, so by the Hoeffding-Azuma bound, with probability $1-\delta/2$, all (x,a) will become known after $O(\frac{m|X||A|HV^0_{\max}}{\epsilon_1} \ln \frac{1}{\delta})$ exploration steps.

On the other hand, if $\Pr(A_M) \leq \epsilon_1/V^0_{\max}$, then the policy is near-optimal with probability $1-\delta$:

$$\begin{aligned}
&Q^{\pi^{OIM}}_M(x_1,a_1) \geq Q^{\pi^{OIM}}_M(x_1,a_1,H) \\
&\geq Q^{\pi^{OIM}}_{\hat{M}}(x_1,a_1,H) - V^0_{\max}\Pr(A_M) \\
&\geq Q^{\pi^{OIM}}_{\hat{M}}(x_1,a_1,H) - \epsilon_1 \geq Q^{\pi^{OIM}}_M(x_1,a_1) - 2\epsilon_1 \\
&\geq Q^{\pi^{OIM}}_{\hat{M}}(x_1,a_1) - 3\epsilon_1 \geq Q^*(x_1,a_1) - 4\epsilon_1 \\
&= Q^*(x_1,a_1) - \epsilon,
\end{aligned}$$

where we applied (in this order) the property that truncation decreases the value function; Eq. (4); our assumption; the ϵ_1-horizon property of H; Eq. (3); Lemma 4.2 and the definition of ϵ_1.

5. Experiments

To assess the practical utility of OIM, we compared its performance to other exploration methods. Experiments were run on several small benchmark tasks challenging exploration algorithms.

For fair comparisons, benchmark problems were taken from the literature without changes, nor did we change the experimental settings or the presentation of experimental data. It also means that the presentation format varies for different benchmarks.

5.1. RiverSwim and SixArms

The first two benchmark problems, *RiverSwim* and *SixArms*, were taken from Strehl and Littman (2006).

The *RiverSwim* MDP has 6 states, representing the position of the agent in a river. The agent has two possible actions: she can swim either upstream or downstream. Swimming down is always successful, but swimming up succeeds only with a 30% chance and there is a 10% chance of slipping down. The lowermost position yields +5 reward per step, while the uppermost position yields +10000.

Table 1. Results on the *RiverSwim* task.

Method	Cumulative reward
E^3	$3.020 \cdot 10^6 \pm 0.027 \cdot 10^6$
R-MAX	$3.014 \cdot 10^6 \pm 0.039 \cdot 10^6$
MBIE(SL)	$3.168 \cdot 10^6 \pm 0.023 \cdot 10^6$
MBIE-EB	$3.093 \cdot 10^6 \pm 0.023 \cdot 10^6$
OIM	$3.201 \cdot 10^6 \pm 0.016 \cdot 10^6$

Table 2. Results on the *SixArms* task.

Method	Cumulative reward
E^3	$1.623 \cdot 10^6 \pm 0.244 \cdot 10^6$
R-MAX	$2.819 \cdot 10^6 \pm 0.256 \cdot 10^6$
MBIE(SL)	$9.205 \cdot 10^6 \pm 0.559 \cdot 10^6$
MBIE-EB	$9.486 \cdot 10^6 \pm 0.587 \cdot 10^6$
OIM	$10.007 \cdot 10^6 \pm 0.654 \cdot 10^6$

The *SixArms* MDP consists of a central state and six 'payoff states'. In the central state, the agent can play 6 one-armed bandits. If she pulls arm k and wins, she is transferred to payoff state k. Here, she can get a reward in each step, if she chooses the appropriate action. The winning probabilities range from 1 to 0.01, while the rewards range from 50 to 6000 (for the exact values, see Strehl & Littman, 2006).

Data for E^3, R-MAX, MBIE and MBIE-EB are taken from Strehl and Littman (2006). Parameters of all four algorithms were chosen optimally. Following a coarse search in parameter space, the $R_{\max}$ parameter for OIM was set to 2000 for *RiverSwim* and to 10000 for *SixArms*. State spaces are small and value iteration instead of prioritized sweeping was completed in each step.

On both problems, each algorithm ran for 5000 time steps and the undiscounted total reward was recorded. The averages and 95% confidence intervals are calculated over 1000 test runs (Tables 5.1 and 5.1).

5.2. 50×50 Maze with Subgoals

Another benchmark problem, *MazeWithSubgoals*, was suggested by Wiering and Schmidhuber (1998). The agent has to navigate in a 50×50 maze from the start position at $(2,2)$ to the goal (with +1000 reward) at the opposite corner $(49,49)$. There are sub-

optimal goals (with +500 reward) at the other two corners. The maze has blocked places and punishing states (−10 reward), set randomly in 20-20% of the squares. The agent can move in four directions, but with a 10% chance, its action is replaced by a random one. If the agent tries to move to a blocked state, it gets a reward of −2. Reaching any of the goals resets the agent to the start state. In all other cases, the agent gets a −1 reward for each step.

Each algorithm was run on 20 different mazes for 100,000 steps. After every 1000 steps, we tested the learned value functions by averaging 20 test runs, in each one following the greedy policy for 10,000 steps, and averaging cumulated (undiscounted) rewards. We measured the number of test runs needed for the algorithms to learn to collect 95%, 99% and 99.8% of the maximum possible rewards in 100,000 steps, and the number of steps this takes on average, if the algorithms can meet the challenge.

The algorithms that we compared were the recency based and frequency based exploration bonus methods, two versions of ϵ-greedy exploration, MBIE(WS) and OIM. All exploration rules applied the improved prioritized sweeping of Wiering and Schmidhuber (1998). OIM's $R_{\max}$ was set to 1000. The results are summarized in Table 3.

5.3. Chain, Loop and FlagMaze

The next three benchmark MDPs, the *Chain*, *Loop* and *FlagMaze* tasks were investigated, e.g., by Meuleau and Bourgine (1999), Strens (2000) and Dearden (2000). In the *Chain* task, 5 states are lined up along a chain. The agent gets +2 reward for being in state 1 and +10 for being in state 5. One of the actions advances one state ahead, the other one resets the agent to state 1. The *Loop* task has 9 states in two loops (arranged in a 8-shape). Completing the first loop (using any combination of the two actions) yields +1 reward, while the second loop yields +2, but one of the actions resets the agent to the start. The *FlagMaze* task consists of a 6×7 maze with several walls, a start state, a goal state and 3 flags. Whenever the agent reaches the goal, her reward is the number of flags collected.

The following algorithms were compared: Q-learning with variance-based and TD error-based exploration bonus (model-free variants), ϵ-greedy exploration, Boltzmann exploration, IEQL+, Bayesian Q-learning, Bayesian DP and OIM. Data were taken from Meuleau and Bourgine (1999), Strens (2000) and Dearden (2000). According to the sources, parameters for all algorithms were set optimally. OIM's $R_{\max}$ parameter was set to 0.5, 10 and 0.005 for the three tasks, respectively.

Each algorithm ran for 8 learning phases. The total cumulated reward over each learning phase was measured. One phase lasted for 1000 steps for the first two tasks and 20,000 steps for the *FlagMaze* task. We carried out 256 parallel runs for the first 2 tasks and 20 for the third one.

6. Summary of the Results

We proposed a new algorithm for exploration and reinforcement learning in Markov decision processes. The algorithm integrates concepts from other advanced exploration methods. The key component of our algorithm is an optimistic initial model. The optimal policy according to the agent's model will either explore new information that helps to make the model

more accurate, or follows a near-optimal path. The extent of optimism regulates the amount of exploration. We have shown that with a suitably optimistic initialization, our algorithm finds a near-optimal policy in polynomial time. Experiments were conducted on a number of benchmark MDPs. According to the experimental results our novel method is robust and compares favorably to other methods.

Abstract

The ν-support vector classification (ν-SVC) algorithm was shown to work well and provide intuitive interpretations, e.g., the parameter ν roughly specifies the fraction of support vectors. Although ν corresponds to a fraction, it cannot take the entire range between 0 and 1 in its original form. This problem was settled by a non-convex extension of ν-SVC and the extended method was experimentally shown to generalize better than original ν-SVC. However, its good generalization performance and convergence properties of the optimization algorithm have not been studied yet. In this paper, we provide new theoretical insights into these issues and propose a novel ν-SVC algorithm that has guaranteed generalization performance and convergence properties.

1. Introduction

Support vector classification (SVC) is one of the most successful classification algorithms in modern machine learning (Schölkopf & Smola, 2002). SVC finds a hyperplane that separates training samples in different classes with maximum margin (Boser et al., 1992). The maximum margin hyperplane was shown to minimize an upper bound of the generalization error according to the Vapnik-Chervonenkis theory (Vapnik, 1995). Thus the generalization performance of SVC is theoretically guaranteed.

SVC was extended to be able to deal with non-separable data by trading the margin size with the data separation error (Cortes & Vapnik, 1995). This soft-margin formulation is commonly referred to as C-SVC since the trade-off is controlled by the parameter C. C-SVC was shown to work very well in a wide range of real-world applications (Schölkopf & Smola, 2002).

An alternative formulation of the soft-margin idea is ν-SVC (Schölkopf et al., 2000)—instead of the parameter C, ν-SVC involves another trade-off parameter ν that roughly specifies the fraction of support vectors (or sparseness of the solution). Thus, the ν-SVC formulation provides us richer interpretation than the original C-SVC formulation, which would be potentially useful in real applications.

Since the parameter ν corresponds to a fraction, it should be able to be chosen between 0 and 1. However, it was shown that admissible values of ν are actually limited (Crisp & Burges, 2000; Chang & Lin, 2001). To cope with this problem, Perez-Cruz et al. (2003) introduced the notion of negative margins and proposed extended ν-SVC (Eν-SVC) which allows ν to take the entire range between 0 and 1. They also experimentally showed that the generalization performance of Eν-SVC is often better than that of original ν-SVC. Thus the extension contributes not only to elucidating the theoretical property of ν-SVC, but also to improving its generalization performance.

However, there remain two open issues in Eν-SVC. The first issue is that the reason why a high generalization performance can be obtained by Eν-SVC was not completely explained yet. The second issue is that the optimization problem involved in Eν-SVC is non-convex and theoretical convergence properties of the Eν-SVC optimization algorithm have not been studied yet. The purpose of this paper is to provide new theoretical insights into these two issues.

After reviewing existing SVC methods in Section 2, we

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

elucidate the generalization performance of Eν-SVC in Section 3. We first show that the Eν-SVC formulation could be interpreted as minimization of the *conditional value-at-risk* (CVaR), which is often used in finance (Rockafellar & Uryasev, 2002; Gotoh & Takeda, 2005). Then we give new generalization error bounds based on the CVaR risk measure. This theoretical result justifies the use of Eν-SVC.

In Section 4, we address non-convexity of the Eν-SVC optimization problem. We first give a new optimization algorithm that is guaranteed to converge to one of the local optima within a finite number of iterations. Based on this improved algorithm, we further show that the global solution can be actually obtained within finite iterations even though the optimization problem is non-convex.

Finally, in Section 5, we give concluding remarks and future prospects. Proofs of all theorems and lemmas are sketched in Appendix unless mentioned.

2. Support Vector Classification

In this section, we formulate the classification problem and briefly review support vector algorithms.

2.1. Classification Problem

Let us address the classification problem of learning a decision function h from $\mathcal{X}$ ($\subset \mathbb{R}^n$) to $\{\pm 1\}$ based on training samples $(\boldsymbol{x}_i, y_i)$ ($i \in M := \{1, ..., m\}$). We assume that the training samples are i.i.d. following the unknown probability distribution $P(\boldsymbol{x}, y)$ on $\mathcal{X} \times \{\pm 1\}$.

The goal of the classification task is to obtain a classifier h that minimizes the generalization error (or the risk):

$$R[h] := \int \frac{1}{2}|h(\boldsymbol{x}) - y| dP(\boldsymbol{x}, y),$$

which corresponds to the misclassification rate for unseen test samples.

For the sake of simplicity, we generally focus on linear classifiers, i.e.,

$$h(\boldsymbol{x}) = \mathrm{sign}(\langle \boldsymbol{w}, \boldsymbol{x} \rangle + b), \tag{1}$$

where $\boldsymbol{w}$ ($\in \mathbb{R}^n$) is a non-zero normal vector, b ($\in \mathbb{R}$) is a bias parameter, and $\mathrm{sign}(\xi) = 1$ if $\xi \geq 0$ and -1 otherwise.

Most of the discussions in this paper can be directly applicable to non-linear kernel classifiers (Schölkopf & Smola, 2002). Thus we may not lose generality by restricting ourselves to linear classifiers.

2.2. Support Vector Classification

The Vapnik-Chervonenkis theory (Vapnik, 1995) showed that a large margin classifier has a small generalization error. Motivated by this theoretical result, Boser et al. (1992) developed an algorithm for finding the hyperplane $(\boldsymbol{w}, b)$ with maximum margin:

$$\min_{\boldsymbol{w}, b} \frac{1}{2}\|\boldsymbol{w}\|^2 \quad \text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) \geq 1, \quad i \in M. \tag{2}$$

This is called (hard-margin) support vector classification (SVC) and valid when the training samples are linearly separable. In the following, we omit "$i \in M$" in the constraint for brevity.

2.3. C-Support Vector Classification

Cortes and Vapnik (1995) extended the SVC algorithm to non-separable cases and proposed trading the margin size with the data separation error (i.e., "soft-margin"):

$$\min_{\boldsymbol{w}, b, \boldsymbol{\xi}} \frac{1}{2}\|\boldsymbol{w}\|^2 + C\sum_{i=1}^{m} \xi_i$$
$$\text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) \geq 1 - \xi_i, \quad \xi_i \geq 0,$$

where C (> 0) controls the trade-off. This formulation is usually referred to as C-SVC, and was shown to work very well in various real-world applications (Schölkopf & Smola, 2002).

2.4. ν-Support Vector Classification

ν-SVC is another formulation of soft-margin SVC (Schölkopf et al., 2000):

$$\min_{\boldsymbol{w}, b, \boldsymbol{\xi}, \rho} \frac{1}{2}\|\boldsymbol{w}\|^2 - \nu\rho + \frac{1}{m}\sum_{i=1}^{m} \xi_i$$
$$\text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) \geq \rho - \xi_i, \quad \xi_i \geq 0, \quad \rho \geq 0,$$

where ν ($\in \mathbb{R}$) is the trade-off parameter.

Schölkopf et al. (2000) showed that if the ν-SVC solution yields $\rho > 0$, C-SVC with $C = 1/(m\rho)$ produces the same solution. Thus ν-SVC and C-SVC are equivalent. However, ν-SVC has additional intuitive interpretations, e.g., ν is an upper bound on the fraction of margin errors and a lower bound on the fraction of support vectors (i.e., sparseness of the solution). Thus, the ν-SVC formulation would be potentially more useful than the C-SVC formulation in real applications.

2.5. Eν-SVC

Although ν has an interpretation as a fraction, it cannot always take its full range between 0 and 1 (Crisp & Burges, 2000; Chang & Lin, 2001).

2.5.1. Admissible Range of ν

For an optimal solution $\{\alpha_i^C\}_{i=1}^m$ of dual C-SVC, let

$$\zeta(C) := \frac{1}{Cm}\sum_{i=1}^m \alpha_i^C,$$
$$\nu_{\min} := \lim_{C\to\infty} \zeta(C) \quad \text{and} \quad \nu_{\max} := \lim_{C\to 0} \zeta(C).$$

Then, Chang and Lin (2001) showed that for $\nu \in (\nu_{\min}, \nu_{\max}]$, the optimal solution set of ν-SVC is the same as that of C-SVC with some C (not necessarily unique). In addition, the optimal objective value of ν-SVC is strictly negative. However, for $\nu \in (\nu_{\max}, 1]$, ν-SVC is unbounded, i.e., there exists no solution; for $\nu \in [0, \nu_{\min}]$, ν-SVC is feasible with zero optimal objective value, i.e., we end up with just having a trivial solution ($\boldsymbol{w} = \boldsymbol{0}$ and $b = 0$).

2.5.2. Increasing Upper Admissible Range

It was shown by Crisp and Burges (2000) that

$$\nu_{\max} = 2\min(m_+, m_-)/m,$$

where m_+ and m_- are the number of positive and negative training samples. Thus, when the training samples are balanced (i.e., $m_+ = m_-$), $\nu_{\max} = 1$ and therefore ν can reach its upper limit 1. When the training samples are imbalanced (i.e., $m_+ \neq m_-$), Perez-Cruz et al. (2003) proposed modifying the optimization problem of ν-SVC as

$$\min_{\boldsymbol{w},b,\boldsymbol{\xi},\rho} \frac{1}{2}\|\boldsymbol{w}\|^2 - \nu\rho + \frac{1}{m_+}\sum_{i:y_i=1}\xi_i + \frac{1}{m_-}\sum_{i:y_i=-1}\xi_i$$
$$\text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i\rangle + b) \geq \rho - \xi_i, \quad \xi_i \geq 0, \quad \rho \geq 0,$$

i.e., the effect of positive and negative samples are balanced. Under this modified formulation, $\nu_{\max} = 1$ holds even when training samples are imbalanced.

For the sake of simplicity, we assume $m_+ = m_-$ in the rest of this paper; when $m_+ \neq m_-$, all the results can be simply extended in a similar way as above.

2.5.3. Decreasing Lower Admissible Range

When $\nu \in [0, \nu_{\min}]$, ν-SVC produces a trivial solution ($\boldsymbol{w} = \boldsymbol{0}$ and $b = 0$) as shown in Chang and Lin (2001). To prevent this, Perez-Cruz et al. (2003) proposed allowing the margin ρ to be negative and enforcing the norm of $\boldsymbol{w}$ to be unity:

$$\min_{\boldsymbol{w},b,\boldsymbol{\xi},\rho} -\nu\rho + \frac{1}{m}\sum_{i=1}^m \xi_i$$
$$\text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i\rangle + b) \geq \rho - \xi_i,\ \xi_i \geq 0,\ \|\boldsymbol{w}\|^2 = 1. \quad (3)$$

By this modification, a non-trivial solution can be obtained even for $\nu \in [0, \nu_{\min}]$. This modified formulation is called extended ν-SVC (Eν-SVC).

The Eν-SVC optimization problem is non-convex due to the equality constraint $\|\boldsymbol{w}\|^2 = 1$. Perez-Cruz et al. (2003) proposed the following iterative algorithm for computing a solution. First, for some initial $\widetilde{\boldsymbol{w}}$, solve the problem (3) with $\|\boldsymbol{w}\|^2 = 1$ replaced by $\langle \widetilde{\boldsymbol{w}}, \boldsymbol{w}\rangle = 1$. Then, using the optimal solution $\widehat{\boldsymbol{w}}$, update $\widetilde{\boldsymbol{w}}$ by

$$\widetilde{\boldsymbol{w}} \longleftarrow \gamma\widetilde{\boldsymbol{w}} + (1-\gamma)\widehat{\boldsymbol{w}} \quad (4)$$

for $\gamma = 9/10$, and iterate this procedure until convergence.

Perez-Cruz et al. (2003) experimentally showed that the generalization performance of Eν-SVC with $\nu \in [0, \nu_{\min}]$ is often better than that with $\nu \in (\nu_{\min}, \nu_{\max}]$, implying that E$\nu$-SVC is a promising classification algorithm. However, it is not clear how the notion of negative margins influences on the generalization performance and how fast the above iterative algorithm converges. The goal of this paper is to give new theoretical insights into these issues.

3. Justification of the Eν-SVC Criterion

In this section, we give a new interpretation of Eν-SVC and theoretically explain why it works well.

3.1. New Interpretation of Eν-SVC as CVaR minimization

Let $f(\boldsymbol{w}, b; \boldsymbol{x}, y)$ be the *margin error* for a sample $(\boldsymbol{x}, y)$:

$$f(\boldsymbol{w}, b; \boldsymbol{x}, y) := -\frac{y(\langle \boldsymbol{w}, \boldsymbol{x}\rangle + b)}{\|\boldsymbol{w}\|}.$$

Let us consider the distribution of margin errors over all training samples:

$$\Phi(\alpha|\boldsymbol{w}, b) := P\{(\boldsymbol{x}_i, y_i) \mid f(\boldsymbol{w}, b; \boldsymbol{x}_i, y_i) \leq \alpha\}.$$

For $\beta \in [0, 1)$, let $\alpha_\beta(\boldsymbol{w}, b)$ be the 100β-percentile of the margin error distribution:

$$\alpha_\beta(\boldsymbol{w}, b) := \min\{\alpha \mid \Phi(\alpha|\boldsymbol{w}, b) \geq \beta\}.$$

Thus only the fraction $(1-\beta)$ of the margin error $f(\boldsymbol{w}, b; \boldsymbol{x}_i, y_i)$ exceeds the threshold $\alpha_\beta(\boldsymbol{w}, b)$ (see Figure 1). $\alpha_\beta(\boldsymbol{w}, b)$ is commonly referred to as the *value-at-risk* (VaR) in finance and is often used by security houses or investment banks to measure the market risk of their asset portfolios (Rockafellar & Uryasev, 2002; Gotoh & Takeda, 2005).

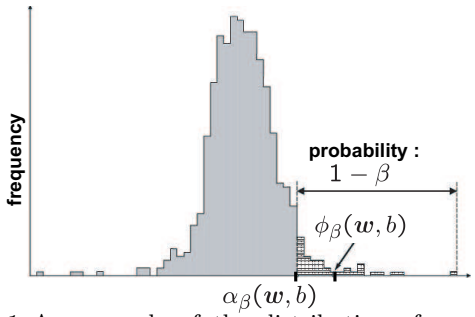

Figure 1. An example of the distribution of margin errors $f(\boldsymbol{w},b;\boldsymbol{x}_i,y_i)$ over all training samples. $\alpha_\beta(\boldsymbol{w},b)$ is the 100β-percentile called the value-at-risk (VaR), and the mean $\phi_\beta(\boldsymbol{w},b)$ of the β-tail distribution is called the conditional VaR (CVaR).

Let us consider the β-tail distribution of $f(\boldsymbol{w},b;\boldsymbol{x}_i,y_i)$:

$$\Phi_\beta(\alpha|\boldsymbol{w},b) := \begin{cases} 0 & \text{for } \alpha < \alpha_\beta(\boldsymbol{w},b), \\ \frac{\Phi(\alpha|\boldsymbol{w},b)-\beta}{1-\beta} & \text{for } \alpha \geq \alpha_\beta(\boldsymbol{w},b). \end{cases}$$

Let $\phi_\beta(\boldsymbol{w},b)$ be the mean of the β-tail distribution of $f(\boldsymbol{w},b;\boldsymbol{x}_i,y_i)$ (see Figure 1 again):

$$\phi_\beta(\boldsymbol{w},b) := \boldsymbol{E}_{\Phi_\beta}[f(\boldsymbol{w},b;\boldsymbol{x}_i,y_i)],$$

where $\boldsymbol{E}_{\Phi_\beta}$ denotes the expectation over the distribution Φ_β. $\phi_\beta(\boldsymbol{w},b)$ is called the *conditional VaR* (CVaR). By definition, the CVaR is always larger than or equal to the VaR:

$$\phi_\beta(\boldsymbol{w},b) \geq \alpha_\beta(\boldsymbol{w},b). \tag{5}$$

Let us consider the problem of minimizing the CVaR $\phi_\beta(\boldsymbol{w},b)$ (which we refer to as minCVaR):

$$\min_{\boldsymbol{w},b} \phi_\beta(\boldsymbol{w},b). \tag{6}$$

Then we have the following theorem.

Theorem 1 *The solution of the minCVaR problem* (6) *is equivalent to the solution of the Eν-SVC problem* (3) *with*

$$\nu = 1-\beta.$$

Theorem 1 shows that Eν-SVC actually minimizes the CVaR $\phi_{1-\nu}(\boldsymbol{w},b)$. Thus, E$\nu$-SVC could be interpreted as minimizing the mean margin error over a set of "bad" training samples. In contrast, the hard-margin SVC problem (2) can be equivalently expressed in terms of the margin error as

$$\min_{\boldsymbol{w},b} \max_{i\in M} f(\boldsymbol{w},b;\boldsymbol{x}_i,y_i).$$

Thus hard-margin SVC minimizes the margin error of the single "worst" training sample. This analysis shows that Eν-SVC can be regarded as an extension of hard-margin SVC to be less sensitive to an outlier (i.e., the single "worst" training sample).

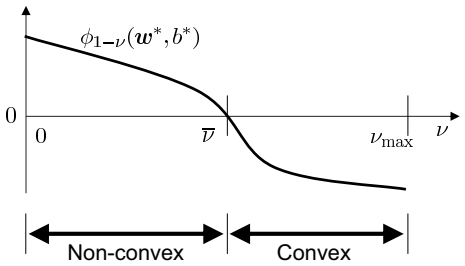

Figure 2. A profile of the CVaR $\phi_{1-\nu}(\boldsymbol{w}^*,b^*)$ as a function of ν. As shown in Section 4, the Eν-SVC optimization problem can be cast as a convex problem if $\nu \in (\overline{\nu},\nu_{\max}]$, while it is essentially non-convex if $\nu \in (0,\overline{\nu})$.

3.2. Justification of Eν-SVC

We have shown the equivalence between Eν-SVC and minCVaR. Here we derive new bounds of the generalization error based on the notion of CVaR and try to justify the use of Eν-SVC.

When training samples are linearly separable, the margin error $f(\boldsymbol{w},b;\boldsymbol{x}_i,y_i)$ is negative for all samples. Then, at the optimal solution $(\boldsymbol{w}^*,b^*)$, the CVaR $\phi_{1-\nu}(\boldsymbol{w}^*,b^*)$ is always negative. However, in non-separable cases, $\phi_{1-\nu}(\boldsymbol{w}^*,b^*)$ could be positive particularly when ν is close to 0. Regarding the CVaR, we have the following lemma.

Lemma 2 *$\phi_{1-\nu}(\boldsymbol{w}^*,b^*)$ is continuous with respect to ν and is strictly decreasing when ν is increased.*

Let $\overline{\nu}$ be such that

$$\phi_{1-\overline{\nu}}(\boldsymbol{w}^*,b^*) = 0$$

if such $\overline{\nu}$ exists; we set $\overline{\nu} = \nu_{\max}$ if $\phi_{1-\nu}(\boldsymbol{w}^*,b^*) > 0$ for all ν and we set $\overline{\nu} = 0$ if $\phi_{1-\nu}(\boldsymbol{w}^*,b^*) < 0$ for all ν. Then we have the following relation (see Figure 2):

$$\phi_{1-\nu}(\boldsymbol{w}^*,b^*) < 0 \text{ for } \nu \in (\overline{\nu},\nu_{\max}],$$
$$\phi_{1-\nu}(\boldsymbol{w}^*,b^*) > 0 \text{ for } \nu \in (0,\overline{\nu}).$$

Below, we analyze the generalization error of Eν-SVC depending on the value of ν.

3.2.1. Justification When $\nu \in (\overline{\nu},\nu_{\max}]$

Theorem 3 *Let $\nu \in (\overline{\nu},\nu_{\max}]$. Suppose that support $\mathcal{X}$ is in a ball of radius R around the origin. Then, for all $(\boldsymbol{w},b)$ such that $\|\boldsymbol{w}\| = 1$ and $\phi_{1-\nu}(\boldsymbol{w},b) < 0$, there exists a positive constant c such that the following bound hold with probability at least $1-$:*

$$R[h] \leq \nu + G(\alpha_{1-\nu}(\boldsymbol{w},b)), \tag{7}$$

where

$$G(\gamma) = \sqrt{\frac{2}{m}\left(\frac{4c^2(R^2+1)^2}{\gamma^2}\log_2(2m) - 1 + \log\frac{2}{}\right)}.$$

The generalization error bound in (7) is furthermore upper-bounded as

$$\nu + G(\alpha_{1-\nu}(\boldsymbol{w}, b)) \leq \nu + G(\phi_{1-\nu}(\boldsymbol{w}, b)).$$

$G(\gamma)$ is monotone decreasing as $|\gamma|$ increases. Thus, the above theorem shows that when $\phi_{1-\nu}(\boldsymbol{w}, b) < 0$, the upper bound $\nu + G(\phi_{1-\nu}(\boldsymbol{w}, b))$ is lowered if the CVaR $\phi_{1-\nu}(\boldsymbol{w}, b)$ is reduced. Since Eν-SVC minimizes $\phi_{1-\nu}(\boldsymbol{w}, b)$ (see Theorem 1), the upper bound of the generalization error is also minimized.

3.2.2. Justification When $\nu \in (0, \overline{\nu}]$

Our discussion below depends on the sign of $\alpha_{1-\nu}(\boldsymbol{w}, b)$. When $\alpha_{1-\nu}(\boldsymbol{w}, b) < 0$, we have the following theorem.

Theorem 4 *Let $\nu \in (0, \overline{\nu}]$. Then, for all $(\boldsymbol{w}, b)$ such that $\|\boldsymbol{w}\| = 1$ and $\alpha_{1-\nu}(\boldsymbol{w}, b) < 0$, there exists a positive constant c such that the following bound holds with probability at least $1 - \ $:*

$$R[h] \leq \nu + G(\alpha_{1-\nu}(\boldsymbol{w}, b)).$$

A proof of the above theorem is omitted since the proof follows a similar line to the proof of Theorem 3. This theorem shows that when $\alpha_{1-\nu}(\boldsymbol{w}, b) < 0$, the upper bound $\nu + G(\alpha_{1-\nu}(\boldsymbol{w}, b))$ is lowered if $\alpha_{1-\nu}(\boldsymbol{w}, b)$ is reduced. On the other hand, Eq.(5) shows that the VaR $\alpha_{1-\nu}(\boldsymbol{w}, b)$ is upper-bounded by the CVaR $\phi_{1-\nu}(\boldsymbol{w}, b)$. Therefore, minimizing $\phi_{1-\nu}(\boldsymbol{w}, b)$ by Eν-SVC may have an effect of lowering the upper bound of the generalization error.

When $\alpha_{1-\nu}(\boldsymbol{w}, b) > 0$, we have the following theorem.

Theorem 5 *Let $\nu \in (0, \overline{\nu}]$. Then, for all $(\boldsymbol{w}, b)$ such that $\|\boldsymbol{w}\| = 1$ and $\alpha_{1-\nu}(\boldsymbol{w}, b) > 0$, there exists a positive constant c such that the following bound hold with probability at least $1 - \ $:*

$$R[h] \geq \nu - G(\alpha_{1-\nu}(\boldsymbol{w}, b)).$$

Moreover, the lower bound of $R[h]$ is bounded from above as

$$\nu - G(\alpha_{1-\nu}(\boldsymbol{w}, b)) \leq \nu - G(\phi_{1-\nu}(\boldsymbol{w}, b)).$$

A proof of the above theorem is also omitted since the proof resembles to Theorem 3. Theorem 5 implies that the lower bound $\nu - G(\alpha_{1-\nu}(\boldsymbol{w}, b))$ of the generalization error is upper-bounded by $\nu - G(\phi_{1-\nu}(\boldsymbol{w}, b))$. On the other hand, Eq.(5) and $\alpha_{1-\nu}(\boldsymbol{w}, b) > 0$ yields $\phi_{1-\nu}(\boldsymbol{w}, b) > 0$. Thus minimizing $\phi_{1-\nu}(\boldsymbol{w}, b)$ by Eν-SVC may contribute to lowering the lower bound $\nu - G(\alpha_{1-\nu}(\boldsymbol{w}, b))$ of the generalization error.

4. New Optimization Algorithm

As reviewed in Section 2.5, Eν-SVC involves a non-convex optimization problem. In this section, we give a new efficient optimization procedure for Eν-SVC. Our proposed procedure involves two optimization algorithms depending on the value of ν. We first describe the two algorithms and then show how these two algorithms are chosen for practical use.

4.1. Optimization When $\nu \in (\overline{\nu}, \nu_{\max}]$

Lemma 6 *When $\nu \in (\overline{\nu}, \nu_{\max}]$, the E$\nu$-SVC problem (3) is equivalent to*

$$\begin{aligned} &\min_{\boldsymbol{w}, b, \boldsymbol{\xi}, \rho} \ -\nu\rho + \frac{1}{m}\sum_{i=1}^{m} \xi_i \\ &\text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) \geq \rho - \xi_i, \ \xi_i \geq 0, \ \|\boldsymbol{w}\|^2 \leq 1. \end{aligned} \quad (8)$$

This lemma shows that the equality constraint $\|\boldsymbol{w}\|^2 = 1$ in the original problem (3) can be replaced by $\|\boldsymbol{w}\|^2 \leq 1$ without changing the solution. Due to the convexity of $\|\boldsymbol{w}\|^2 \leq 1$, the above optimization problem is convex and therefore we can easily obtain the global solution by a standard optimization software.

4.2. Optimization When $\nu \in (0, \overline{\nu}]$

If $\nu \in (0, \overline{\nu}]$, the E$\nu$-SVC optimization problem is essentially non-convex and therefore we need a more elaborate algorithm.

4.2.1. Local Optimum Search

Here, we propose the following iterative algorithm for finding a local optimum.

Algorithm 7 (The Eν-SVC local optimum search algorithm for $\nu \in (0, \overline{\nu}]$)

Step 1: Initialize $\widetilde{\boldsymbol{w}}$.
Step 2: Solve the following linear program:

$$\begin{aligned} &\min_{\boldsymbol{w}, b, \boldsymbol{\xi}, \rho} \ -\nu\rho + \frac{1}{m}\sum_{i=1}^{m} \xi_i \\ &\text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) \geq \rho - \xi_i, \ \xi_i \geq 0, \ \langle \widetilde{\boldsymbol{w}}, \boldsymbol{w} \rangle = 1, \end{aligned} \quad (9)$$

and let the optimal solution be $(\widehat{\boldsymbol{w}}, \widehat{b}, \widehat{\boldsymbol{\xi}}, \widehat{\rho})$.
Step 3: If $\widetilde{\boldsymbol{w}} = \widehat{\boldsymbol{w}}$, terminate and output $\widetilde{\boldsymbol{w}}$. Otherwise, update $\widetilde{\boldsymbol{w}}$ by $\widetilde{\boldsymbol{w}} \longleftarrow \widehat{\boldsymbol{w}}/\|\widehat{\boldsymbol{w}}\|$.
Step 4: Repeat Steps 2–3.

The linear program (9) is the same as the one proposed by Perez-Cruz et al. (2003), i.e., the equality constrained $\|\boldsymbol{w}\|^2 = 1$ of the original problem (3) is

replaced by $\langle \widetilde{\boldsymbol{w}}, \boldsymbol{w} \rangle = 1$. The updating rule of $\widetilde{\boldsymbol{w}}$ in Step 3 is different from the one proposed by Perez-Cruz et al. (2003) (cf. Eq.(4)).

We define a "corner" (or "0-dimensional face") of Eν-SVC (3) as the intersection of an edge of the polyhedral cone formed by linear constraints of (3) and $\|\boldsymbol{w}\|^2 = 1$. Under the new update rule, the algorithm visits a corner of Eν-SVC (3) in each iteration. Since Eν-SVC has finite corners, we can show that Algorithm 7 with the new update rule terminates in a finite number of iterations, i.e., less than or equal to the number of corners of Eν-SVC.

Theorem 8 *Algorithm 7 terminates within a finite number of iterations of Steps 2–3. Furthermore, a solution of the modified Eν-SVC algorithm is a local minimizer if it is unique and non-degenerate.*

4.2.2. Global Optimum Search

Next, we show that the global solution can be actually obtained within finite iterations, despite the non-convexity of the optimization problem.

A naive approach to searching for the global solution is to run the local optimum search algorithm many times with different initial values and choose the best local solution. However, there is no guarantee that this naive approach can find the global solution. Below, we give a more systematic way to find the global solution based on the following lemma.

Lemma 9 *When $\nu \in (0, \overline{\nu}]$, the E$\nu$-SVC problem* (3) *is equivalent to*

$$\min_{\boldsymbol{w}, b, \boldsymbol{\xi}, \rho} \; -\nu\rho + \frac{1}{m}\sum_{i=1}^{m} \xi_i$$
$$\text{s.t. } y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) \geq \rho - \xi_i,\ \xi_i \geq 0,\ \|\boldsymbol{w}\|^2 \geq 1. \quad (10)$$

Lemma 9 could be proved in a similar way as Lemma 6, so we omit the proof. This lemma shows that the equality constraint $\|\boldsymbol{w}\|^2 = 1$ in the original Eν-SVC problem (3) can be replaced by $\|\boldsymbol{w}\|^2 \geq 1$ without changing the solution if $\nu \in (0, \overline{\nu}]$.

The problem (10) is called a *linear reverse convex program* (LRCP), which is a class of non-convex problems consisting of linear constraints and one concave inequality ($\|\boldsymbol{w}\|^2 \geq 1$ in the current case). The feasible set of the problem (10) consists of a finite number of *faces*. For LRCPs, Horst and Tuy (1995) showed that the local optimal solutions correspond to 0-dimensional faces (or corners). This implies that all the local optimal solutions of the Eν-SVC problem (10) can be traced by checking all the faces.

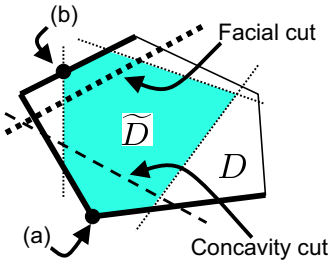

Figure 3. A 0-dimensional face (a) and three proper faces (bold solid lines) of D are identified in $\widetilde{D}$. If the corner (a) is found in Step 2, a concavity cut is constructed. If the corner (b) is found, a facial cut is constructed. If these two cuts are added to $\widetilde{D}$, the remaining area includes no face of D.

Let D be the feasible set of Eν-SVC (3). Below, we summarize the Eν-SVC training algorithm based on the *cutting plane method*, which is an efficient method of tracing faces.

Algorithm 10 (The Eν-SVC global optimum search algorithm for $\nu \in (0, \overline{\nu}]$)

Step 1: $\widetilde{D} \longleftarrow D$.
Step 2: Find a local solution by Algorithm 7.
Step 3: Identify a face of D in $\widetilde{D}$ that corresponds the local solution.
Step 4a: If the face is a corner, construct a "concavity cut".
Step 4b: If the face is a proper face, construct a "facial cut".
Step 5: Add the cut to the problem (9) and $\widetilde{D}$.
Step 6: Repeat Steps 2–5 until $\widetilde{D}$ includes no face of D.
Step 7: Output the best local optimal solution as the global solution.

If the local solution obtained in Step 2 is a corner of D (i.e., the local solution is not on any cutting plane as (a) in Figure 3), a *concavity cut* (Horst & Tuy, 1995) is constructed. The concavity cut has a role of removing the local solution, i.e., a 0-dimensional face of D and its neighborhood. Otherwise, a *facial cut* (Majthay & Whinston, 1974) is constructed to eliminate the proper face (see (b) in Figure 3).

Since the total number of distinct faces of D is finite in the current setting and a facial cut or a concavity cut eliminates at least one face at a time, Algorithm 10 is guaranteed to terminate within finite iterations (precisely, less than or equal to the number of all dimensional faces of Eν-SVC). Furthermore, since the addition of a concavity cut or a facial cut does not remove local solutions which are better than the best local solution found so far, Algorithm 10 is guaranteed to

trace all *sufficient* local solutions. Thus we can always find a global solution within finite iterations by Algorithm 10. A more detailed discussion on the concavity cut and the facial cut is shown in Horst and Tuy (1995) and Majthay and Whinston (1974), respectively.

4.3. Choice of Two Algorithms

We have two convergent algorithms when $\nu \in (\overline{\nu}, \nu_{\max}]$ and $\nu \in (0, \overline{\nu}]$. Thus, choosing a suitable algorithm depending on the value of ν would be an ideal procedure. However, the value of the threshold $\overline{\nu}$ is difficult to explicitly compute since it is defined via the optimal value $\phi_{1-\overline{\nu}}(\boldsymbol{w}^*, b^*)$ (see Figure 2). Therefore, it is not straightforward to choose a suitable algorithm for a given ν.

When we use Eν-SVC in practice, we usually compute the solutions for several different values of ν and choose the most promising one based on, e.g., cross-validation. In such scenarios, we can properly switch two algorithms without explicitly knowing the value of $\overline{\nu}$—our key idea is that the solution of the problem (8) is non-trivial (i.e., $\boldsymbol{w} \neq \boldsymbol{0}$) if and only if $\nu \in (\overline{\nu}, \nu_{\max}]$. Thus if the solutions are computed from large ν to small ν, the switching point can be identified by checking the triviality of the solution. The proposed algorithm is summarized as follows.

Algorithm 11 (The Eν-SVC algorithm for ($\nu_{\max} \geq$) $\nu_1 > \nu_2 > \cdots > \nu_k > 0$)

Step 1: $i \longleftarrow 1$.
Step 2: Compute $(\boldsymbol{w}^*, b^*)$ for ν_i by solving (8).
Step 3a: If $\boldsymbol{w}^* \neq \boldsymbol{0}$, accept $(\boldsymbol{w}^*, b^*)$ as the solution for ν_i, increment i, and go to Step 2.
Step 3b: If $\boldsymbol{w}^* = \boldsymbol{0}$, reject $(\boldsymbol{w}^*, b^*)$.
Step 4: Compute $(\boldsymbol{w}^*, b^*)$ for ν_i by Algorithm 10.
Step 5: Accept $(\boldsymbol{w}^*, b^*)$ as the solution for ν_i, increment i, and go to Step 4 unless $i > k$.

5. Conclusions

We characterized the generalization error of Eν-SVC in terms of the *conditional value-at-risk* (CVaR, see Figure 1) and showed that a good generalization performance is expected by Eν-SVC. We then derived a globally convergent optimization algorithm even though the optimization problem involved in Eν-SVC is non-convex.

We introduced the threshold $\overline{\nu}$ based on the sign of the CVaR (see Figure 2). We can check that the problem (8) is equivalent to ν-SVC in the sense that they share the same negative optimal value in $(\overline{\nu}, \nu_{\max}]$ and $(\nu_{\min}, \nu_{\max}]$, respectively (Gotoh & Takeda, 2005). On the other hand, the problem (8) and ν-SVC have the zero optimal value in $(0, \overline{\nu}]$ and $[0, \nu_{\min}]$, respectively. Thus, although the definitions of $\overline{\nu}$ and $\nu_{\min}$ are different, they would be essentially the same. We will study the relation between $\overline{\nu}$ and $\nu_{\min}$ in more detail in the future work.

A. Sketch of Proof of Theorem 1

Let $(\boldsymbol{w}^*, b^*, \alpha^*)$ be the optimal solution of

$$\min_{\boldsymbol{w}, b, \alpha} F_\beta(\boldsymbol{w}, b, \alpha), \tag{11}$$

where, for $[X]^+ := \max\{X, 0\}$,

$$F_\beta(\boldsymbol{w}, b, \alpha) := \alpha + \frac{\sum_{i \in M} [f(\boldsymbol{w}, b; \boldsymbol{x}_i, y_i) - \alpha]^+}{(1-\beta)m}. \tag{12}$$

Then Rockafellar and Uryasev (2002) showed that

$$F_\beta(\boldsymbol{w}^*, b^*, \alpha^*) = \phi_\beta(\boldsymbol{w}^*, b^*) = \min_{\boldsymbol{w}, b} \phi_\beta(\boldsymbol{w}, b), \qquad (13)$$

i.e, the problems (6) and (11) are equivalent.

Introducing slack variables ξ_i, imposing $\|\boldsymbol{w}\|^2 = 1$ (which does not change the solution essentially; only the scale is changed), and letting $\nu = 1 - \beta$ and $\rho = -\alpha$ in Eq.(11), we establish the theorem.

B. Sketch of Proof of Lemma 2

Since Eq.(11) only involves continuous functions, continuity of $F_\beta(\boldsymbol{w}^*, b^*, \alpha^*)$ with respect to β is clear. From Eq.(13), $\phi_\beta(\boldsymbol{w}^*, b^*)$ is also continuous. Let $(\boldsymbol{w}^*_{\beta_i}, b^*_{\beta_i}, \alpha^*_{\beta_i})$ be the optimal solutions of Eq.(11) for $0 < \beta_1 < \beta_2 < 1$. Then we have

$$\begin{aligned}\phi_{\beta_1}(\boldsymbol{w}^*_{\beta_1}, b^*_{\beta_1}) &= F_{\beta_1}(\boldsymbol{w}^*_{\beta_1}, b^*_{\beta_1}, \alpha^*_{\beta_1}) \leq F_{\beta_1}(\boldsymbol{w}^*_{\beta_2}, b^*_{\beta_2}, \alpha^*_{\beta_2}) \\ &< F_{\beta_2}(\boldsymbol{w}^*_{\beta_2}, b^*_{\beta_2}, \alpha^*_{\beta_2}) = \phi_{\beta_2}(\boldsymbol{w}^*_{\beta_2}, b^*_{\beta_2}),\end{aligned}$$

where the first inequality is due to optimality of $(\boldsymbol{w}^*_{\beta_1}, b^*_{\beta_1}, \alpha^*_{\beta_1})$ and the second strict inequality is clear from Eq.(12). Thus $\phi_\beta(\boldsymbol{w}^*, b^*)$ is strictly increasing with respect to β, implying that $\phi_{1-\nu}(\boldsymbol{w}^*, b^*)$ is strictly decreasing with respect to ν.

C. Sketch of Proof of Theorem 3

For a homogeneous classifier $h(\widetilde{\boldsymbol{x}}) = \mathrm{sign}(\langle \widetilde{\boldsymbol{w}}, \widetilde{\boldsymbol{x}} \rangle)$, the following lemma holds:

Lemma 12 *(Schölkopf et al., 2000) Suppose that support $\mathcal{X}$ of $\widetilde{\boldsymbol{x}}$ is in a ball of radius $\widetilde{R}$ around the origin. Then, for all $\widetilde{\boldsymbol{w}}$ such that $\|\widetilde{\boldsymbol{w}}\| = 1$, there exists a positive constant c such that the following bound holds with probability at least $1 - \delta$:*

$$\begin{aligned}R[h] \leq & \frac{|\{i \mid y_i \langle \widetilde{\boldsymbol{w}}, \widetilde{\boldsymbol{x}}_i \rangle < \widetilde{\gamma}\}|}{m} \\ & + \sqrt{\frac{2}{m}\left(\frac{4c^2\widetilde{R}^2}{\widetilde{\gamma}^2}\log_2(2m) - 1 + \log\frac{2}{\delta}\right)}.\end{aligned}$$

Let $\widetilde{\boldsymbol{w}} = \frac{(\boldsymbol{w}^\top, b)^\top}{\sqrt{1+b^2}}$ and $\widetilde{\boldsymbol{x}} = (\boldsymbol{x}^\top, 1)^\top$. Then our classifier (1) can be regarded as homogeneous. The assumption that all the data points $\boldsymbol{x}$ live in a centered ball of radius R implies that all the data points $\widetilde{\boldsymbol{x}}$ live in a centered ball of radius

$$\widetilde{R} = \sqrt{R^2 + 1}.$$

The assumption $\|\boldsymbol{w}\| = 1$ implies $\|\widetilde{\boldsymbol{w}}\| = 1$. Then we can apply Lemma 12 to the current setting. The condition $y_i \langle \widetilde{\boldsymbol{w}}, \widetilde{\boldsymbol{x}}_i \rangle < \widetilde{\gamma}$ results in

$$y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) < \widetilde{\gamma}\sqrt{1+b^2} := \gamma.$$

When all the data points $\boldsymbol{x}$ live in a centered ball of radius R, we can assume without loss of generality that $|b| \leq R$. Then we have

$$\frac{1}{\widetilde{\gamma}^2} = \frac{1+b^2}{\gamma^2} \leq \frac{1+R^2}{\gamma^2}.$$

Now let us set

$$\gamma = -\alpha_{1-\nu}(\boldsymbol{w}, b).$$

Then we can show that

$$\tfrac{1}{m}|\{i \mid y_i(\langle \boldsymbol{w}, \boldsymbol{x}_i \rangle + b) < -\alpha_{1-\nu}(\boldsymbol{w}, b)\}| \leq \nu.$$

We omit its proof due to lack of space. Then we obtain the upper bound $\nu + G(\alpha_{1-\nu}(\boldsymbol{w}, b))$; the upper bound $\nu + G(\phi_{1-\nu}(\boldsymbol{w}, b))$ is clear from Eq.(5).

D. Sketch of Proof of Lemma 6

Since the difference between the problems (3) and (8) is only the norm constraint of $\boldsymbol{w}$, it is enough to show that for $\nu \in (\overline{\nu}, \nu_{\max}]$, $\|\boldsymbol{w}^*\|^2 = 1$ holds at the optimal solution $(\boldsymbol{w}^*, b^*, \boldsymbol{\xi}^*, \rho^*)$ of the problem (8). For such ν, $\phi_{1-\nu}(\boldsymbol{w}^*, b^*) < 0$ holds, i.e., the optimal value of Eν-SVC is negative. If we suppose $\|\boldsymbol{w}^*\|^2 < 1$, another feasible solution $(\boldsymbol{w}^*, b^*, \boldsymbol{\xi}^*, \rho^*)/\|\boldsymbol{w}^*\|$ achieves a smaller optimal value than $(\boldsymbol{w}^*, b^*, \boldsymbol{\xi}^*, \rho^*)$. This contradicts to the optimality of (8), and hence $\|\boldsymbol{w}^*\|^2 = 1$ is proved.

E. Sketch of Proof of Theorem 8

Let $(\widehat{\boldsymbol{w}}_k, \widehat{b}_k, \widehat{\boldsymbol{\xi}}_k, \widehat{\rho}_k)$ be an optimal solution of the linear program (9) in the k-th iteration. Then, a feasible solution of Eν-SVC (3) is given by

$$(\widetilde{\boldsymbol{w}}_k, \widetilde{b}_k, \widetilde{\boldsymbol{\xi}}_k, \widetilde{\rho}_k) = (\widehat{\boldsymbol{w}}_k, \widehat{b}_k, \widehat{\boldsymbol{\xi}}_k, \widehat{\rho}_k)/\|\widehat{\boldsymbol{w}}_k\|.$$

Since $(\widehat{\boldsymbol{w}}_k, \widehat{b}_k, \widehat{\boldsymbol{\xi}}_k, \widehat{\rho}_k)$ is at a corner of the feasible set of the linear program (9), $(\widetilde{\boldsymbol{w}}_k, \widetilde{b}_k, \widetilde{\boldsymbol{\xi}}_k, \widetilde{\rho}_k)$ is also a corner of the feasible set of Eν-SVC (3).

Let $q(\cdot)$ be the objective function of Eν-SVC (3), which is also the objective function of the linear program (9). Then we have

$$q(\widetilde{\boldsymbol{\xi}}_{k-1}, \widetilde{\rho}_{k-1}) > q(\widehat{\boldsymbol{\xi}}_k, \widehat{\rho}_k) \geq q(\widetilde{\boldsymbol{\xi}}_k, \widetilde{\rho}_k) = q(\widehat{\boldsymbol{\xi}}_k, \widehat{\rho}_k)/\|\widehat{\boldsymbol{w}}_k\|,$$

where the first inequality comes from the optimality of $(\widehat{\boldsymbol{\xi}}_k, \widehat{\rho}_k)$ of the linear program (9). The second inequality comes from $\|\widehat{\boldsymbol{w}}_k\| > 1$, which is ensured by $\langle \widetilde{\boldsymbol{w}}_{k-1}, \widehat{\boldsymbol{w}}_k \rangle = 1$. Thus the algorithm finds a distinct corner of Eν-SVC (3) in each iteration. Since the number of corners of Eν-SVC (3) is finite, the algorithm terminates within finite iterations.

Let $\Delta\boldsymbol{d} = (\Delta\boldsymbol{w}^\top\ \Delta b^\top\ \Delta\rho^\top\ \Delta\boldsymbol{\xi}^\top)^\top$ be a perturbation from the solution $\boldsymbol{d}^* = (\boldsymbol{w}^*, b^*, \rho^*, \boldsymbol{\xi}^*)$ of Algorithm 7. Note that $\boldsymbol{d}^*$ is an optimal solution of the linear program (9) with $\widetilde{\boldsymbol{w}} = \boldsymbol{w}^*$. Using the Karush-Kuhn-Tucker (KKT) optimality conditions, we can express the increase Δq of the objective value as

$$\begin{aligned}\Delta q &:= -\nu\Delta\rho + \frac{1}{m}\sum_{i \in M}\Delta\xi_i \\ &= \Delta\boldsymbol{d}^\top \left(\begin{array}{ccc|c} y_1\boldsymbol{x}_1 & \dots & y_m\boldsymbol{x}_m & \boldsymbol{O} \\ y_1 & \dots & y_m & \boldsymbol{0} \\ 1 & \dots & 1 & \boldsymbol{0} \\ & \boldsymbol{I} & & \boldsymbol{I} \end{array}\right) \begin{pmatrix} \boldsymbol{\lambda}^* \\ \boldsymbol{\mu}^* \end{pmatrix} - \delta^*\Delta\boldsymbol{w}^\top\boldsymbol{w}^*,\end{aligned}$$

where $\boldsymbol{\lambda}^* \in \mathbb{R}^m_+$, $\boldsymbol{\mu}^* \in \mathbb{R}^m_+$, and $\delta^* \leq 0$ are KKT multipliers. If $\Delta\boldsymbol{d}$ is a feasible perturbation (i.e., $\boldsymbol{d}^* + \Delta\boldsymbol{d}$ is feasible), we can show that $\Delta q > 0$ (we omit its proof due to lack of space), which implies that $\boldsymbol{d}^*$ is locally optimal.

Training Restricted Boltzmann Machines using Approximations to the Likelihood Gradient

Tijmen Tieleman TIJMEN@CS.TORONTO.EDU
Department of Computer Science, University of Toronto, Toronto, Ontario M5S 3G4, Canada

Abstract

A new algorithm for training Restricted Boltzmann Machines is introduced. The algorithm, named Persistent Contrastive Divergence, is different from the standard Contrastive Divergence algorithms in that it aims to draw samples from almost exactly the model distribution. It is compared to some standard Contrastive Divergence and Pseudo-Likelihood algorithms on the tasks of modeling and classifying various types of data. The Persistent Contrastive Divergence algorithm outperforms the other algorithms, and is equally fast and simple.

1. Introduction

Restricted Boltzmann Machines (RBMs) (Hinton et al., 2006; Smolensky, 1986) are neural network models for unsupervised learning, but have recently seen a lot of application as feature extraction methods for supervised learning algorithms (Salakhutdinov et al., 2007; Larochelle et al., 2007; Bengio et al., 2007; Gehler et al., 2006; Hinton et al., 2006; Hinton & Salakhutdinov, 2006). The success of these models raises the issue of how best to train them.

Most training algorithms are based on gradient descent, but the standard objective function (training data likelihood) is intractable, so the algorithms differ in their choice of approximation to the gradient of the objective function. At present, the most popular gradient approximation is the Contrastive Divergence (CD) approximation (Hinton et al., 2006; Hinton, 2002; Bengio & Delalleau, 2007); more specifically the CD-1 approximation. However, it is not obvious whether it is the best. For example, the CD algorithm has a parameter specifying the number of Markov Chain transitions performed, and although the most commonly chosen value is 1, other choices are possible and reasonable, too (Carreira-Perpinan & Hinton, 2005).

In this paper, a new gradient approximation algorithm is presented and compared to a variety of CD-based algorithms. The quantitative measures of test data likelihood (for unsupervised learning) and classification error rate (for supervised learning) are investigated, and the type of feature detectors that are developed are also shown. We find that the new algorithm produces more meaningful feature detectors, and outperforms the other algorithms.

The RBMs on which these experiments were done all had binary units. However, this special case can easily be generalized to other *harmoniums* (Smolensky, 1986; Welling et al., 2005) in which the units have Gaussian, Poisson, multinomial, or other distributions in the exponential family, and the training algorithms described here require only minor modifications to work in most of those models.

In Section 2, the RBM model and CD gradient estimator are discussed. In Section 3, the Persistent Contrastive Divergence algorithm is introduced. In Sections 4 and 5, the experiments and results are described, and Section 6 concludes with a discussion and some plans for future work.

2. RBMs and the CD Gradient Approximation

2.1. Restricted Boltzmann Machines

An RBM is an energy-based model for unsupervised learning (Hinton, 2002; Smolensky, 1986). It consists of two layers of binary units: one *visible*, to represent the data, and one *hidden*, to increase learning capacity. Standard notation is to use i for indices of visible units, j for indices of hidden units, and w_{ij} for the strength of the connection between the i^{th} visible unit and the j^{th} hidden unit. If v_i denotes the state of the

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

i^{th} visible unit, and h_j denotes the state of the j^{th} hidden unit, an *energy* function is defined on states: $E(v,h) = -\sum_{i,j} v_i h_j w_{ij} - \sum_i v_i b_i - \sum_j h_j b_j$, where b stands for the biases. Through these energies, probabilities are defined as $P(v,h) = \frac{e^{-E(v,h)}}{Z}$ where Z is the normalizing constant $Z = \sum_{x,y} e^{-E(x,y)}$. The probability of a data point (represented by the state v of the visible layer) is defined as the marginal: $P(v) = \sum_h P(v,h) = \frac{\sum_h e^{-E(v,h)}}{Z}$. Thus, the training data likelihood, using just one training point for simplicity, is $\phi = \log P(v) = \phi^+ - \phi^-$ where $\phi^+ = \log \sum_h e^{-E(v,h)}$ and $\phi^- = \log Z = \log \sum_{x,y} e^{-E(x,y)}$. The *positive* gradient $\frac{\partial \phi^+}{\partial w_{ij}}$ is simple: $\frac{\partial \phi^+}{\partial w_{ij}} = v_i \cdot P(h_j = 1|v)$. The *negative* gradient $\frac{\partial \phi^-}{\partial w_{ij}} = P(v_i = 1, h_j = 1)$, however, is intractable. If we could get samples from the model, we could Monte Carlo approximate it, but even getting those samples is intractable.

2.2. The Contrastive Divergence Gradient Approximation

To get a tractable approximation of $\frac{\partial \phi^-}{\partial w_{ij}}$, one uses some algorithm to *approximately* sample from the model. The Contrastive Divergence (CD) algorithm is one way to do this. It is designed in such a way that at least the *direction* of the gradient estimate is somewhat accurate, even when the size is not. CD-1 is, at present, the most commonly used algorithm for training RBMs. One of the algorithms we compare is regular CD-1; another is CD-10, which is generally considered to be better if the required computer time is available.

A variation on CD is *mean field* CD (Welling & Hinton, 2002), abbreviated MF CD. This has the advantage of being a deterministic gradient estimate, which means that larger learning rates can be used. We include mean field CD-1 in the comparison.

3. The Persistent Contrastive Divergence Algorithm

CD-1 is fast, has low variance, and is a reasonable approximation to the likelihood gradient, but it is still significantly different from the likelihood gradient when the mixing rate is low. This can be seen by drawing samples from the distribution that it learns (see Figure 4). Generally speaking, CD-n for greater n is preferred over CD-1, if enough running time is available. In Neal's 1992 paper about Sigmoid Belief Networks (1992), a solution is suggested for such situations. In the context of RBMs, the idea is as follows (see also (Yuille, 2004)).

What we need for approximating $\frac{\partial \phi^-}{\partial w_{ij}}$ is a sample from the model distribution. The standard way to get it is by using a Markov Chain, but running a chain for many steps is too time-consuming. However, between parameter updates, the model changes only slightly. We can take advantage of that by initializing a Markov Chain at the state in which it ended for the previous model. This initialization is often fairly close to the model distribution, even though the model has changed a bit in the parameter update. Neal uses this approach with Sigmoid Belief Networks to approximately sample from the posterior distribution over hidden layer states given the visible layer state. For RBMs, the situation is a bit simpler: there is only one distribution from which we need samples, as opposed to one distribution per training data point. Thus, the algorithm can be used to produce gradient estimates *online* or using mini-batches, using only a few training data points for the positive part of each gradient estimate, and only a few 'fantasy' points for the negative part. The fantasy points are updated by one full step of the Markov Chain each time a mini-batch is processed.

Of course this still is an approximation, because the model does change slightly with each parameter update. With infinitesimally small learning rate it becomes exact, and in general it seems to work best with small learning rates.

We call this algorithm *Persistent Contrastive Divergence* (PCD), to emphasize that the Markov Chain is not reset between parameter updates.

4. Experiments

We did a variety of experiments, using different data sets (digit images, emails, artificial data, horse image segmentations, digit image patches), different models (RBMs, classification RBMs, fully visible Markov Random Fields), different training procedures (PCD, CD-1, CD-10, MF CD, pseudo likelihood), and different tasks (unsupervised vs. supervised learning).

4.1. Data Sets

The first data set that we used was the MNIST dataset of handwritten digit images (LeCun & Cortes,). The images are 28 by 28 pixels, and the data set consists of 60,000 training cases and 10,000 test cases. To have a validation set, we split the official training set of 60,000 cases into a training set of 50,000 cases and a validation set of 10,000 cases. To have binary data, we treat the pixel intensities as probabilities. Each time a binary data point is required, a real-valued MNIST im-

age is binarized by sampling from the given Bernoulli distribution for each pixel. Thus, in effect, our data set is a mixture of 70,000 factorial distributions: one for each of the data points in the MNIST data set.

Another data set was obtained by taking small patches of 5 by 5 pixels, from the MNIST images. To have somewhat smooth-looking data, we binarized by thresholding at 1/2. The 70,000 MNIST data points were thus turned into 70,000 times $(28 - 5 + 1)^2$ is 4,032,000 patches. This data set was split into training (60%), validation (20%), and test (20%) sets.

A data set consisting of descriptions of e-mails was made available by Sam Roweis. It describes 5,000 e-mails using a variety of binary features - mostly word presence vs. absence features. The e-mails are labeled as spam or non-spam.

An artificial data set was created by combining the outlines of rectangles and triangles. Because this data set is artificially generated, there is an infinite amount of it, which helps shed some light on the reasons for using weight decay regularization.

Lastly, we used a data set of image segmentations: in pictures of horses, the segmentation indicates which pixels are part of the horse and which are background (Borenstein et al., 2004). By using only the segmentation, we have a binary data set.

4.2. Models

The first model we used is an RBM, exactly as described above. For the MNIST and horse segmentation data sets, we used 500 hidden units; for the artificial data set we used 100.

One of the evaluations is how well the learned RBM models the test data, i.e. log likelihood. This is intractable for regular size RBMs, because the time complexity of that computation is exponential in the size of the smallest layer (visible or hidden). One experiment, therefore, was done using only 25 hidden units, so that log likelihood could be calculated exactly in about two hours. Another experiment uses an approximate assessment of the normalization constant Z, that was developed recently in our group (Salakhutdinov & Murray, 2008). This algorithm works for any number of hidden units, but its reliability has not been researched extensively. Nonetheless, it seems to give a reasonable indication, and can be used to complement other results.

RBMs, however, are models for unsupervised learning, so for classification we used a slightly different model, described in more detail in (Hinton et al., 2006). We used an RBM with one added visible unit, which represented the label. The training data points are then combinations of inputs with their labels, and testing is done by choosing the most likely label given the input, under the learned model. This model we call a 'classification RBM'. Note that the label unit is not necessarily binary (although in the spam classification task it is). In the MNIST classification task it is multinomial: it can have 10 different values. This, however, does not significantly change the algorithms (Hinton, 2002). For MNIST classification we used 500 hidden units; for spam classification we used 100.

The third model we tested is significantly different: a fully visible, fully connected Markov Random Field (MRF) (see for example (Wainwright & Jordan, 2003)). One can use the PCD algorithm on it, although it looks a bit different in this case. We compared its performance to the more commonly used Pseudo-Likelihood optimization algorithm (Besag, 1986). To have exact test data log likelihood measurements, we used small models, with only 25 units.

4.3. The Mini-batch Optimization Procedure

We used the *mini-batch* learning procedure: we only used a small number of training points for each gradient estimate. We used 100 training points in each mini-batch for most data sets.

4.4. Algorithm Details

The PCD algorithm can be implemented in various ways. One could, for example, choose to randomly reset some of the Markov Chains at regular intervals. Initial tests showed that the best implementation is as follows: no Markov Chains get reset; one full Gibbs update is done on each of the Markov Chains for each gradient estimate; and the number of Markov Chains is equal to the number of training data points in a mini-batch.

PCD for fully visible MRFs is a bit different from PCD for RBMs. A pleasant difference is that $\frac{\partial \phi^+}{\partial \theta}$ is constant, so it can be precomputed for the entire training set. Thus, no variance results from the use of mini-batches, and the training set can be discarded after $\frac{\partial \phi^+}{\partial \theta}$ is computed over it. An unpleasant difference is that the Markov Chain defined by Gibbs sampling has slower mixing: MRFs with connections between the visible units lack the pleasant property of RBMs that all visible units can be updated at the same time.

A Pseudo-Likelihood (PL) gradient computation requires more work than a PCD gradient computation, because it requires a logistic regression gradient esti-

mate for each of the units. As a result, we found that using mini-batches of 50 training points instead of 100 took only a little bit more time per training point, and did allow updating the model parameters almost twice as often, which is preferable in the mini-batch optimization procedure.

4.5. Other Technical Details

The learning rates used in the experiments are not constant. In practice, decaying learning rates often work better. In these experiments, the learning rate was linearly decayed from some initial learning rate to zero, over the duration of the learning. Preliminary experiments showed that this works better than the $\frac{1}{t}$ schedule suggested in theoretical work by (Robbins & Monro, 1951), which is preferable when infinitely much time is available for the optimization.

Some experiment parameters, such as the number of hidden units, and the size of the mini-batches, were fixed. However, the initial learning rate was chosen using a validation set, as was weight decay for the (shorter) experiments on the spam, horses, MNIST patches, and artificial data sets. For each algorithm, each task, and each training duration, 30 runs were performed with evaluation on validation data, trying to find the settings that worked best. Then a choice of initial learning rate and, for the shorter experiments, weight decay, were made, and with those chosen settings, 10 more runs were performed, evaluating on test data. This provided 10 test performance numbers, which were summarized by their average and standard deviation (shown as error bars).

5. Results

5.1. The three MNIST Tasks

The results on the three MNIST tasks are shown in Figures 1, 2, and 3.

It is clear that PCD outperforms the other algorithms. PCD, CD-1, and MF CD all take approximately the same amount of time per gradient estimate, with MF CD being a little bit faster because it does not have to create random numbers. CD-10 takes about four times as long as PCD, CD-1, and MF CD, but it is indeed better than CD-1.

While CD-1 is good for some purposes, it is substantially different from the true likelihood gradient. This can be seen by drawing samples from an RBM that was trained with CD-1. Figure 4 shows those next to samples drawn from an RBM that was trained using PCD. It is clear that PCD is a better approximation

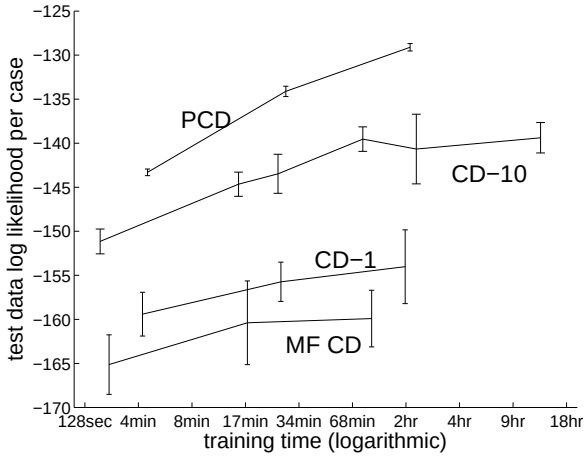

Figure 1. Modeling MNIST data with 25 hidden units (exact log likelihood)

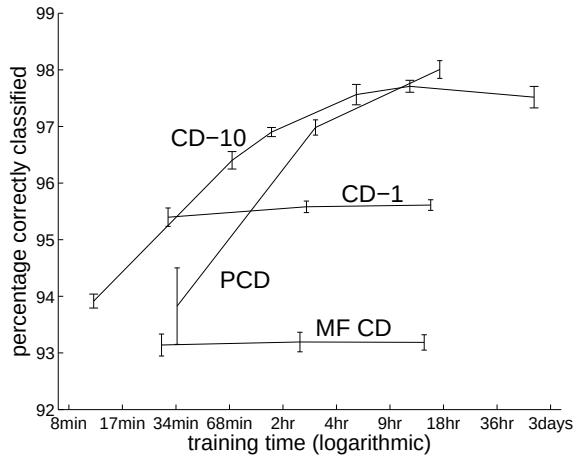

Figure 3. Classification of MNIST data

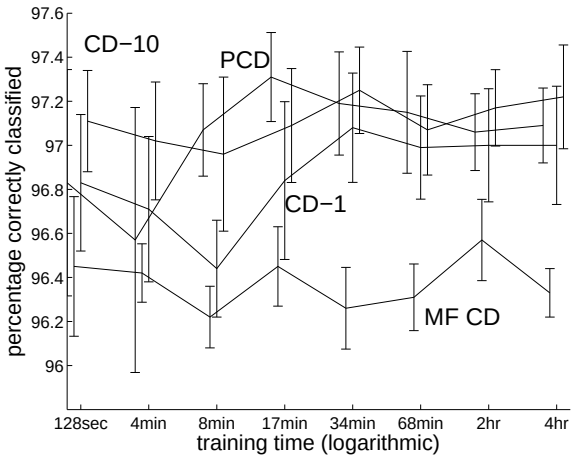

Figure 6. Classifying e-mail as spam versus non-spam

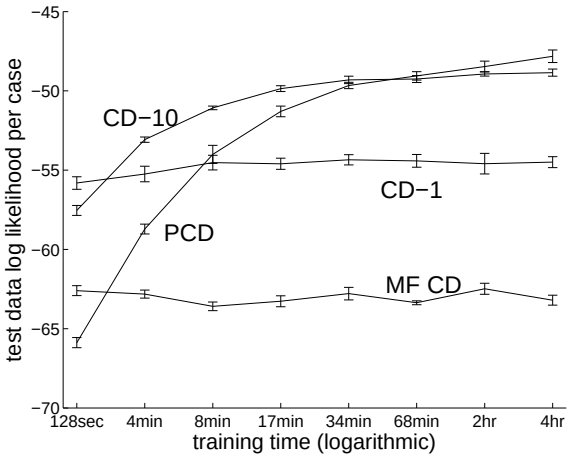

Figure 5. Modeling artificial data

to the likelihood gradient.

Classification is a particularly interesting task because it gives an indication of how well the model can extract relevant features from the input. RBMs are most often used as feature detectors, and this finding suggests that PCD creates feature detectors that give better classification than CD-1.

5.2. Modeling Artificial Data

In Figure 5 we see essentially the same as what happened on the MNIST tasks. MF CD is clearly the worst of the algorithms, CD-1 works better, and CD-10 and PCD work best, with CD-10 being preferable when little time is available and PCD being better if more time is available.

This data set was artificially generated, so there was an infinite amount of data available. Thus, one might think that the use of weight decay serves no purpose. However, all four algorithms did work best with some weight decay. The explanation for this is that CD algorithms are quite dependent on the mixing rate of the Markov Chain defined by the Gibbs sampler, and that mixing rate is higher when the parameters of the model are smaller. Thus, weight decay keeps the model mixing reasonably well, and makes CD algorithms work better. The effect is strongest for MF CD, which performs only one Gibbs update and does so without introducing noise. MF CD worked best with a weight decay strength of 10^{-3}. CD-1 does introduce some noise in the update procedure, and required less weight decay: $3 \cdot 10^{-4}$. CD-10 performs more updates, and is less dependent on the mixing rate. The best weight decay value for CD-10 turned out to be approximately $1.3 \cdot 10^{-4}$. Finally, the mixing mechanism used by PCD is even better, but it is still based on the Gibbs sampler, so it, too, works better with some weight decay. The best weight decay strength for PCD was approximately $2.5 \cdot 10^{-5}$.

5.3. Classifying E-mail Data

In Figure 6 the results on the e-mail classification task are shown. Because this is a small data set (5,000 data points in total, i.e. only 1000 test data points), we see that the error bars on the performace are quite large. Thus, we cannot carefully compare the performance of CD-1, CD-10, and PCD. We only see that MF CD is, again, not the best method.

However, we can conclude that RBMs can be used for this task, too, with acceptable performance, and that

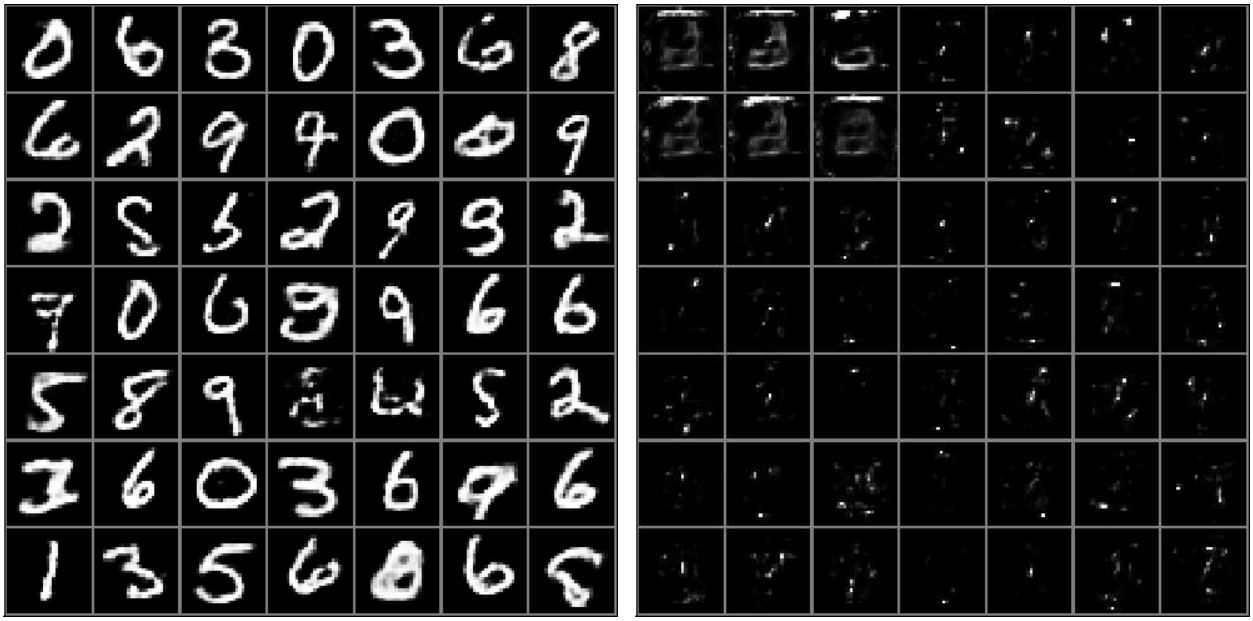

Figure 4. Samples from an RBM that was trained using PCD (left) and an RBM that was trained using CD-1 (right). Clearly, CD-1 did not produce an accurate model of the MNIST digits. Notice, however, that some of the CD-1 samples vaguely resemble a three.

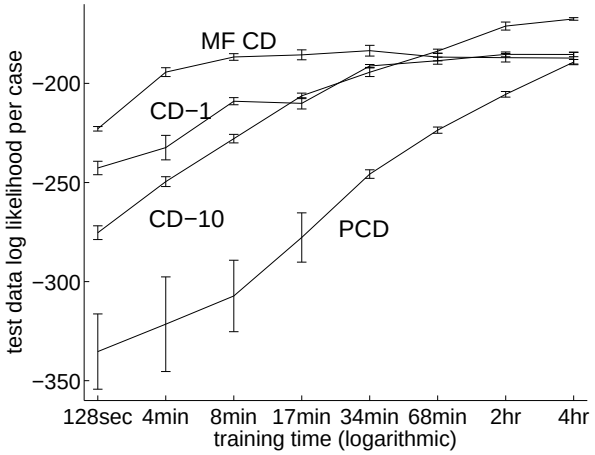

Figure 7. Modeling horse segmentation data

PCD is a reasonable choice of training algorithm.

5.4. Modeling Horse Contours

In Figure 7 we see a different picture: PCD is not the best algorithm here. The most plausible explanation is that although the same amount of training time was used, the data is much bigger: 1024 visible units, and 500 hidden units. Thus, there were 20 times as many connections in the RBM to be learned, which also means processing one mini-batch took more than 10 times as long as for the artificial data. Thus, we are essentially looking at a short optimization. Above, we already saw that CD-10 is better than PCD when little time is available, and that is confirmed here. We conjecture that, given significantly more training time, PCD would perform better than the other algorithms.

5.5. PCD on Fully Visible MRFs

To verify that PCD also works well with other models, we did some experiments with fully visible, fully connected MRFs. To be able to have exact test data likelihood evaluation, we made the MRFs small, and modeled 5 by 5 pixel patches from the MNIST digit images.

Pseudo-Likelihood (PL) training works reasonably well on this data set, but it does not produce the best probability models. Presumably this is simply because PL optimizes a different objective function. As a result, PL needed early stopping to prevent diverging too much from the data likelihood objective function, and the optimal learning rates are more or less inversely proportional to the duration of the optimization. Even with only a few seconds training time, the best test data likelihood is already achieved: -5.35.

PCD training does go more in the direction of the data likelihood function - asymptotically it gives its exact gradient. Thus, PCD did profit from having more time to run. Figure 8 shows the performance. The asymptotic value of approximately -5.15 does seem to be the best possible model: we also used exact gradient

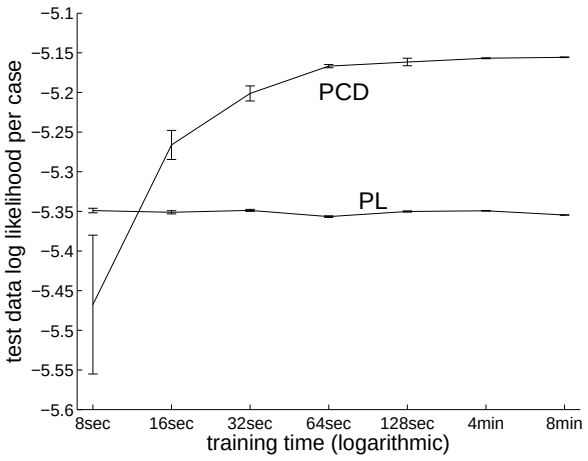

Figure 8. Training a fully visible MRF

optimization (which is slow, but possible), and this equally ended up with test data log likelihood of −5.15. However, the entropy of the training data distribution is significantly less than 5.15 'nats': it is 4.78 nats. This difference is probably due to the fact that the model has insufficient complexity to completely learn the training data distribution.

Incidentally, the training data log likelihood is only 0.004 better than the test data log likelihood - presumably because this data set is quite large and the model is quite small.

6. Discussion and Future Work

One issue not investigated is the use of weight decay. It is quite possible that the more approximate algorithms (such as CD-1 and MF CD) would benefit more from weight decay than CD-10 and PCD. In an RBM with zero weights, CD-1 and MF CD give exactly the likelihood gradient, and in general, in RBMs with small weights those algorithms give better approximations to the likelihood gradient than in RBMs with large weights. Weight decay keeps the weights small, and thus enables gradient estimates that approximate the likelihood gradient more closely. For many tasks, however, large weights may be required for good performance, so strong weight decay is undesirable if it can be avoided.

Also, the amount of training time used in these experiments is insufficient to find the asymptotic performance. In Figure 3 one can see, for example, that PCD clearly profits from more training time. To find out what its performance would be with more training time is future work, but we have seen runs (with more training time and more hidden units) where as few as 104 out of the 10,000 test cases were misclassified. Clearly, this is worth investigating further.

Another issue suggesting future work is that the classification RBMs in these experiments were not trained to maximize classification performance. They were trained to accurately model the joint distribution over images and labels. It is possible to train classification RBMs directly for classification performance; the gradient is fairly simple and certainly tractable. A natural way to use this classification error gradient is *after* training the RBM for joint density modeling. However, in preliminary experiments we found that this procedure begins to overfit very quickly (often after improving performance by less than 0.1%), so we did not include it in this paper. It is, however, still possible that *combining* the classification gradient with the density modeling gradient is a method that could yield more improvements. This is future work.

The main limitation of PCD is that it appears to require a low learning rate in order to allow the "fantasy" points to be sampled from a distribution that is close to the stationary distribution for the current weights. A theoretical analysis of this requirement can be found in (Yuille, 2004) and (Younes, 1999). Some preliminary experiments, however, suggest that PCD can be made to work well even when the learning rate is much larger than the one suggested by the asymptotic justification of PCD and we are currently exploring variations that allow much larger learning rates.

Acknowledgements

I thank Geoffrey Hinton and Ruslan Salakhutdinov for many useful discussions and helpful suggestions. Nikola Karamanov and Alex Levinshtein helped by providing data sets. The anonymous reviewers also provided many useful suggestions. This research was supported by NSERC and Microsoft.

Abstract

Reinforcement learning (RL) methods based on least-squares temporal difference (LSTD) have been developed recently and have shown good practical performance. However, the quality of their estimation has not been well elucidated. In this article, we discuss LSTD-based policy evaluation from the new viewpoint of semiparametric statistical inference. In fact, the estimator can be obtained from a particular estimating function which guarantees its convergence to the true value asymptotically, without specifying a model of the environment. Based on these observations, we 1) analyze the asymptotic variance of an LSTD-based estimator, 2) derive the optimal estimating function with the minimum asymptotic estimation variance, and 3) derive a suboptimal estimator to reduce the computational burden in obtaining the optimal estimating function.

1. Introduction

Reinforcement learning (RL) is a machine learning framework based on reward-related interactions with environments (Sutton & Barto, 1998). In many RL methods, policy evaluation, in which a value function is estimated from sample trajectories, is an important step for improving a current policy. Since RL problems often involve high-dimensional state spaces, the value functions are often approximated by low-dimensional parametric models. Linear function approximation has mostly been used due to their simplicity and computational convenience.

To estimate the value function with a linear model, an online procedure called temporal difference (TD) learning (Sutton & Barto, 1998) and a batch procedure called least-squares temporal difference (LSTD) learning are widely used (Bradtke & Barto, 1996). LSTD can achieve fast learning, because it uses entire sample trajectories simultaneously. Recently, efficient procedures for policy improvement combined with policy evaluation by LSTD have been developed, and have shown good performance in realistic problems. For example, the least squares policy iteration (LSPI) method maximizes the Q-function estimated by LSTD (Lagoudakis & Parr, 2003), and the natural actor-critic (NAC) algorithm uses the natural policy gradient obtained by LSTD (Peters et al., 2005). Although variance reduction techniques have been proposed for other RL algorithms (Greensmith et al., 2004; Mannor et al., 2007), the important issue of how to evaluate and reduce the estimation variance of LSTD learning remains unresolved.

In this article, we discuss LSTD-based policy evaluation in the framework of semiparmetric statistical inference, which is new to the RL field. Estimation of linearly-represented value functions can be formulated as a semiparametric inference problem, where the statistical model includes not only the parameters of interest but also additional nuisance parameters with innumerable degrees of freedom (Godambe, 1991; Amari & Kawanabe, 1997; Bickel et al., 1998). We approach this problem by using estimating functions, which provide a well-established method for semiparametric estimation (Godambe, 1991). We then show that the instrumental variable method, a technique used in LSTD

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

learning, can be constructed from an estimating function which guarantees its consistency (asymptotic lack of bias) by definition.

As the main results, we show the asymptotic estimation variance in a general instrumental variable method (Lemma 2) and the optimal estimating function that yields the minimum asymptotic variance of the estimation (Theorem 1). We also derive a suboptimal instrumental variable, based on the idea of the c-estimator (Amari & Kawanabe, 1997), to reduce the computational difficulty of estimating the optimal instrumental variable (Theorem 2). As a proof of concept, we compare the mean squared error (MSE) of our new estimators with that of LSTD on a simple example of the Markov decision process (MDP).

2. Background

2.1. MDPs and Policy Evaluation

RL is an approach to finding an optimal policy for sequential decision-making in an unknown environment. We consider a finite MDP, which is defined as a quadruple $(\mathcal{S}, \mathcal{A}, p, r)$: $\mathcal{S}$ is a finite set of states; $\mathcal{A}$ is a finite set of actions; $p(s_{t+1}|s_t, a_t)$ is the transition probability to a next state s_{t+1} when taking an action a_t at state s_t; and $r(s_t, a_t, s_{t+1})$ is a reward received with the state transition. Let $\pi(s_t, a_t) = p(a_t|s_t)$ be a stochastic policy that the agent follows. We introduce the following assumption concerning the MDP.

Assumption 1. *An MDP has a stationary state distribution $d^\pi(s) = p(s)$ under the policy $\pi(s_t, a_t)$.*

There are two major choices in definition of the state value function: discounted reward accumulation and average reward (Bertsekas & Tsitsiklis, 1996). With the former choice, the value function is defined as

$$V^\pi(s) := \sum_{t=0}^{\infty} \mathbb{E}^\pi \left[\gamma^t r_{t+1} | s_0 = s\right], \tag{1}$$

where $\mathbb{E}^\pi[\cdot|s_0 = s]$ is the expectation with respect to the sample trajectory conditioned on $s_0 = s$ and $r_{t+1} := r(s_t, a_t, s_{t+1})$. $\gamma \in [0, 1)$ is the discount factor. With the latter choice, on the other hand, the value function is defined as

$$V^\pi(s) := \sum_{t=0}^{\infty} \mathbb{E}^\pi \left[r_{t+1} - \bar{r} | s_0 = s\right], \tag{2}$$

where $\bar{r} := \sum_{s\in\mathcal{S}} \sum_{a\in\mathcal{A}} \sum_{s'\in\mathcal{S}} d^\pi(s)\pi(s, a)p(s'|s, a)r(s, a, s')$ denotes the average reward over the stationary distribution.

According to the Bellman equation, eq. (2) can be rewritten as

$$V^\pi(s_t) = \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\bar{r}(s_t, s_{t+1}) - \bar{r} + \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)V^\pi(s_{t+1}), \tag{3}$$

where $p(s_{t+1}|s_t) := \sum_{a_t\in\mathcal{A}} \pi(s_t, a_t)p(s_{t+1}|s_t, a_t)$ and $\bar{r}(s_t, s_{t+1}) := \frac{\sum_{a_t\in\mathcal{A}} \pi(s_t,a_t)p(s_{t+1}|s_t,a_t)r(s_t,a_t,s_{t+1})}{p(s_{t+1}|s_t)}$. Throughout this article, we assume that the linear function approximation is faithful, and discuss only asymptotic estimation variance. (In general cases, bias becomes non-negligible and selection of basis functions is more important.)

Assumption 2. *The value function can be represented as a linear function of some features:*

$$V^\pi(s_t) = \boldsymbol{\phi}(s_t)^\top \boldsymbol{\theta} = \boldsymbol{\phi}_t^\top \boldsymbol{\theta}, \tag{4}$$

where $\boldsymbol{\phi}(s) : \mathcal{S} \to \mathcal{R}^m$ is a feature vector and $\boldsymbol{\theta} \in \mathcal{R}^m$ is a parameter vector.

Here, the symbol $\top$ denotes a transpose and the dimensionality of the feature vector m is smaller than the number of states $|\mathcal{S}|$. Substituting eq. (4) for eq. (3), we obtain the following equation

$$\left\{\boldsymbol{\phi}_t - \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\boldsymbol{\phi}_{t+1}\right\}^\top \boldsymbol{\theta} = \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\bar{r}(s_t, s_{t+1}) - \bar{r}. \tag{5}$$

When the matrix $\mathbb{E}^\pi\left[\left(\boldsymbol{\phi}_t - \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\boldsymbol{\phi}_{t+1}\right)\left(\boldsymbol{\phi}_t - \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\boldsymbol{\phi}_{t+1}\right)^\top\right]$ is non-singular and $p(s_{t+1}|s_t)$ is known, we can easily obtain the parameter $\boldsymbol{\theta}$. However, since $p(s_{t+1}|s_t)$ is unknown in normal RL settings, we have to estimate this parameter from the sample trajectory $\{s_0, a_0, r_1, \cdots, s_{N-1}, a_{N-1}, r_N\}$ alone, instead of using it directly.

Eq. (5) can be rewritten as

$$y_t = \boldsymbol{x}_t^\top \boldsymbol{\theta} + \epsilon_t, \tag{6}$$

where y_t, $\boldsymbol{x}_t$ and ϵ_t are defined as

$$y_t := r_{t+1} - \bar{r}, \quad \boldsymbol{x}_t := \boldsymbol{\phi}_t - \boldsymbol{\phi}_{t+1}$$
$$\epsilon_t := \left\{\boldsymbol{\phi}_{t+1} - \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\boldsymbol{\phi}_{t+1}\right\}^\top \boldsymbol{\theta} + r_{t+1} - \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\bar{r}(s_t, s_{t+1}). \tag{7}$$

When we use the discounted reward accumulation for the value function, eq. (6) also holds with

$$y_t := r_{t+1}, \quad \boldsymbol{x}_t := \boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}$$
$$\epsilon_t := \gamma \left\{ \boldsymbol{\phi}_{t+1} - \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\boldsymbol{\phi}_{t+1} \right\}^\top \boldsymbol{\theta} + r_{t+1} - \sum_{s_{t+1}\in\mathcal{S}} p(s_{t+1}|s_t)\bar{r}(s_t, s_{t+1}). \tag{8}$$

Because $\mathbb{E}^\pi[\epsilon_t] = 0$, eq. (6) can be seen as a linear regression problem, where $\boldsymbol{x}$, y and ϵ are an input, an output and observation noise, respectively (Bradtke & Barto, 1996). Note that

$$\mathbb{E}^\pi[\epsilon_t g(s_t, s_{t-1}, \cdots, s_0)] = 0 \tag{9}$$

holds for any function $g(s_t, s_{t-1}, \cdots, s_0)$ because of the Markov property. The regression problem (6) has an undesirable property, however, which is known as an "error-in-variable problem" (Young, 1984): the input $\boldsymbol{x}_t$ and observation noise variables ϵ_t are mutually dependent.

It is not easy to solve such an error-in-variable problem in a rigorous manner; the simple least-squares method lacks consistency. Therefore, LSTD learning has used the instrumental variable method (Bradtke & Barto, 1996), a standard method to solve the error-in-variable problem that employs an "instrumental variable" to remove the effects of correlation between the input and the observation noise. When $\boldsymbol{X} = [\boldsymbol{x}_0, \boldsymbol{x}_1, \cdots, \boldsymbol{x}_{N-1}]$ and $\boldsymbol{y} = [y_0, y_1, \cdots, y_{N-1}]^\top$, the estimator of the instrumental variable method is given by

$$\hat{\boldsymbol{\theta}} = [\boldsymbol{Z}\boldsymbol{X}^\top]^{-1}[\boldsymbol{Z}\boldsymbol{y}], \tag{10}$$

where $\boldsymbol{Z} = [\boldsymbol{z}_0, \boldsymbol{z}_1, \cdots, \boldsymbol{z}_{N-1}]$, and $\boldsymbol{z}_t$ is an instrumental variable that is assumed to be correlated with the input $\boldsymbol{x}_t$ but uncorrelated with the observation noise ϵ_t.

2.2. Semiparametric Model and Estimating Functions

In the error-in-variable problem, if it is possible to assume a reasonable model with a small number of parameters on the joint input-output probability $p(\boldsymbol{x}, y)$, a proper estimator with consistency can be obtained by the maximum likelihood method. Since the transition probability $p(s_{t+1}|s_t)$ is unknown and usually difficult to estimate, it is practically impossible to construct such a parametric model. Let $\boldsymbol{k}_x$ and $\boldsymbol{k}_\epsilon$ be parameters which characterize the input distribution $p(\boldsymbol{x})$ and the conditional distribution $p(y|\boldsymbol{x})$ of output y given $\boldsymbol{x}$, respectively. Then, the joint distribution becomes

$$p(\boldsymbol{x}, y; \boldsymbol{\theta}, \boldsymbol{k}_x, \boldsymbol{k}_\epsilon) = p(y|\boldsymbol{x}; \boldsymbol{\theta}, \boldsymbol{k}_\epsilon)p(\boldsymbol{x}; \boldsymbol{k}_x). \tag{11}$$

We would like to estimate the parameter $\boldsymbol{\theta}$ representing the value function in the presence of the extra unknowns $\boldsymbol{k}_x$ and $\boldsymbol{k}_\epsilon$, which can have innumerable degrees of freedom. Statistical models which contain such (possibly infinite-dimensional) nuisance parameters in addition to parameters of interest are called semiparametric (Bickel et al., 1998). In semiparametric inference, one established way of estimating parameters is to employ an estimating function (Godambe, 1991), which can give a consistent estimator of $\boldsymbol{\theta}$ without estimation of the nuisance parameters $\boldsymbol{k}_x$ and $\boldsymbol{k}_\epsilon$. Now we begin with a short overview of the estimating function in the simple i.i.d. case, and then discuss the Markov chain case.

We consider a general semiparametric model $p(\boldsymbol{x}|\boldsymbol{\theta}, \boldsymbol{\kappa})$, where $\boldsymbol{\theta}$ is an m-dimensional parameter and $\boldsymbol{\kappa}$ is a nuisance parameter. An m-dimensional vector function $\boldsymbol{f}(\boldsymbol{x}; \boldsymbol{\theta})$ is called an estimating function when it satisfies the following conditions for any $\boldsymbol{\theta}$, $\boldsymbol{\kappa}$;

$$\mathbb{E}[\boldsymbol{f}(\boldsymbol{x}; \boldsymbol{\theta})|\boldsymbol{\theta}, \boldsymbol{\kappa}] = \boldsymbol{0} \tag{12}$$
$$\det \left| \mathbb{E}\left[\frac{\partial}{\partial \boldsymbol{\theta}} \boldsymbol{f}(\boldsymbol{x}; \boldsymbol{\theta}) \middle| \boldsymbol{\theta}, \boldsymbol{\kappa} \right] \right| \neq 0 \tag{13}$$
$$\mathbb{E}\left[||\boldsymbol{f}(\boldsymbol{x}; \boldsymbol{\theta})||^2 | \boldsymbol{\theta}, \boldsymbol{\kappa} \right] < \infty, \tag{14}$$

where $\mathbb{E}[\cdot|\boldsymbol{\theta}, \boldsymbol{\kappa}]$ denotes the expectation with respect to $\boldsymbol{x}$, which obeys the distribution $p(\boldsymbol{x}; \boldsymbol{\theta}, \boldsymbol{\kappa})$. The notations $\det|\cdot|$ and $||\cdot||$ denote the determinant and the Euclidean norm, respectively. Consider that i.i.d. samples $\{\boldsymbol{x}_0, \boldsymbol{x}_1, \cdots, \boldsymbol{x}_{N-1}\}$ are obtained from the true model $p(\boldsymbol{x}; \boldsymbol{\theta} = \boldsymbol{\theta}^*, \boldsymbol{\kappa} = \boldsymbol{\kappa}^*) = p(\boldsymbol{x}; \boldsymbol{\theta}^*, \boldsymbol{\kappa}^*)$ for the observed trajectory. If there is an estimating function $\boldsymbol{f}$, by solving the estimating equation

$$\sum_{t=0}^{N-1} \boldsymbol{f}(\boldsymbol{x}_t; \hat{\boldsymbol{\theta}}) = \boldsymbol{0}, \tag{15}$$

we can obtain an estimator $\hat{\boldsymbol{\theta}}$ with good asymptotic properties. A solution of eq. (15) is called an "M-estimator" in statistics; the M-estimator is consistent, i.e., converges to the true parameter $\boldsymbol{\theta}^*$ regardless of the true nuisance parameter $\boldsymbol{\kappa}^*$ when the sample size N reaches infinity. In addition, the asymptotic variance $\mathrm{AV}[\hat{\boldsymbol{\theta}}]$ is given by

$$\mathrm{AV}[\hat{\boldsymbol{\theta}}] = \mathbb{E}[(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}^*)(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}^*)^\top] = \frac{1}{N}\boldsymbol{A}^{-1}\boldsymbol{M}\boldsymbol{A}^{-\top}, \tag{16}$$

where $\boldsymbol{A} = \mathbb{E}\left[\frac{\partial}{\partial \boldsymbol{\theta}} f(\boldsymbol{x};\boldsymbol{\theta})|\boldsymbol{\theta}^*, \boldsymbol{\kappa}^*\right]$ and $\boldsymbol{M} = \mathbb{E}\left[\boldsymbol{f}(\boldsymbol{x};\boldsymbol{\theta})\boldsymbol{f}^\top(\boldsymbol{x};\boldsymbol{\theta})|\boldsymbol{\theta}^*, \boldsymbol{\kappa}^*\right]$. The symbol $-\top$ denotes transpose of the inverse matrix. We omit the time index t, unless it is necessary to clarify. Note that the asymptotic variance AV depends on the true parameters, $\boldsymbol{\theta}^*$ and $\boldsymbol{\kappa}^*$, not on the samples $\{\boldsymbol{x}_0, \boldsymbol{x}_1, \cdots, \boldsymbol{x}_{N-1}\}$.

The notion of the estimating function can be extended to cases in which samples are given by a certain stochastic process (Godambe, 1985). In the semiparametric model for policy evaluation, under Assumption 1, there exist sufficient conditions of estimating functions which are almost the same as eqs. (12) - (14). The instrumental variable method is a type of estimating function method for semiparametric problems where the unknown distribution is given by eq. (11).

Lemma 1. *Suppose $\{\boldsymbol{x}_t, y_t\}$ is given by eq. (7) or (8), and $\boldsymbol{z}_t$ is given by a function of $\{s_t, \cdots, s_{t-T}\}$. If $\mathbb{E}^\pi[\boldsymbol{z}_t\boldsymbol{x}_t^\top]$ is nonsingular and $\mathbb{E}^\pi\left[||\boldsymbol{z}_t(\boldsymbol{x}_t^\top\boldsymbol{\theta} - y_t)||^2\right]$ is finite, then*

$$\boldsymbol{z}_t(\boldsymbol{x}_t^\top\boldsymbol{\theta} - y_t) \tag{17}$$

is an estimating function for the parameter $\boldsymbol{\theta}$. Therefore, the estimating equation is given by

$$\sum_{t=0}^{N-1} \boldsymbol{z}_t(\boldsymbol{x}_t^\top\boldsymbol{\theta} - y_t) = \boldsymbol{0}. \tag{18}$$

Proof For all t, the conditions corresponding to (13) and (14) are satisfied by the assumptions, and the condition (12) is satisfied as $\mathbb{E}^\pi[\boldsymbol{z}_t(\boldsymbol{x}_t^\top\boldsymbol{\theta} - y_t)] = \mathbb{E}^\pi[\boldsymbol{z}_t\epsilon_t] = \boldsymbol{0}$ from the property in eq. (9). (Q.E.D.)

LSTD is specifically an instrumental variable method in which the feature vector $\boldsymbol{z}_t = \boldsymbol{\phi}(s_t) = \boldsymbol{\phi}_t$ is used as an instrumental variable:

$$\boldsymbol{f}_{\mathrm{LSTD}} = \boldsymbol{\phi}_t(\boldsymbol{x}_t^\top\boldsymbol{\theta} - y_t). \tag{19}$$

The solution of the estimating equation is an M-estimator, and its asymptotic variance is given as follows.

Lemma 2. *Let $\boldsymbol{z}_t$ be a function of $\{s_t, ..., s_{t-T}\}$ satisfying the two conditions in Lemma 1 and $\epsilon_t^* = \boldsymbol{x}_t^\top\boldsymbol{\theta}^* - y_t$ be the residual for the true parameter $\boldsymbol{\theta}^*$. Then, the solution $\hat{\boldsymbol{\theta}}$ of the estimating equation (18) has the asymptotic variance*

$$\mathrm{AV}[\hat{\boldsymbol{\theta}}] = \frac{1}{N}\boldsymbol{A}_{\mathrm{IV}}^{-1}\boldsymbol{M}_{\mathrm{IV}}\boldsymbol{A}_{\mathrm{IV}}^{-\top}, \tag{20}$$

where $\boldsymbol{A}_{\mathrm{IV}} = \mathbb{E}_d[\boldsymbol{z}_t\boldsymbol{x}_t^\top]$, $\boldsymbol{M}_{\mathrm{IV}} = \mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{z}_t\boldsymbol{z}_t^\top]$. $E_d[\cdot]$ denotes the expectation when the sample trajectory starts from the stationary distribution $d^\pi(s_0)$. [1]

Proof The estimating equation (18) can be expressed as

$$\boldsymbol{Z}\boldsymbol{y} = \boldsymbol{Z}\boldsymbol{X}^\top\hat{\boldsymbol{\theta}} \tag{21}$$

where $\boldsymbol{Z} = [\boldsymbol{z}_0, \cdots, \boldsymbol{z}_{N-1}]$, $\boldsymbol{X} = [\boldsymbol{x}_0, \cdots, \boldsymbol{x}_{N-1}]$, $\boldsymbol{y} = [y_0, \cdots, y_{N-1}]^\top$. On the other hand, from eq. (6), the left hand side of eq. (21) is equal to $\boldsymbol{Z}\boldsymbol{X}^\top\boldsymbol{\theta}^* + \boldsymbol{Z}\boldsymbol{X}^\top\boldsymbol{\epsilon}$, where $\boldsymbol{\epsilon} = [\epsilon_0^*, \cdots, \epsilon_{N-1}^*]^\top$. Thus the asymptotic variance of the estimator $\hat{\boldsymbol{\theta}}$ is obtained as

$$\mathbb{E}^\pi[(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}^*)(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}^*)^\top] = \mathbb{E}^\pi[(\boldsymbol{Z}\boldsymbol{X}^\top)^{-1}\boldsymbol{Z}\boldsymbol{\epsilon}\boldsymbol{\epsilon}^\top\boldsymbol{Z}^\top(\boldsymbol{X}\boldsymbol{Z}^\top)^{-1}] \overset{N\to\infty}{\longrightarrow} \boldsymbol{A}_{\mathrm{IV}}^{-1}\frac{1}{N^2}\mathbb{E}^\pi[\boldsymbol{Z}\boldsymbol{\epsilon}\boldsymbol{\epsilon}^\top\boldsymbol{Z}^\top]\boldsymbol{A}_{\mathrm{IV}}^{-\top}$$

where we used the fact that the matrix $\boldsymbol{Z}\boldsymbol{X}^\top$ has the limit

$$\frac{1}{N}(\boldsymbol{Z}\boldsymbol{X}^\top) = \frac{1}{N}\sum_{t=0}^{N-1}\boldsymbol{z}_t\boldsymbol{x}_t^\top \overset{N\to\infty}{\longrightarrow} \boldsymbol{A}_{\mathrm{IV}}.$$

Also, the matrix $\mathbb{E}^\pi[\boldsymbol{Z}\boldsymbol{\epsilon}\boldsymbol{\epsilon}^\top\boldsymbol{Z}^\top]$ has the following limit:

$$\frac{1}{N}\mathbb{E}^\pi[\boldsymbol{Z}\boldsymbol{\epsilon}\boldsymbol{\epsilon}^\top\boldsymbol{Z}^\top] = \frac{1}{N}\sum_{t=0}^{N-1}\mathbb{E}^\pi[(\epsilon_t^*)^2\boldsymbol{z}_t\boldsymbol{z}_t^\top] \overset{N\to\infty}{\longrightarrow} \boldsymbol{M}_{\mathrm{IV}},$$

where we used the property in eq. (9). Therefore, we have

$$\mathbb{E}^\pi[(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}^*)(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}^*)^\top] \overset{N\to\infty}{\longrightarrow} \frac{1}{N}\boldsymbol{A}_{\mathrm{IV}}^{-1}\boldsymbol{M}_{\mathrm{IV}}\boldsymbol{A}_{\mathrm{IV}}^{-\top}.$$

(Q.E.D.)

To summarize, if we have an instrumental variable which satisfies the assumptions in Lemmas 1 and 2, we can obtain an M-estimator from the estimating equation (18) with the asymptotic variance eq. (20). When more than one instrumental variable exists, it is appropriate to choose the one whose estimator has the minimum asymptotic variance.

3. Main Results

In this section, we show that estimating functions for the semiparametric model of policy evaluation are limited to the type of equation used in the instrumental variable method. Furthermore, we derive the optimal

[1] We remark that the definitions of $\boldsymbol{A}_{\mathrm{IV}}$ and $\boldsymbol{M}_{\mathrm{IV}}$ do not depend on the t. Nevertheless, we keep the time index t for clarification.

instrumental variable having the minimum asymptotic variance of the estimation.

We first remark on the invariance property of the instrumental variable method.

Lemma 3. *The value function estimation* $\hat{V}(s_t) = \boldsymbol{\phi}_t^\top \hat{\boldsymbol{\theta}} = \boldsymbol{\phi}_t^\top [\boldsymbol{Z}\boldsymbol{X}^\top]^{-1}[\boldsymbol{Z}\boldsymbol{y}]$ *is invariant with respect to the application of any regular linear transformation to either the instrumental variable* $\boldsymbol{z}_t$ *or the basis functions* $\boldsymbol{\phi}_t$.

Proof Assume that the instrumental variable and the basis functions are both transformed by any regular matrices $\boldsymbol{W}_z$ and $\boldsymbol{W}_\phi$ as $\boldsymbol{z}'_t = \boldsymbol{W}_z \boldsymbol{z}_t$ and $\boldsymbol{\phi}'_t = \boldsymbol{W}_\phi \boldsymbol{\phi}_t$. Noting that the linear transformation of $\boldsymbol{\phi}_t$ yields the linear transformation of the input $\boldsymbol{x}'_t = \boldsymbol{W}_\phi \boldsymbol{x}_t$, the estimator of the instrumental variable method given by eq. (10) becomes $\hat{\boldsymbol{\theta}}' = [\boldsymbol{Z}'(\boldsymbol{X}')^\top]^{-1}[\boldsymbol{Z}'\boldsymbol{y}] = \boldsymbol{W}_\phi^{-1}\hat{\boldsymbol{\theta}}$. This means that the estimated value function is invariant as $(\boldsymbol{\phi}'_t)^\top \hat{\boldsymbol{\theta}}' = \boldsymbol{\phi}_t^\top \hat{\boldsymbol{\theta}}$. (Q.E.D.)

When the basis functions span over the whole space of functions of the state, any set of basis functions can be represented by applying a linear transformation to another set of basis functions. This observation leads to the following Corollary.

Corollary 1. *When the basis functions* $\boldsymbol{\phi}_t$ *span the whole space of functions of the state, the value function estimation is invariant with respect to the choice of basis functions and of the instrumental variable.*

An instrumental variable may depend not only on the current state s_t, but also on the previous states $\{s_{t-1}, \cdots, s_{t-T}\}$, because such an instrumental variable does not violate the condition, $\mathrm{cov}[\boldsymbol{z}_t, \epsilon_t] = \boldsymbol{0}$. However, we do not need to consider such instrumental variables, as the following Lemma shows.

Lemma 4. *Let* $\boldsymbol{z}_t(s_t, \cdots, s_{t-T})$ *be any instrumental variable depending on the current and previous states which satisfies the conditions in Lemmas 1 and 2. Then, there is necessarily an instrumental variable depending only on the current state whose corresponding estimator has equal or minimum asymptotic variance.*

Proof We show that the conditional expectation $\tilde{\boldsymbol{z}}_t = \mathbb{E}^\pi[\boldsymbol{z}_t | s_t]$ which depends only on the current state s_t, gives an equally good or better estimator. The matrices in the asymptotic variance, eq. (20), can be calculated as

$$\begin{aligned}\boldsymbol{A}_{\boldsymbol{z}} &= \mathbb{E}_d\left[\tilde{\boldsymbol{z}}_t \boldsymbol{x}_t^\top\right] + \mathbb{E}_d\left[(\tilde{\boldsymbol{z}}_t - \boldsymbol{z}_t)\boldsymbol{x}_t^\top\right] = \boldsymbol{A}_{\tilde{\boldsymbol{z}}} \\ \boldsymbol{M}_{\boldsymbol{z}} &= \mathbb{E}_d[(\epsilon_t^*)^2(\tilde{\boldsymbol{z}}_t + \boldsymbol{z}_t - \tilde{\boldsymbol{z}}_t)(\tilde{\boldsymbol{z}}_t + \boldsymbol{z}_t - \tilde{\boldsymbol{z}}_t)^\top] \\ &= \boldsymbol{M}_{\tilde{\boldsymbol{z}}} + \mathbb{E}_d[(\epsilon_t^*)^2(\boldsymbol{z}_t - \tilde{\boldsymbol{z}}_t)(\boldsymbol{z}_t - \tilde{\boldsymbol{z}}_t)^\top],\end{aligned}$$

where we have used eq. (9). This implies that

$$\mathrm{AV}[\hat{\boldsymbol{\theta}}_{\boldsymbol{z}}] = \frac{1}{N}\boldsymbol{A}_{\boldsymbol{z}}^{-1}\boldsymbol{M}_{\boldsymbol{z}}\boldsymbol{A}_{\boldsymbol{z}}^{-\top} \succeq \frac{1}{N}\boldsymbol{A}_{\tilde{\boldsymbol{z}}}^{-1}\boldsymbol{M}_{\tilde{\boldsymbol{z}}}\boldsymbol{A}_{\tilde{\boldsymbol{z}}}^{-\top} = \mathrm{AV}[\hat{\boldsymbol{\theta}}_{\tilde{\boldsymbol{z}}}].$$

(Q.E.D.)

Here, the inequality $\succeq$ denotes the semipositive definiteness of the subtraction. Now, we consider the general form of estimating functions for inference of the value function. In the following, we consider only 'admissible' estimating functions. More precisely, we discard 'inadmissible' estimating functions whose estimators are always inferior to those of other estimating functions in the sense of asymptotic variance. To simplify analysis, we only consider the limited set of estimating functions which are defined on a one-step sample $\{s, a, s'\}$.

Proposition 1. *For the semiparametric model of eqs. (6), (7) or eqs. (6), (8), all admissible estimating functions of only the one-step sample* $\{s, a, s'\}$ *must have the form of* $\boldsymbol{f} = \boldsymbol{z}(y - \boldsymbol{x}^\top\boldsymbol{\theta})$, *where* $\boldsymbol{z}$ *is any function which does not depend on* s' *and satisfies the assumption in Lemma 1.*

Proof Due to space limitation, we will just outline the proof. To be an estimating function, the function $\boldsymbol{f}$ must satisfy $\mathbb{E}_d[\boldsymbol{f}] = \sum_{s\in\mathcal{S}} d^\pi(s) \sum_{s'\in\mathcal{S}} \sum_{a\in\mathcal{A}} p(s'|s,a)\pi(s,a)\boldsymbol{f}(s,a,s') = \boldsymbol{0}$. Because we can prove that the stationary distribution $d^\pi(s)$ takes any probability vector, $\sum_{s\in\mathcal{S}} d^\pi(s)\boldsymbol{v}(s) = \boldsymbol{0}$ implies that $\boldsymbol{v}(s) = \boldsymbol{0}$ for any state s, where $\boldsymbol{v}(s) := \sum_{s'\in\mathcal{S}} \sum_{a\in\mathcal{A}} p(s'|s,a)\pi(s,a)\boldsymbol{f}(s,a,s')$. Furthermore, the Bellman equation (6) holds, whatever the $p(s'|s,a)$ is. To fulfil $\boldsymbol{v} = \boldsymbol{0}$, $\boldsymbol{f}$ must have the form of $\boldsymbol{f} = \boldsymbol{z}(y - \boldsymbol{x}^\top\boldsymbol{\theta}) + \boldsymbol{h}$, where $\boldsymbol{z}$ does not depend on s' or a, and $\boldsymbol{h}$ is any function that satisfies $\sum_{a\in\mathcal{A}} \pi(s,a)\boldsymbol{h}(s,a,s') = \boldsymbol{0}$. However, the addition of such a function $\boldsymbol{h}$ necessarily enlarges the asymptotic variance of the estimation. Therefore, the admissible estimating function is restricted to the form of $\boldsymbol{f} = \boldsymbol{z}(y - \boldsymbol{x}^\top\boldsymbol{\theta})$. (Q.E.D)

We are currently working on the conjecture that whether Proposition 1 can be extended to general estimating functions depend on all previous states and actions. If this is true, from Lemma 4, it is sufficient to consider the instrumental variable method with $\boldsymbol{z}_t$ depending only on the current state s_t for the semiparametric inference problem. Therefore, we next discuss the optimal instrument variable of this type in terms of asymptotic variance, which corresponds to the optimal estimating function.

Algorithm 1 The pseudo code of gLSTD.

gLSTD($\mathcal{D}$, ϕ)
// $D = \{s_0, r_1, \cdots, s_{N-1}, r_N\}$: Sample sequence
// ϕ: Basis functions
// Calculate the initial parameter and its residual
$\hat{\boldsymbol{\theta}}_0 \leftarrow \left[\sum_{t=0}^{N-1} \boldsymbol{\phi}_t \boldsymbol{x}_t^\top\right]^{-1} \left[\sum_{t=0}^{N-1} \boldsymbol{\phi}_t y_t\right]$
$\hat{\epsilon}_t \leftarrow \boldsymbol{x}_t^\top \hat{\boldsymbol{\theta}}_0 - y_t$
// Calculate the estimator $\widetilde{\mathbb{E}^\pi[(\hat{\epsilon}_t)^2|s_t]}, \widetilde{\mathbb{E}^\pi[\boldsymbol{x}_t|s_t]}$
// of the conditional expectations
// and construct the instrumental variable
$\hat{\boldsymbol{z}}_t \leftarrow \widetilde{\mathbb{E}^\pi[(\hat{\epsilon}_t)^2|s_t]}^{-1} \widetilde{\mathbb{E}^\pi[\boldsymbol{x}_t|s_t]}$
// Calculate the parameter
$\hat{\boldsymbol{\theta}}_g \leftarrow \left[\sum_{t=0}^{N-1} \hat{\boldsymbol{z}}_t \boldsymbol{x}_t^\top\right]^{-1} \left[\sum_{t=0}^{N-1} \hat{\boldsymbol{z}}_t y_t\right]$
Return $\hat{\boldsymbol{\theta}}_g$

Theorem 1. *The optimal instrumental variable gives the minimum asymptotic variance*

$$\boldsymbol{z}_t^* = \begin{cases} \mathbb{E}^\pi\left[(\epsilon_t^*)^2|s_t\right]^{-1}\left(\boldsymbol{\phi}_t - \gamma\mathbb{E}^\pi[\boldsymbol{\phi}_{t+1}|s_t]\right) \\ \quad (\textit{discounted reward accumulation}) \\ \mathbb{E}^\pi\left[(\epsilon_t^*)^2|s_t\right]^{-1}\left(\boldsymbol{\phi}_t - \mathbb{E}^\pi[\boldsymbol{\phi}_{t+1}|s_t]\right) \\ \quad (\textit{average reward}). \end{cases} \tag{22}$$

The proof is given in Appendix A. Note that the definition of the optimal instrumental variable includes both the residual ϵ_t^* and the conditional expectations $\mathbb{E}^\pi[\boldsymbol{\phi}_{t+1}|s_t]$ and $\mathbb{E}^\pi[(\epsilon_t^*)^2|s_t]$. To make this estimator practical, we replace the residual ϵ_t^* with that of the LSTD estimator, and approximate the expectation, $\mathbb{E}^\pi[\boldsymbol{\phi}_{t+1}|s_t]$ and $\mathbb{E}^\pi[(\epsilon_t^*)^2|s_t]$, by using function approximation. We call this procedure "gLSTD learning" (see Algorithm 1 for its pseudo code).

To avoid estimating the functions depending on the current state, $\mathbb{E}^\pi[\boldsymbol{\phi}_{t+1}|s_t]$ and $\mathbb{E}^\pi[(\epsilon_t^*)^2|s_t]$, which appear in the instrumental variable, we simply replace them by constants. When $\boldsymbol{z}$ is an instrumental variable, addition of any constant value to $\boldsymbol{z}$, $\boldsymbol{z}' = \boldsymbol{z} + \boldsymbol{c}$, leads to another valid instrumental variable; because of Lemma 1, it is easily confirmed that $\boldsymbol{f}_{\mathrm{c}} = (\boldsymbol{z}_t + \boldsymbol{c})(\boldsymbol{x}_t^\top\boldsymbol{\theta} - y_t)$ is an estimating function. Therefore, obtaining the optimal constant $\boldsymbol{c}$ yields a suboptimal instrumental variable within instrumental variables produced by constant shifts.

Theorem 2. *The optimal shift is given by*

$$\boldsymbol{c}^* := -\frac{\mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{z}_t] - \mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{z}_t\boldsymbol{z}_t^\top]\mathbb{E}_d[\boldsymbol{x}_t\boldsymbol{z}_t^\top]^{-1}\mathbb{E}_d[\boldsymbol{x}_t]}{\mathbb{E}_d[(\epsilon_t^*)^2] - \mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{z}_t^\top]\mathbb{E}_d[\boldsymbol{x}_t\boldsymbol{z}_t^\top]^{-1}\mathbb{E}_d[\boldsymbol{x}_t]}. \tag{23}$$

Algorithm 2 The pseudo code of LSTDc

LSTDc($\mathcal{D}$, ϕ)
// $D = \{s_0, r_1, \cdots, s_{N-1}, r_N\}$: Sample sequence
// ϕ: Basis functions
// Calculate the initial parameter and its residual
$\hat{\boldsymbol{\theta}}_0 \leftarrow \left[\sum_{t=0}^{N-1} \boldsymbol{\phi}_t \boldsymbol{x}_t^\top\right]^{-1} \left[\sum_{t=0}^{N-1} \boldsymbol{\phi}_t y_t\right]$
$\hat{\epsilon}_t \leftarrow \boldsymbol{x}_t^\top \hat{\boldsymbol{\theta}}_0 - y_t$
// Construct the suboptimal
// instrumental variable with optimal shift
$$\hat{\boldsymbol{c}} \leftarrow -\frac{\left[\sum_{t=0}^{N-1} \hat{\epsilon}_t^2\boldsymbol{\phi}_t\right] - \left[\sum_{t=0}^{N-1} \hat{\epsilon}_t^2\boldsymbol{\phi}_t\boldsymbol{\phi}_t^\top\right]\left[\sum_{t=0}^{N-1} \boldsymbol{x}_t\boldsymbol{\phi}_t^\top\right]^{-1}\left[\sum_{t=0}^{N-1} \boldsymbol{x}_t\right]}{\left[\sum_{t=0}^{N-1} \hat{\epsilon}_t^2\right] - \left[\sum_{t=0}^{N-1} \hat{\epsilon}_t^2\boldsymbol{\phi}_t^\top\right]\left[\sum_{t=0}^{N-1} \boldsymbol{x}_t\boldsymbol{\phi}_t^\top\right]^{-1}\left[\sum_{t=0}^{N-1} \boldsymbol{x}_t\right]}$$
$\hat{\boldsymbol{z}}_t = \boldsymbol{\phi}_t + \hat{\boldsymbol{c}}$
//Calculate the parameter
$\hat{\boldsymbol{\theta}}_c \leftarrow \left[\sum_{t=0}^{N-1} \hat{\boldsymbol{z}}_t \boldsymbol{x}_t^\top\right]^{-1} \left[\sum_{t=0}^{N-1} \hat{\boldsymbol{z}}_t y_t\right]$
Return $\hat{\boldsymbol{\theta}}_c$

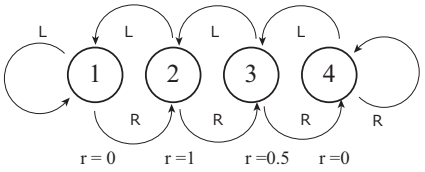

Figure 1. A four-state MDP.

The proof is given in Appendix B. In eq. (23), however, the residual ϵ_t^* is again unknown; hence, we need to approximate this, too, as in the gLSTD learning. We call this procedure "LSTDc learning" (see Algorithm 2 for its pseudo code).

4. Simulation Experiments

So far, we have discussed the asymptotic variance under the assumption that we have an infinite number of samples. In this section, we evaluate the performance of the proposed estimator in a practical situation with a finite number of samples. We use an MDP defined on a simple Markov random walk, which was also used in a previous study (Lagoudakis & Parr, 2003). This MDP incorporates a one-dimensional chain walk with four states (Figure 1). Two actions, "left"(L) and "right"(R), are available at every state. Rewards 1 and 0.5 are given when states '2' and '3' are visited, respectively.

We adopt the simplest direct representation of states; the state variable took $s = 1$, $s = 2$, $s = 3$ or $s = 4$,

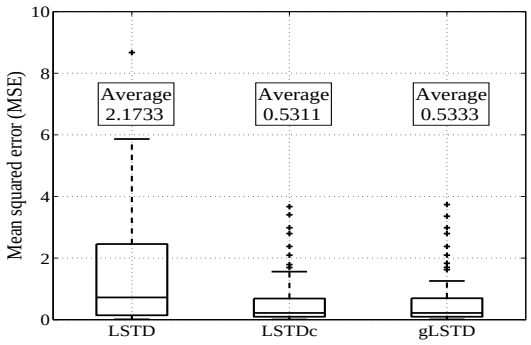

Figure 2. Simulation result.

when the corresponding state was visited. The value function was defined as the average reward, eq. (2), and was approximated by a linear function with a three-dimensional basis function: $\boldsymbol{\phi}(s) = [s, s^2, s^3]^\top$. The policy was set at random, and at the beginning of each episode an initial state was randomly selected according to the stationary distribution of this Markov chain.

Under these conditions, we performed 100 episodes each of which consisted of 100 random walk steps. We evaluated the "mean squared error" (MSE) of the value function, i.e., $\sum_{i\in\{1,2,3,4\}} d^\pi(i)|\hat{V}(i) - V^*(i)|^2$; where $\hat{V}$ and V^* denote $\hat{V}(i) = \boldsymbol{\phi}(s=i)^\top\hat{\boldsymbol{\theta}}$ and $V^*(i) = \boldsymbol{\phi}(s=i)^\top\boldsymbol{\theta}^*$, respectively.

Figure 2 shows box-plots of the MSEs of LSTD, LSTDc, and gLSTD. For this example, estimators of the conditional expectations in gLSTD can be calculated by sample average in each state, because there were only four discrete states. In continuous state problems, however, estimation of such conditional expectations would become much harder.

In Figure 2, the y-axis denotes the MSE of the value function. The center line and the upper and lower sides of each box denote the median of MSEs and the upper and lower quartiles, respectively. The number above each box represents the average MSE. There is significant difference between the MSE of LSTD and those of LSTDc and gLSTD. The estimators for LSTDc and for gLSTD both achieved a much smaller MSE than that for the ordinary LSTD.

5. Conclusion

In this study, we have discussed LSTD-based policy evaluation in the framework of semiparametric statistical inference. We showed that the standard LSTD algorithm is indeed an estimating function method which is guaranteed to be consistent regardless of the stochastic properties of the environments. Based on the optimal estimating functions in the two classes of estimating functions, we constructed two new policy evaluation methods called gLSTD and LSTDc. We also evaluated the asymptotic variance of the general instrumental variable methods for MDP. Moreover, we showed that the form of possible estimating functions for the value function estimation is restricted to be the same as those used in the instrumental variable methods. We then demonstrated, through an experiment using a simple MDP problem, that the gLSTD and LSTDc estimators reduce substantially the asymptotic variance of the LSTD estimator.

Further work is necessary to construct procedures for policy updating based on evaluation by gLSTD and LSTDc. It should be possible to incorporate our proposed ideas into the least-squares policy iteration (Lagoudakis & Parr, 2003) and the natural actor-critic method (Peters et al., 2005).

A. Proof of Theorem 1: The Optimal Instrumental Variable

As shown in eq. (20), the asymptotic variance of the estimator $\hat{\boldsymbol{\theta}}_{\boldsymbol{z}}$ is given by

$$\mathrm{AV}[\hat{\boldsymbol{\theta}}_{\boldsymbol{z}}] = \frac{1}{N}\boldsymbol{A}_{\boldsymbol{z}}^{-1}\boldsymbol{M}_{\boldsymbol{z}}\boldsymbol{A}_{\boldsymbol{z}}^{-\top},$$

where $\boldsymbol{A}_{\boldsymbol{z}} := \mathbb{E}_d[\boldsymbol{z}_t\boldsymbol{x}_t^\top]$ and $\boldsymbol{M}_{\boldsymbol{z}} := \mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{z}_t\boldsymbol{z}_t^\top]$. If we add a small change $\boldsymbol{\delta}_t(s_t, \cdots, s_{t-T})$ to the instrumental variable $\boldsymbol{z}_t$, the matrices become

$$\begin{aligned}\boldsymbol{A}_{\boldsymbol{z}+\boldsymbol{\delta}} &= \boldsymbol{A}_{\boldsymbol{z}} + \mathbb{E}_d[\boldsymbol{\delta}_t\boldsymbol{x}_t^\top],\\ \boldsymbol{M}_{\boldsymbol{z}+\boldsymbol{\delta}} &= \boldsymbol{M}_{\boldsymbol{z}} + \mathbb{E}_d[(\epsilon_t^*)^2(\boldsymbol{\delta}_t\boldsymbol{z}_t^\top + \boldsymbol{z}_t\boldsymbol{\delta}_t^\top)].\end{aligned}$$

Therefore, the deviation of the trace of asymptotic variance can be calculated as

$$\begin{aligned}&\mathrm{Tr}\left[\boldsymbol{A}_{\boldsymbol{z}+\boldsymbol{\delta}}^{-1}\boldsymbol{M}_{\boldsymbol{z}+\boldsymbol{\delta}}\boldsymbol{A}_{\boldsymbol{z}+\boldsymbol{\delta}}^{-\top}\right] - \mathrm{Tr}\left[\boldsymbol{A}_{\boldsymbol{z}}^{-1}\boldsymbol{M}_{\boldsymbol{z}}\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\right]\\ =&-\mathrm{Tr}\left\{\boldsymbol{A}_{\boldsymbol{z}}^{-1}\mathbb{E}_d\left[\boldsymbol{\delta}_t\boldsymbol{x}_t^\top\right]\boldsymbol{A}_{\boldsymbol{z}}^{-1}\boldsymbol{M}_{\boldsymbol{z}}\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\right\}\\ &-\mathrm{Tr}\left\{\boldsymbol{A}_{\boldsymbol{z}}^{-1}\mathbb{E}_d\left[\boldsymbol{x}_t\boldsymbol{\delta}_t^\top\right]\boldsymbol{A}_{\boldsymbol{z}}^{-1}\boldsymbol{M}_{\boldsymbol{z}}\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\right\}\\ &+\mathrm{Tr}\left\{\boldsymbol{A}_{\boldsymbol{z}}^{-1}\mathbb{E}_d\left[(\epsilon_t^*)^2\left(\boldsymbol{z}_t\boldsymbol{\delta}_t^\top + \boldsymbol{\delta}\boldsymbol{z}_t^\top\right)\right]\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\right\}\\ =&2\mathbb{E}_d\left[\boldsymbol{\delta}_t^\top\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\boldsymbol{A}_{\boldsymbol{z}}^{-1}\mathbb{E}^\pi\left[(\epsilon_t^*)^2|s_t,\cdots,s_{t-T}\right]\boldsymbol{z}_t\right]\\ &-2\mathbb{E}_d\left[\boldsymbol{\delta}_t^\top\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\boldsymbol{A}_{\boldsymbol{z}}^{-1}\boldsymbol{M}_{\boldsymbol{z}}\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\mathbb{E}^\pi[\boldsymbol{x}_t|s_t,\cdots,s_{t-T}]\right].\end{aligned}$$

By using the condition that the deviation becomes $\mathbf{0}$ for any small change $\boldsymbol{\delta}_t(s_t, \cdots, s_{t-T})$, the optimal instrumental variable can be obtained as

$$\boldsymbol{z}_t^* = \mathbb{E}^\pi\left[(\epsilon_t^*)^2|s_t\right]^{-1}\boldsymbol{M}_{\boldsymbol{z}}\boldsymbol{A}_{\boldsymbol{z}}^{-\top}\mathbb{E}^\pi[\boldsymbol{x}_t|s_t].$$

Considering Lemma 3, the optimal instrumental variable is restricted as

$$\boldsymbol{z}_t^* = \mathbb{E}^\pi\left[(\epsilon_t^*)^2|s_t\right]^{-1}\mathbb{E}^\pi[\boldsymbol{x}_t|s_t],$$

or as its transformation by any regular matrix.

Now, we show that eq. (22) also satisfies the global optimality. Substituting $\boldsymbol{z}_t^*$ to the matrix $\boldsymbol{A}_{\boldsymbol{z}^*}$, we obtain

$$\boldsymbol{A}_{\boldsymbol{z}^*} = \boldsymbol{M}_{\boldsymbol{z}^*}\boldsymbol{A}_{\boldsymbol{z}^*}^{-\top}\boldsymbol{F},$$

where

$$\boldsymbol{F} := \mathbb{E}_d\left[\mathbb{E}^\pi[(\epsilon_t^*)^2|s_t]^{-1}\mathbb{E}^\pi[\boldsymbol{x}_t|s_t]\mathbb{E}^\pi[\boldsymbol{x}_t^\top|s_t]\right].$$

Furthermore, the matrices at $\boldsymbol{z}_t^* + \boldsymbol{\delta}_t$ become

$$\begin{aligned}
\boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}} &= \boldsymbol{M}_{\boldsymbol{z}^*}\boldsymbol{A}_{\boldsymbol{z}^*}^{-\top}\boldsymbol{F} + \mathbb{E}_d[\boldsymbol{x}_t\boldsymbol{\delta}_t^\top],\\
\boldsymbol{M}_{\boldsymbol{z}^*+\boldsymbol{\delta}} &= \boldsymbol{M}_{\boldsymbol{z}^*}\boldsymbol{A}_{\boldsymbol{z}^*}^{-\top}\boldsymbol{F}\boldsymbol{A}_{\boldsymbol{z}^*}^{-1}\boldsymbol{M}_{\boldsymbol{z}^*} + \boldsymbol{M}_{\boldsymbol{z}^*}\boldsymbol{A}_{\boldsymbol{z}^*}^{-\top}\mathbb{E}_d[\boldsymbol{x}_t\boldsymbol{\delta}_t^\top]\\
&\quad + \mathbb{E}_d[\boldsymbol{\delta}_t\boldsymbol{x}_t^\top]\boldsymbol{A}_{\boldsymbol{z}^*}^{-1}\boldsymbol{M}_{\boldsymbol{z}^*} + \mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{\delta}_t\boldsymbol{\delta}_t^\top].
\end{aligned}$$

Therefore,

$$\begin{aligned}
&\boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-1}\boldsymbol{M}_{\boldsymbol{z}^*+\boldsymbol{\delta}}\boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-\top} - \boldsymbol{A}_{\boldsymbol{z}^*}^{-1}\boldsymbol{M}_{\boldsymbol{z}^*}\boldsymbol{A}_{\boldsymbol{z}^*}^{-\top}\\
&= \boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-1}(\boldsymbol{M}_{\boldsymbol{z}^*+\boldsymbol{\delta}} - \boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}\boldsymbol{A}_{\boldsymbol{z}^*}^{-1}\boldsymbol{M}_{\boldsymbol{z}^*}\boldsymbol{A}_{\boldsymbol{z}^*}^{-\top}\boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{\top})\boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-\top}\\
&= \boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-1}(\mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{\delta}_t\boldsymbol{\delta}_t^\top] - \mathbb{E}_d[\boldsymbol{\delta}_t\boldsymbol{x}_t^\top]\boldsymbol{F}^{-1}\mathbb{E}_d[\boldsymbol{x}_t\boldsymbol{\delta}_t^\top])\boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-\top}\\
&= \boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-1}\Big\{\mathbb{E}_d\Big[\mathbb{E}^\pi[(\epsilon_t^*)^2|s_t]\\
&\quad\times\left(\boldsymbol{\delta}_t - \mathbb{E}^\pi[(\epsilon_t^*)^2|s_t]^{-1}\mathbb{E}_d[\boldsymbol{\delta}_t\boldsymbol{x}_t^\top]\boldsymbol{F}^{-1}\mathbb{E}^\pi[\boldsymbol{x}_t|s_t]\right)\\
&\quad\times\left(\boldsymbol{\delta}_t - \mathbb{E}^\pi[(\epsilon_t^*)^2|s_t]^{-1}\mathbb{E}_d[\boldsymbol{\delta}_t\boldsymbol{x}_t^\top]\boldsymbol{F}^{-1}\mathbb{E}^\pi[\boldsymbol{x}_t|s_t]\right)^\top\Big]\\
&\quad\Big\}\boldsymbol{A}_{\boldsymbol{z}^*+\boldsymbol{\delta}}^{-\top} \succeq \boldsymbol{0}.
\end{aligned}$$

The equality holds only when $\boldsymbol{\delta}_t(s_t) \propto \boldsymbol{z}_t^*$. (Q.E.D.)

B. Proof of Theorem 2: The Optimal $\boldsymbol{c}$

By differentiating the trace of eq. (20), the optimal constant $\boldsymbol{c}$ must satisfy

$$\mathbb{E}_d[(\epsilon_t^*)^2]\boldsymbol{c} + \mathbb{E}_d[(\epsilon_t^*)^2\boldsymbol{\phi}_t] = \boldsymbol{M}_{\boldsymbol{c}}\boldsymbol{A}_{\boldsymbol{c}}^{-\top}\mathbb{E}_d[\boldsymbol{x}_t].$$

Using the well-known matrix inversion lemma (Horn & Johnson, 1985), the solution can be obtained as eq. (23).

In addition, the global optimality among those applied by constant shifts can be proved using a similar argument to that in Appendix A. (Q.E.D.)

Abstract

In dimensionality reduction approaches, the data are typically embedded in a Euclidean latent space. However for some data sets this is inappropriate. For example, in human motion data we expect latent spaces that are cylindrical or a toroidal, that are poorly captured with a Euclidean space. In this paper, we present a range of approaches for embedding data in a non-Euclidean latent space. Our focus is the Gaussian Process latent variable model. In the context of human motion modeling this allows us to (a) learn models with interpretable latent directions enabling, for example, style/content separation, and (b) generalise beyond the data set enabling us to learn transitions between motion styles even though such transitions are not present in the data.

1. Introduction

Dimensionality reduction is a popular approach to dealing with high dimensional data sets. It is often the case that linear dimensionality reduction, such as principal component analysis (PCA) does not adequately capture the structure of the data. For this reason there has been considerable interest in the machine learning community in non-linear dimensionality reduction. Approaches such as locally linear embedding (LLE), Isomap and maximum variance unfolding (MVU) (Roweis & Saul, 2000; Tenenbaum et al., 2000; Weinberger et al., 2004) all define a topology through interconnections between points in the data space. However, if a given data set is relatively sparse or particularly noisy, these interconnections can stray beyond the 'true' local neighbourhood and the resulting embedding can be poor.

Probabilistic formulations of latent variable models do not usually include explicit constraints on the embedding and therefore the natural topology of the data manifold is not always respected [1]. Even with the correct topology and dimension of the latent space, the learning might get stuck in local minima if the initialization of the model is poor. Moreover, the maximum likelihood solution may not be a good model, due e.g., to the sparseness of the data. To get better models in such cases, more constraints on the model are needed.

This paper shows how explicit topological constraints can be imposed within the context of probabilistic latent variable models. We describe two approaches, both within the context of the Gaussian process latent variable model (GP-LVM) (Lawrence, 2005). The

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] An exception is the back-constrained GP-LVM (Lawrence & Quiñonero-Candela, 2006) where a constrained maximum likelihood algorithm is used to enforce these constraints.

first uses prior distributions on the latent space that encourage a given topology. The second influences the latent space and optimisation through constrained maximum likelihood.

Our approach is motivated by the problem of modeling human pose and motion for character animation. Human motion is an interesting domain because, while there is an increasing amount of motion capture data available, the diversity of human motion means that we will necessarily have to incorporate a large amount of prior knowledge to learn probabilistic models that can accurately reconstruct a wide range of motions. Despite this, most existing methods for learning pose and motion models (Elgammal & Lee, 2004; Grochow et al., 2004; Urtasun et al., 2006) do not fully exploit useful prior information, and many are limited to modeling a single human activity (e.g., walking with a particular style).

This paper describes how prior information can be used effectively to learn models with specific topologies that reflect the nature of human motion. Importantly, with this information we can also model multiple activities, including transitions between them (e.g. from walking to running), even when such transitions are not present in the training data. As a consequence, we can now learn latent variable models with training motions comprising multiple subjects with stylistic diversity, as well as multiple activities, such as running and walking. We demonstrate the effectiveness of our approach in a character animation application, where the user specifies a set of constraints (e.g., foot locations), and the remaining kinematic degrees of freedom are infered.

2. Gaussian Process Latent Variable Models (GP-LVM)

We begin with a brief review of the GP-LVM (Lawrence, 2005). The GP-LVM represents a high-dimensional data set, $\mathbf{Y}$, through a low dimensional latent space, $\mathbf{X}$, and a Gaussian process mapping from the latent space to the data space. Let $\mathbf{Y} = [\mathbf{y}_1, ..., \mathbf{y}_N]^T$ be a matrix in which each row is a single training datum, $\mathbf{y}_i \in \Re^D$. Let $\mathbf{X} = [\mathbf{x}_1, ..., \mathbf{x}_N]^T$ denote the matrix whose rows represent the corresponding positions in latent space, $\mathbf{x}_i \in \Re^d$. Given a covariance function for the Gaussian process, $k_Y(\mathbf{x}, \mathbf{x}')$, the likelihood of the data given the latent positions is,

$$p(\mathbf{Y} \mid \mathbf{X}, \bar{\beta}) = \frac{1}{Z_1} \exp\left(-\frac{1}{2}\mathrm{tr}\left(\mathbf{K}_Y^{-1}\mathbf{Y}\mathbf{Y}^T\right)\right), \qquad (1)$$

where Z_1 is a normalization factor, $\mathbf{K}_Y$ is known as the kernel matrix, and $\bar{\beta}$ denotes the kernel hyperparameters. The elements of the kernel matrix are defined by the covariance function, $(\mathbf{K}_Y)_{i,j} = k_Y(\mathbf{x}_i, \mathbf{x}_j)$. A common choice is the radial basis function (RBF), $k_Y(\mathbf{x}, \mathbf{x}') = \beta_1 \exp(-\frac{\beta_2}{2}||\mathbf{x} - \mathbf{x}'||^2) + \frac{\delta_{\mathbf{x},\mathbf{x}'}}{\beta_3}$, where the kernel hyperparameters $\bar{\beta} = \{\beta_1, \beta_2, \beta_3\}$ determine the output variance, the RBF support width, and the variance of the additive noise. Learning in the GP-LVM consists of maximizing (1) with respect to the latent positions, $\mathbf{X}$, and the hyperparameters, $\bar{\beta}$.

When one has time-series data, $\mathbf{Y}$ represents a sequence of observations, and it is natural to augment the GP-LVM with an explicit dynamical model. For example, the Gaussian Process Dynamical Model (GPDM) models the sequence as a latent stochastic process with a Gaussian process prior (Wang et al., 2008) , i.e.,

$$p(\mathbf{X} \mid \bar{\alpha}) = \frac{p(\mathbf{x}_1)}{Z_2} \exp\left(-\frac{1}{2}\mathrm{tr}\left(\mathbf{K}_X^{-1}\mathbf{X}_{out}\mathbf{X}_{out}^T\right)\right) \qquad (2)$$

where Z_2 is a normalization factor, $\mathbf{X}_{out} = [\mathbf{x}_2, ..., \mathbf{x}_N]^T$, $\mathbf{K}_X \in \Re^{(N-1)\times(N-1)}$ is the kernel matrix constructed from $\mathbf{X}_{in} = [\mathbf{x}_1, ..., \mathbf{x}_{N-1}]$, $\mathbf{x}_1$ is given an isotropic Gaussian prior and $\bar{\alpha}$ are the kernel hyperparameters for $\mathbf{K}_X$; below we use an RBF kernel for $\mathbf{K}_X$. Like the GP-LVM the GPDM provides a generative model for the data, but additionally it provides one for the dynamics. One can therefore predict future observation sequences given past observations, and simulate new sequences.

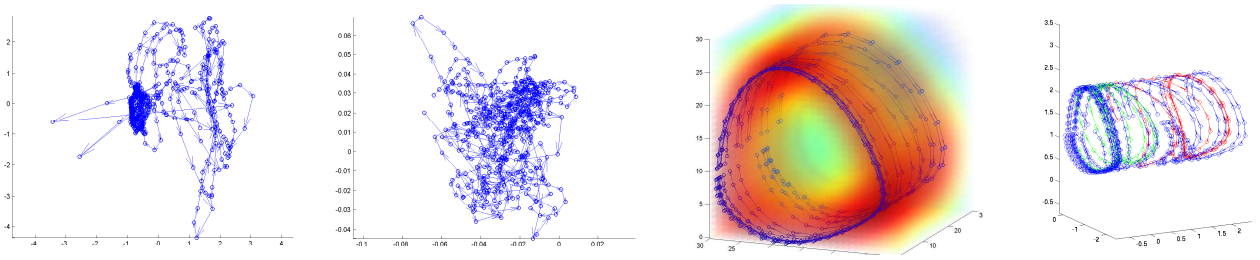
3. Top Down Imposition of Topology

The smooth mapping in the GP-LVM ensures that distant points in data space remain distant in latent space. However, as discussed in (Lawrence & Quiñonero-Candela, 2006), the mapping in the opposite direction is not required to be smooth. While the GPDM may mitigate this effect, it often produces models that are neither smooth nor generalize well (Urtasun et al., 2006; Wang et al., 2008).

To help ensure smoother, well-behaved models, (Lawrence & Quiñonero-Candela, 2006) suggested the use of *back-constraints*, where each point in the latent space is a smooth function of its corresponding point in data space, $x_{ij} = g_j(\mathbf{y}_i; \mathbf{a}_j)$, where $\{\mathbf{a}_j\}_{1\le j\le d}$ is the set of parameters of the mappings. One possible mapping is a kernel-based regression model, where regression on a kernel induced feature space provides the mapping,

$$x_{ij} = \sum_{m=1}^{N} a_{jm} k(\mathbf{y}_i, \mathbf{y}_m) \; . \qquad (3)$$

This approach is known as the back-constrained GP-LVM. When learning the back-constrained GP-LVM,



(a) (b) (c) (d)

Figure 1. When training data contain large stylistic variations and multiple motions, the generic GPDM (a) and the back-constrained GPDM (b) do not produce useful models. Simulations of both models here do not look realistic. (c,d) Hybrid model learned using local linearities for smoothness (i.e., style) and backconstraints for topologies (i.e., content). The training data is composed of 9 walks and 10 runs performed by different subjects and speeds. (c) Likelihood for the reconstruction of the latent points (d) 3D view of the latent trajectories for the training data in blue, and the automatically generated motions of Figs. 3 and 4 in green and red respectively.

one needs to determine the hyperparameters of the kernel matrices (for the back-constraints and the covariance of the GP), as well as the mapping weights, $\{\mathbf{a}_j\}$. (Lawrence & Quiñonero-Candela, 2006) fixed the hyperparameters of the back-constraint's kernel matrix, optimizing over the remaining parameters.

Nevertheless, when learning human motion data with large stylistic variations or different motions, neither GPDM nor back-constrained GP-LVM produce smooth models that generalize well. Fig. 1 depicts three 3–D models learned from 9 walks and 10 runs. The GPDM (Fig. 1(a)) and the back-constrainted GPDM[2] (Fig. 1 (b)) do not generalize well to new runs and walks, nor do they produce realistic animations.

In this paper we show that with a well designed set of back-constraints good models can be learned (Fig. 1(c)). We also consider an alternative approach to the hard constraints on the latent space arising from $g_j(\mathbf{y}_i; \mathbf{a}_j)$. We introduce topological constraints through a prior distribution in the latent space, based on a neighborhood structure learned through a generalized local linear embedding (LLE) (Roweis & Saul, 2000). We then show how to incorporate domain-specific prior knowledge, which allows us to develop motion models with specific topologies that incorporate different activities within a single latent space and transitions between them.

3.1. Locally Linear GP-LVM

The locally linear embedding (LLE) (Roweis & Saul, 2000) preserves topological constraints by finding a representation based on reconstruction in a low dimensional space with an optimized set of local weightings. Here we show how the LLE objective can be combined with the GP-LVM, yielding a *locally linear GP-LVM* (LL-GPLVM).

[2]We use an RBF kernel for the inverse mapping in (3).

The locally linear embedding assumes that each data point and its neighbors lie on, or close to, a locally linear patch on the data manifold. The local geometry of these patches can then be characterized by linear coefficients that reconstruct each data point from its neighbors. This is done in a three step procedure: (1) the K nearest neighbors, $\{\mathbf{y}_j\}_{j\in\eta_i}$, of each point, $\mathbf{y}_i$, are computed using Euclidean distance in the input space, $d_{ij} = ||\mathbf{y}_i - \mathbf{y}_j||^2$; (2) the weights $\mathbf{w} = \{w_{ij}\}$ that best reconstruct each data point from its neighbors are obtained by minimizing $\Phi(\mathbf{w}) = \sum_{i=1}^{N} ||\mathbf{y}_i - \sum_{j\in\eta_i} w_{ij}\mathbf{y}_j||^2$; and (3) the latent positions $\mathbf{x}_i$ best reconstructed by the weights w_{ij} are computed by minimizing $\Phi(\mathbf{X}) = \sum_{i=1}^{N} ||\mathbf{x}_i - \sum_{j\in\eta_i} w_{ij}\mathbf{x}_j||^2$.

In the LLE, the weight matrix $\mathbf{w}$ is sparse (only a small number of neighbors is used), and the two minimizations can be computed in closed form. In particular, computing the weights can be done by solving, $\forall j \in \eta_i$, the following system,

$$\sum_k C_{kj}^{sim} w_{ij}^{sim} = 1 \ , \tag{4}$$

where $C_{kj}^{sim} = (\mathbf{y}_i - \mathbf{y}_k)^T(\mathbf{y}_i - \mathbf{y}_j)$ if $j,k \in \eta_i$, and 0 otherwise. Once the weights are computed, they are rescaled so that $\sum_j w_{ij} = 1$.

The LLE energy function can be interpreted, for a given set of weights $\mathbf{w}$, as a prior that forces each latent point to be locally reconstructed by its neighbors,i.e., $p(\mathbf{X}|\mathbf{w}) = \frac{1}{Z}\exp\left\{-\frac{1}{\sigma^2}\Phi(\mathbf{X})\right\}$, where Z is a normalization constant, and σ^2 represents a global scaling of the prior. Note that strictly speaking this is not a proper prior as it is conditioned on the weights which depend on the training data. Following (Roweis & Saul, 2000), we first compute the neighbors based on the Euclidean distance. For each training point $\mathbf{y}_i$, we then compute the weights solving Eq. (4).

Learning the LL-GPLVM is then equivalent to mini-

mizing the negative log posterior of the model, [3] i.e.,

$$\begin{aligned}\mathcal{L}_{\mathcal{S}} &= \log\ p(\mathbf{Y}|\mathbf{X},\bar{\beta})\ \ p(\bar{\beta})\ \ p(\mathbf{X}|\mathbf{w}) \\ &= \frac{D}{2}\ln|\mathbf{K}_Y| + \frac{1}{2}\mathrm{tr}\left(\mathbf{K}_Y^{-1}\mathbf{Y}\mathbf{Y}^T\right) + \sum_i \ln\beta_i \\ &\quad + \frac{1}{\sigma^2}\sum_{k=1}^{d}\sum_{i=1}^{N}\|x_i^k - \sum_{j=1}^{N} w_{ij}^k x_j^k\|^2 + C\ , \quad (5)\end{aligned}$$

where C is a constant, and x_i^k is the k-th component of $\mathbf{x}_i$. Note that we have extended the LLE to have a different prior for each dimension. This will be useful below as we incorporate different sources of prior knowledge. Fig. 2 (a) shows a model of 2 walks and 2 runs learned with the locally linear GPDM. Note how smooth the latent trajectories are.

We now have general tools to influence the structure of the models. In what follows we generalize the top-down imposition of topology strategies (i.e. back-constraints and locally linear GP-LVM) to incorporate domain specific prior knowledge.

4. Reflecting Knowledge in Latent Space Structure

A problem for modeling human motion data is the sparsity of the data relative to the diversity of naturally plausible motions. For example, while we might have a data set comprising different motions, such as runs, walks *etc.*, the data may not contain transitions between motions. In practice however, we know that these motions will be approximately cyclic and that transitions can only physically occur at specific points in the cycle. How can we encourage a model to respect such topological constraints which arise from prior knowledge?

We consider two alternatives to solve this problem. First, we show how one can adjust the distance metric used in the locally linear embedding to better reflect different types of prior knowledge. We then show how one can define similarity measures for use with the back-constrained GP-LVM. Both these approaches encourage the latent space to construct a representation that reflects our prior knowledge. They are complementary and can be combined to learn better models.

[3] When learning a locally linear GPDM, the dynamics and the locally linear prior are combined as a product of potentials. The objective function becomes $\mathcal{L}_{\mathcal{S}} + \frac{d}{2}\ln|\mathbf{K}_X| + \frac{1}{2}\mathrm{tr}\left(\mathbf{K}_X^{-1}\mathbf{X}_{out}\mathbf{X}_{out}^T\right) + \sum_i \ln\alpha_i$, with $\mathcal{L}_{\mathcal{S}}$ defined as in (5).

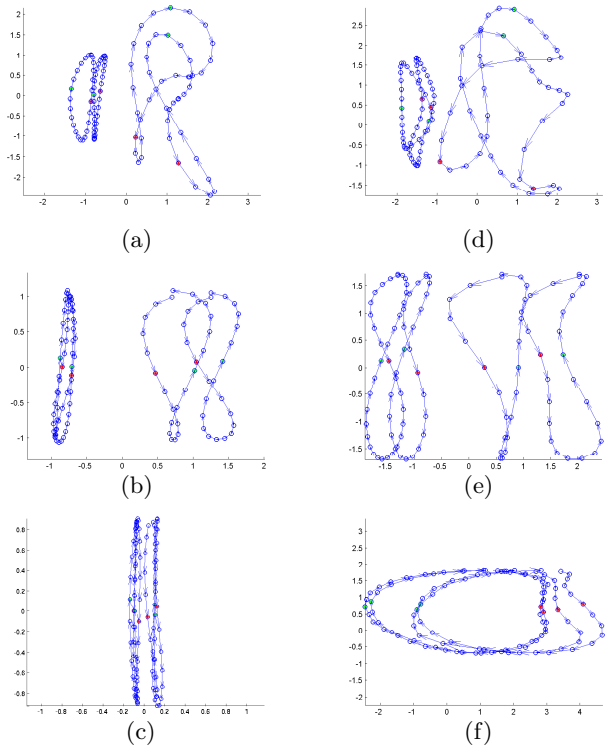


Figure 2. First two dimensions of 3–D models learned using (a) LL-GPDM (b) LL-GPDM with topology (c) LL-GPDM with topology and transitions. (d) Back-constrained GPDM with an RBF mapping. (e) GPDM with topology through backconstraints. (f) GPDM with backconstraints for the topology and transitions. For the models using topology, the cyclic structure is imposed in the last 2 dimensions. The two types of transition points (left and right leg contact points) are shown in red and green, and are used as prior knowledge in (c,f).

4.1. Prior Knowledge through Local Linearities

We now turn to consider how one might incorporate prior knowledge in the LL-GPLVM framework. This is accomplished by replacing the local Euclidean distance measures used in Section 3.1 with other similarity measures. That is, we can modify the covariance used to compute the weights in Eq. (4) to reflect our prior knowledge in the latent space. We consider two examples: the first involves transitions between activities; with the second we show how topological constraints can be placed on the form of the latent space.

Covariance for Transitions Modeling transitions between motions is important in character animation. Transitions can be infered automatically based on similarity between poses (Kovar et al., 2002) or at points of non-linearity of the dynamics (Bissacco, 2005), and they can be used for learning. For example, for motions as walking or running, two types of transitions can be identified: left and right foot ground contacts.

To model such transitions, we define an index on the frames of the motion sequence, $\{t_i\}_{i=1}^N$. We then define subsets of this set, $\{\hat{t}_i\}_{i=1}^M$, which represents frames where transitions are possible. To capture transitions in the latent model we define the elements for the covariance matrix as follows,

$$C_{kj}^{trans} = 1 - \left[\delta_{kj} \exp(-\zeta(t_k - t_j)^2)\right] \quad (6)$$

with ζ a constant, and $\delta_{ij} = 1$ if t_i and t_j are in the same set $\{\hat{t}_k\}_{k=1}^M$, and otherwise $\delta_{ij} = 0$. This covariance encourages the latent points at which transitions are physically possible to be close together.

Covariance for Topologies We now consider covariances that encourage the latent space to have a particular topology. Specifically we are interested in suitable topologies for walking and running data. Because the data are approximately periodic, it seems appropriate to have a non-Cartesian topology. To this end one can extract the phase of the motion[4], ϕ, and use it with a covariance to encourage the latent points to exhibit a periodic topological structure within a Cartesian space. As an example we consider a cylindrical topology within a 3–D latent space by constraining two of the latent dimensions with the phase. In particular, to represent the cyclic motion we construct a distance function on the unit circle, where a latent point corresponding to phase ϕ is represented with coordinates $(\cos(\phi), \sin(\phi))$. To force a cylindrical topology on the latent space, we specify different covariances for each latent dimension

$$C_{k,j}^{cos} = (\cos(\phi_i) - \cos(\phi_k))\,(\cos(\phi_i) - \cos(\phi_j)) \quad (7)$$

$$C_{k,j}^{sin} = (\sin(\phi_i) - \sin(\phi_k))\,(\sin(\phi_i) - \sin(\phi_j))\,, \quad (8)$$

with $k, j \in \eta_i$. The covariance for the remaining dimension is constructed as usual, based on Euclidean distance in the data space. Fig. 2 (b) shows a GPDM constrained in this way, and in Fig. 2 (c) the covariance is augmented with transitions.

Note that the use of different distance measures for each dimension of the latent space implies that the neighborhood and the weights in the locally linear prior will also be different for each dimension. Here, three different locally linear embeddings form the prior distribution.

4.2. Prior Knowledge with Back Constraints

As explained above, we can also design back-constraints to influence the topology and learn useful transitions. This can be done by replacing the kernel of Eq. (3). Many kernels have interpretations as similarity measures. In particular, any similarity measure that leads to a positive semi-definite matrix can be interpreted as a kernel. Here, just as we define covariance matrices above, we extend the original formulation of back constraints by constructing similarity measures (i.e., kernels) to reflect prior knowledge.

Similarity for Transitions To capture transitions between two motions, we wish to design a kernel that expresses strong similarity between points in the respective motions where transitions may occur. We can encourage transition points of different sequences to be proximal with the following kernel matrix for the back-constraint mapping:

$$k^{trans}(t_i, t_j) = \sum_m \sum_l \delta_{ml} k(t_i, \hat{t}_m) k(t_j, \hat{t}_l) \quad (9)$$

where $k(t_i, \hat{t}_l)$ is an RBF centered at $\hat{t}_l$, and $\delta_{ml} = 1$ if $\hat{t}_m$ and $\hat{t}_l$ are in the same set. The influence of the back-constraints is controlled by the support width of the RBF kernel.

Topologically Constrained Latent Spaces We now consider kernels that force the latent space to have a particular topology. To force a cylindrical topology on the latent space, we can introduce similarity measures based on the phase, specifying different similarity measures for each latent dimension. As before we construct a distance function in the unit circle, that takes into account the phase. A periodic mapping can be constructed from a kernel matrix as follows,

$$x_{n,1} = \sum_{m=1}^{N} a_m^{cos} k(\cos(\phi_n), \cos(\phi_m)) + a_0^{cos} \delta_{n,m},$$

$$x_{n,2} = \sum_{m=1}^{N} a_m^{sin} k(\sin(\phi_n), \sin(\phi_m)) + a_0^{sin} \delta_{n,m},$$

where k is an RBF kernel function, and $x_{n,i}$ is the i^{th} coordinate of the n^{th} latent point. These two mappings project onto two dimensions of the latent space, forcing them to have a periodic structure (which comes about through the sinusoidal dependence of the kernel on phase). Fig. 2 (e) shows a model learned using GPDM with the last two dimensions constrained in this way (the third dimension is out of plane). The first dimension is constrained by an RBF mapping on the input space. Each dimension's kernel matrix can then be augmented by adding the transition similarity of Eq.(9), resulting in the model shown in Fig. 2 (f).

4.3. Model Combination

One advantage of our framework is that covariance matrices can be combined in a principled manner to form

[4]The phase can be easily extracted from the data by Fourier analysis or by detecting key postures and interpolating the phases between them. Another idea, not further explored here, would be to optimize the GP-LVM with respect to the phase.

new covariance matrices. Covariances can be multiplied (on an element by element basis) or added together. Similarly, similarities can be combined. Multiplication has, loosely speaking, an 'AND gate effect', i.e. both similarity measures must agree that an object is similar for their product to express similarity. Adding them produces more of an 'OR gate effect', i.e. if either representation expresses similarity the resulting measure will also express similarity.

The two sections above have shown how to incorporate prior knowledge in the GP-LVM by means of 1) local linearities and 2) back-constraints. In general, the latter should be used when the manifold has a well-defined topology, since it has more influence on the learning. When the topology is not so well defined (e.g., due to noise) one should use local linearities. Both techniques are complementary and can be combined straightforwardly by including priors over some dimensions, and constraining the others through back-constraint mappings. Fig. 1 shows a model learned with LL-GPDM for smoothness and back-constraints for topology.

4.4. Multiple Activities and Transitions

Once we know how to ensure that transition points are close together and that the latent structure has the desired topology, we still need to address two issues. How do we learn models that have very different dynamics? How can we simulate dynamical models that lie somewhere between the different training motions? Our goal in this section is to show how latent models for different motions can be learned independently, but in a shared latent space that facilitates transitions between activities with different dynamics.

Let $\mathbf{Y} = [\mathbf{Y}_1^T, ..., \mathbf{Y}_M^T]^T$ denote training data for M different activities. Each $\mathbf{Y}_m$ comprises several different motions. Let $\mathbf{X} = [\mathbf{X}_1^T, ..., \mathbf{X}_M^T]^T$ denote the corresponding latent positions. When dealing with multiple activities, a single dynamical model cannot cope with the complexity of the different dynamics. Instead, we consider a model where the dynamics of each activity are modeled independently[5]. This has the advantage that a different kernel can be used for each activity.

To enable interpolation between motions with different dynamics, we combined these independent dynamical models in the form of a mixture model. This allows us to produce motions that gracefully transition between different styles and motion types (Figs. 3 and 4).

[5] Another interpretation is that we have a block diagonal kernel matrix for the GP that governs the dynamics.

5. Results

We demonstrate the effectiveness of our approach with two applications. First we show how models of multiple activities can be learned, and realistic animations can be produced by drawing samples from the model. We then show an interactive character animation application, where the user specifies a set of sparse constraints and the remaining kinematic degrees of freedom are infered.

5.1. Learning multiple activities

We first considered a small training set comprised of 4 gait cycles (2 walks and 2 runs) performed by one subject at different speeds. Fig. 2 shows the latent spaces learned under different prior constraints. All the models are learned using two independent dynamical models, one for walking and one for running. Note how the phases are aligned when imposing a cylindrical topology, and how the LL-GPDM is smooth. Notice the difference between the LL-GPDM (Fig. 2 (c)) and the backconstrained GPDM (Fig. 2 (f)) when transition constraints are included. Neverthess, both models ensure that the transition points (shown in red and green) are proximal.

Fig. 1 (c) shows a hybrid model learned using LL-GPDM for smoothness, and back-constraints for topology. The larger training set comprises approximately one gait cycle from each of 9 walking and 10 running motions performed by different subjects at different speeds (3 km/h for walking, 6–12 km/h for running). Colors in Fig. 1 (a) represent the variance of the GP as a function of latent position. Only points close to the surface of the cylinder produce poses with high certainty.

We now illustrate the model's ability to simulate different motions and transitions. Given an initial latent position $\mathbf{x}_0$, we generate new motions by sampling the mixture model, and using mean prediction for the reconstruction. Choosing different initial conditions results in very different simulations (Fig. 1 (d)). The training data are shown in blue. For the first simulation (depicted in green), the model is initialized to a running pose with a latent position not far from walking data. The system transitions to walking quite naturally. The resulting animation is depicted in Fig. 3. For the second example (in red), we initialize the simulation to a latent position far from walking data. The system evolves to different running styles and speeds (Fig. 4). Note how the dynamics, and the strike length, change considerably during simulation.

Figure 3. **Transition from running to walking**: The system transitions from running to walking in a smooth and realistic way. The transition is encouraged by incorporating prior knowledge in the model. The latent trajectories are shown in green in Fig. 1 (d).

Figure 4. **Different running styles and speeds**: The system is able to simulate a motion with considerably changes in speed and style. The latent trajectories are shown in red in Fig. 1 (d).

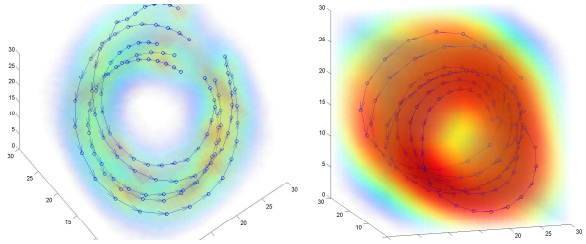

Figure 5. Single activity 3D latent models learned from (left) 5 jumps of 2 different subjects using local linearities, (b) 7 walking cycles of one subject using back-constraints.

5.2. Character animation from constraints

A key problem in the film and game industry is the lack of tools to allow designers to easily generate animations. Traditional techniques such as keyframing are time consuming; an expert can expend days in generating a few seconds of animation. A very useful tool would provide the user with a simple way of generating motions from constraints that she/he defined. Typical constraints are keyframes (i.e., specification of the position of the full body in a particular time instant), or joint trajectories. Here we use the topologically constrained motion models as priors over the space of possible motions.

Our motion estimation formulation is based on a state-space model with a GPDM prior over pose and motion. Given the state, $\phi_t = (\mathbf{y}_t, \mathbf{x}_t)$, the goal is to estimate the state sequence $\phi_{1:T} = (\phi_1, \cdots, \phi_T)$ that satisfies the user constraints $\mathbf{u}_{1:J}$. Inference is performed in a *Batch* mode, so that the state is infered all at once. The posterior can be expressed as

$$p(\phi_{1:T}|\mathbf{u}_{1:J}, \mathbf{M}) \propto p(\mathbf{u}_{1:J}|\phi_{1:T})p(\phi_{1:T}|\mathbf{M}) \qquad (10)$$

where we assumed that $p(\mathbf{u}_{1:J})$ is uniformily distributed; all the user constraints are equally probable. The prediction distribution $p(\phi_{1:T}|\mathbf{M})$ can be further factored as follows

$$p(\phi_{1:T}|\mathbf{M}) = p(\mathbf{x}_{1:T}|\mathbf{M}) \prod_{t=1}^{T} p(\mathbf{y}_t|\mathbf{x}_t, \mathbf{M}) \qquad (11)$$

Rather than approximating the entire posterior, we use hill-climbing to find MAP estimates. Assuming that the user constraints are noise-free, the minimization can be expressed as

$$\begin{aligned} \min_{\phi_{1:T}} \quad & \mathcal{L}_{pose} + \mathcal{L}_{dyn} + \mathcal{L}_{smooth} \\ \text{subject to} \quad & ||\mathbf{u} - \mathbf{f}(\mathbf{y}_{\psi(\mathbf{u})})|| = \mathbf{0} \end{aligned} \qquad (12a)$$

where $\mathbf{f}$ is a forward kinematics function (i.e., a function that maps joint angles to positions in the 3D world), $\psi(\mathbf{u})$ is a function that outputs the frame where each constraint $\mathbf{u}_j$ is defined, $\mathcal{L}_{pose} = -\sum_i \ln p(\mathbf{y}_t|\mathbf{x}_t, \mathbf{M})$ and $\mathcal{L}_{dyn} = -\ln p(\mathbf{x}_{1:T}|M)$ are the pose and dynamics likelihood from the GPDM prior (Urtasun et al., 2006), and $\mathcal{L}_{smooth} = \frac{1}{\sigma_s^2}\sum_{t=1}^{T-1}\sum_{j=1}^{P}\frac{1}{\sigma_j^2}(y_{t+1}^j - y_t^j)^2$ is a term that encourage smooth motions, where y_t^j is the j-th component of $\mathbf{y}_t$, and σ_j^2 is a constant that encounters from the fact that each degree of freedom has a different variance.

Initialization is important since a large number of variables need to be optimised and our objective function is non-convex. In particular, we sample the model starting at each training point and use as initialization the sample that is closest to the user constraints.

To demonstrate the effectiveness of our approach we learned models of two different motions, walking and jumping (Fig. 5). We impose smoothness and cyclic topologies using back-constraints for the walking and local linearities for the jumping. We demonstrate the ability of the model to generalize to unseen styles.

We first show how the model can produce realistic animations from a very small set of user defined constraints. The user specifies the contact points of the foot with the ground (first row of Fig. 6) for walking and the foot trajectories for the jumping (third row of Fig. 6), and the rest of the degrees of freedom are infered producing very realistic animations.

The model can also generalize to styles very different

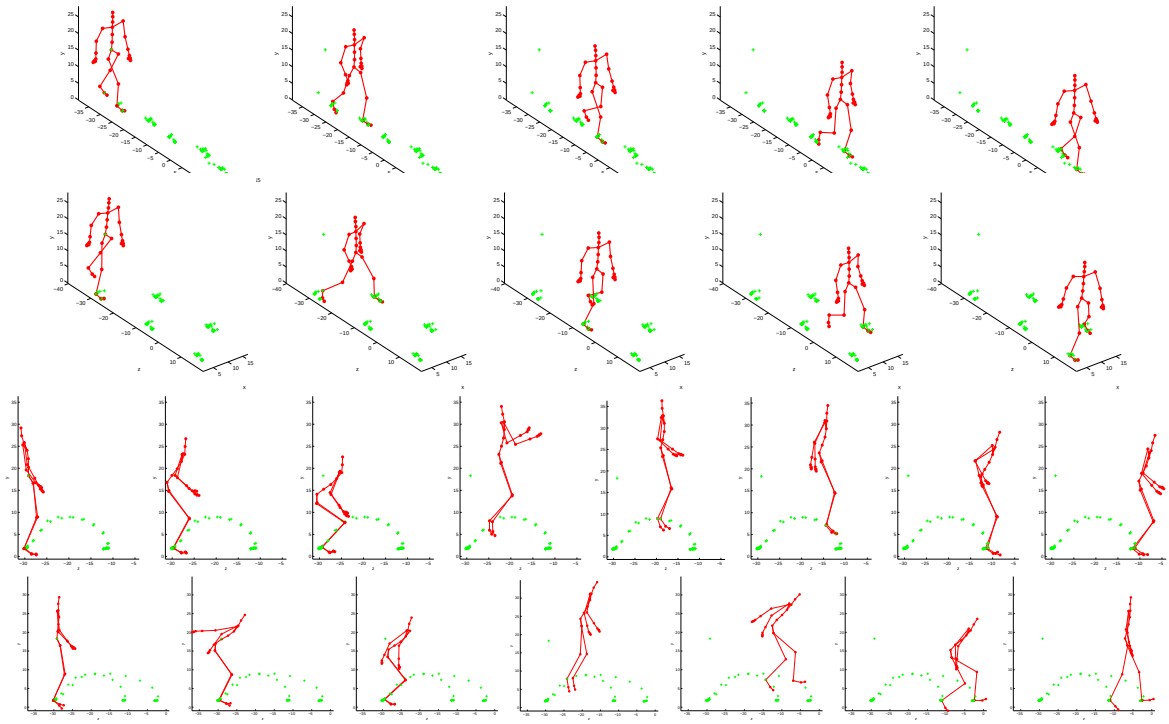

Figure 6. Animations generated from a set of foot constraints (green). **First row**: Normal walk. **Second row**: Generalization a different style by changing the user constraints to be separate in the coronal plane. **Third row**: Short jump. **Last row**: Longer stylistic jump. *See video at http://people.csail.mit.edu/rurtasun*

from the ones in the training set, by imposing constraints that can be satisfied only by motions very different from the training data. In particular, the user placed the foot constraints far in the coronal plane for walking. Consequently the character opens the legs to satisfy the constraints (second row of Fig. 6). In the last row of Fig. 6 the user places the foot trajectories to create a jump with a style very different from the traning data (the character opens his legs and bends his body and arms in an exaggerated way).

6. Conclusions

In this paper we have proposed a general framework of probabilistic models that learn smooth latent variable models of different activities within a shared latent space. We have introduced a principled way to include prior knowledge, that allow us to learn specific topologies and transitions between the different motions. Although we have learned models composed of walking, running and jumping, our framework is general, being applicable in any data sets where there is a large degree of prior knowledge for the problem domain, but the data availability is relatively sparse compared to its complexity.

Abstract

The infinite hidden Markov model is a nonparametric extension of the widely used hidden Markov model. Our paper introduces a new inference algorithm for the infinite Hidden Markov model called *beam sampling*. Beam sampling combines slice sampling, which limits the number of states considered at each time step to a finite number, with dynamic programming, which samples whole state trajectories efficiently. Our algorithm typically outperforms the Gibbs sampler and is more robust. We present applications of iHMM inference using the beam sampler on changepoint detection and text prediction problems.

1. Introduction

The hidden Markov model (HMM) (Rabiner, 1989) is one of the most widely used models in machine learning and statistics for sequential or time series data. The HMM consists of a hidden state sequence with Markov dynamics, and independent observations at each time given the corresponding state. There are three learning related tasks associated with the HMM: inference of the hidden state sequence, learning of the parameters, and selection of the right model size.

Inference for the hidden state trajectory can be performed exactly using the forward-backward algorithm (Rabiner, 1989), a dynamic programming algorithm with $O(TK^2)$ computational costs where T is the number of time steps and K number of states.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

The standard approach to learning uses the Baum-Welch algorithm, a special instance of the EM algorithm (Dempster et al., 1977) which produces (locally) maximum likelihood (ML) parameters. Such ML learning of parameters can potentially lead to overfitting if the model size is inappropriate for the amount of data available. This can be partially mitigated using a more fully Bayesian learning procedure, e.g. using variational approximations (MacKay, 1997) or Markov chain Monte Carlo (MCMC) sampling (Scott, 2002). Such Bayesian approaches also produce estimates of the marginal probability of data, which can be used to select for the appropriate model size (or to average over model sizes if ones desires a more Bayesian analysis). Such model selection procedures can be computationally expensive since multiple HMMs of different sizes need to be explored.

A new twist on the problem of model selection has emerged in recent years with the increasing popularity of nonparametric Bayesian models. These are models of infinite capacity, a finite portion of which will be used to model a finite amount of observed data. The idea of searching/averaging over the space of finite models is replaced with Bayesian inference over the size of submodel used to explain data. Examples of successful applications of nonparametric Bayesian methods include Gaussian Processes (Rasmussen & Williams, 2005) for regression and classification, Dirichlet Process (DP) mixture models (Escobar & West, 1995; Rasmussen, 2000) for clustering heterogeneous data and density estimation, Indian Buffet Processes for latent factor analysis (Griffiths & Ghahramani, 2006), and defining distributions over non-trivial combinatorial objects such as trees (Teh et al., 2008).

The Infinite Hidden Markov Model (iHMM), otherwise known as the HDP-HMM, (Beal et al., 2002) is a non-

parametric Bayesian extension of the HMM with an infinite number of hidden states. Exact Bayesian inference for the iHMM is intractable. Specifically, given a particular setting of the parameters the forward-backward algorithm cannot be applied since the number of states K is infinite, while with the parameters marginalized out all hidden state variables will be coupled and the forward-backward algorithm cannot be applied either. Currently the only approximate inference algorithm available is Gibbs sampling, where individual hidden state variables are resampled conditioned on all other variables (Teh et al., 2006). Unfortunately convergence of Gibbs sampling is notoriously slow in the HMM setting due to the strong dependencies between consecutive time steps often exhibited by time series data (Scott, 2002).

In this paper we propose a new sampler for the iHMM called *beam sampling*. Beam sampling combines two ideas—slice sampling and dynamic programming—to sample whole state trajectories efficiently. Our application of slice sampling (Neal, 2003) is inspired by (Walker, 2007), who used it to limit the number of clusters considered when sampling assignment variables in DP mixtures to a finite number. We apply slice sampling to limit to a finite number the states considered in each time step of the iHMM, so that dynamic programming can be used to sample whole state trajectories efficiently. We call our proposal beam sampling due to its similarity to beam search, a heuristic procedure for finding the maximum a posteriori trajectory given observations in non-linear dynamical systems. The underlying idea in both is to limit the search to a small number of states so that a good trajectory can be found using reasonable computational resources. However, ours is a MCMC sampling method with guaranteed convergence to the true posterior.

We first present a self-contained description of the iHMM using the Hierarchical Dirichlet process (HDP) formalism (Teh et al., 2006) in Section 2, followed by a discussion of Gibbs sampling in Section 3. We introduce beam sampling in Section 4 and compare it against Gibbs sampling on both artificial and real datasets in Section 5. We find that beam sampling is (1) at least as fast if not faster than Gibbs sampling; (2) more robust than Gibbs sampling as its performance is not as dependent on initialization and hyperparameter choice; (3) handles non-conjugacy in the model more naturally; (4) straightforward to implement. We conclude in Section 6 with a discussion and suggestions for other cases in which beam sampling might prove useful. All software is available from *http://mlg.eng.cam.ac.uk/jurgen* to encourage more widespread adoption of the iHMM and the beam sampler.

2. The Infinite Hidden Markov Model

We start this section by describing the finite HMM, then taking the infinite limit to obtain an intuition for the infinite HMM, followed by a more precise definition. A finite HMM consists of a hidden state sequence $\boldsymbol{s} = (s_1, s_2, \ldots, s_T)$ and a corresponding observation sequence $\boldsymbol{y} = (y_1, y_2, \ldots, y_T)$. Each state variable s_t can take on a finite number of states, say $1 \ldots K$. Transitions between states are governed by Markov dynamics parameterized by the transition matrix $\boldsymbol{\pi}$, where $\pi_{ij} = p(s_t = j | s_{t-1} = i)$, while the initial state probabilities are $\pi_{0i} = p(s_1 = i)$. For each state $s_t \in \{1 \ldots K\}$ there is a parameter ϕ_{s_t} which parametrizes the observation likelihood for that state: $y_t | s_t \sim F(\phi_{s_t})$. Given the parameters $\{\pi_0, \boldsymbol{\pi}, \boldsymbol{\phi}, K\}$ of the HMM, the joint distribution over hidden states $\boldsymbol{s}$ and observations $\boldsymbol{y}$ can be written (with $s_0 = 0$):

$$p(\boldsymbol{s}, \boldsymbol{y} | \pi_0, \boldsymbol{\pi}, \boldsymbol{\phi}, K) = \prod_{t=1}^{T} p(s_t | s_{t-1}) p(y_t | s_t)$$

We complete the Bayesian description by specifying the priors. Let the observation parameters $\boldsymbol{\phi}$ be iid drawn from a prior distribution H. With no further prior knowledge on the state sequence, the typical prior for the transition (and initial) probabilities are symmetric Dirichlet distributions.

A naïve way to obtain a nonparametric HMM with an infinite number of states might be to use symmetric Dirichlet priors over the transition probabilities with parameter α/K and take $K \to \infty$. Such an approach has been successfully used to derive DP mixture models (Rasmussen, 2000) but unfortunately does not work in the HMM context. The subtle reason is that there is no coupling across transitions out of different states since the transition probabilities are given independent priors (Beal et al., 2002). To introduce coupling across transitions, one may use a hierarchical Bayesian formalism where the Dirichlet priors have shared parameters and given a higher level prior, e.g.

$$\begin{aligned} \boldsymbol{\pi}_k &\sim \mathsf{Dirichlet}\left(\alpha \boldsymbol{\beta}\right), \\ \boldsymbol{\beta} &\sim \mathsf{Dirichlet}\left(\gamma/K \ldots \gamma/K\right) \end{aligned} \tag{1}$$

where $\boldsymbol{\pi}_k$ are transition probabilities out of state k and $\boldsymbol{\beta}$ are the shared prior parameters. As $K \to \infty$, the hierarchical prior (1) approaches (with some alterations) a *hierarchical Dirichlet process* (Teh et al., 2006).

A hierarchical Dirichlet process (HDP) is a set of Dirichlet processes (DPs) coupled through a shared random base measure which is itself drawn from a DP (Teh et al., 2006). Specifically, each $G_k \sim \mathsf{DP}(\alpha, G_0)$ with shared base measure G_0, which can be understood as the mean of G_k, and concentration parameter $\alpha > 0$, which governs variability around G_0,

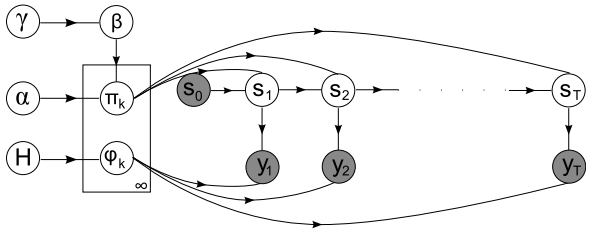

Figure 1. iHMM Graphical Model

with small α implying greater variability. The shared base measure is itself given a DP prior: $G_0 \sim \mathsf{DP}(\gamma, H)$ with H a global base measure. The stick-breaking construction for HDPs shows that the random measures can be expressed as follows: $G_0 = \sum_{k'=1}^{\infty} \beta_{k'} \delta_{\phi_{k'}}$ and $G_k = \sum_{k'=1}^{\infty} \pi_{kk'} \delta_{\phi_{k'}}$, where $\boldsymbol{\beta} \sim \mathsf{GEM}(\gamma)$ is the stick-breaking construction for DPs (Sethuraman, 1994), $\boldsymbol{\pi}_k \sim \mathsf{DP}(\alpha, \boldsymbol{\beta})$, and each $\phi_{k'} \sim H$ independently.

Identifying each G_k as describing both the transition probabilities $\pi_{kk'}$ from state k to k' and the emission distributions parametrized by $\phi_{k'}$, we can now formally define the iHMM as follows:

$$\boldsymbol{\beta} \sim \mathsf{GEM}(\gamma), \qquad \boldsymbol{\pi}_k | \boldsymbol{\beta} \sim \mathsf{DP}(\alpha, \boldsymbol{\beta}), \qquad \phi_k \sim H, \quad (2)$$

$$s_t | s_{t-1} \sim \mathsf{Multinomial}(\boldsymbol{\pi}_{s_{t-1}}), \qquad y_t | s_t \sim F(\phi_{s_t}). \quad (3)$$

The graphical model corresponding to this hierarchical model is shown in figure 1. Thus $\beta_{k'}$ is the prior mean for transition probabilities leading into state k', and α governs the variability around the prior mean. If we fix $\boldsymbol{\beta} = (\frac{1}{K} \ldots \frac{1}{K}, 0, 0 \ldots)$ where the first K entries are $\frac{1}{K}$ and the remaining are 0, then transition probabilities into state k' will be non-zero only if $k' \in \{1 \ldots K\}$, and we recover the Bayesian HMM of (MacKay, 1997).

Finally we place priors over the hyperparameters α and γ. A common solution, when we do not have strong beliefs about the hyperparameters, is to use gamma hyperpriors: $\alpha \sim \mathsf{Gamma}(a_\alpha, b_\alpha)$ and $\gamma \sim \mathsf{Gamma}(a_\gamma, b_\gamma)$. (Teh et al., 2006) describe how these hyperparameters can be sampled efficiently, and we will use this in the experiments to follow.

3. The Gibbs Sampler

The Gibbs sampler was the first sampling algorithm for the iHMM that converges to the true posterior. One proposal builds on the direct assignment sampling scheme for the HDP in (Teh et al., 2006) by marginalizing out the hidden variables $\boldsymbol{\pi}, \boldsymbol{\phi}$ from (2), (3) and ignoring the ordering of states implicit in $\boldsymbol{\beta}$. Thus we only need to sample the hidden trajectory $\boldsymbol{s}$, the base DP parameters $\boldsymbol{\beta}$ and the hyperparameters α, γ. Sampling $\boldsymbol{\beta}, \alpha, \gamma$ is exactly the same as for the HDP so we refer to (Teh et al., 2006) for details.

In order to resample s_t, we need to compute the probability $p(s_t | s_{-t}, \boldsymbol{\beta}, \boldsymbol{y}, \alpha, H) \propto p(y_t | s_t, \boldsymbol{s}_{-t}, \boldsymbol{y}_{-t}, H) \cdot p(s_t | \boldsymbol{s}_{-t}, \boldsymbol{\beta}, \alpha)$. The first factor is the conditional likelihood of y_t given $\boldsymbol{s}$, $\boldsymbol{y}$ and H: $\int p(y_t | s_t, \boldsymbol{\phi}_{s_t}) p(\boldsymbol{\phi}_{s_t} | \boldsymbol{s}_{-t}, \boldsymbol{y}_{-t}, H) d\boldsymbol{\phi}_{s_t}$. This is easy to compute when the base distribution H and likelihood F from equations (2) and (3) are conjugate. For the second factor we can use the fact that the hidden state sequence is Markov. Let n_{ij} be the number of transitions from state i to state j excluding time steps $t-1$ and t. Let $n_{\cdot i}, n_{i \cdot}$ be the number of transitions in and out of state i. Finally, let K be the number of distinct states in $\boldsymbol{s}_{-t}$. Then we have that[1] $p(s_t = k | \boldsymbol{s}_{-t}, \boldsymbol{\beta}, \alpha) \propto$

$$\begin{cases} (n_{s_{t-1},k} + \alpha\beta_k) \frac{n_{k,s_{t+1}} + \alpha\beta_{s_{t+1}}}{n_{k\cdot} + \alpha} & \text{if } k \le K,\ k \ne s_{t-1} \\ (n_{s_{t-1},k} + \alpha\beta_k) \frac{n_{k,s_{t+1}} + 1 + \alpha\beta_{s_{t+1}}}{n_{k\cdot} + 1 + \alpha} & \text{if } k = s_{t-1} = s_{t+1} \\ (n_{s_{t-1},k} + \alpha\beta_k) \frac{n_{k,s_{t+1}} + \alpha\beta_{s_{t+1}}}{n_{k\cdot} + 1 + \alpha} & \text{if } k = s_{t-1} \ne s_{t+1} \\ \alpha\beta_k \beta_{s_{t+1}} & \text{if } k = K+1. \end{cases}$$

For each $1 \le t \le T$ we need to compute $\mathcal{O}(K)$ probabilities, hence the Gibbs sampler has an $\mathcal{O}(TK)$ computational complexity. Non-conjugate models can be handled using more sophisticated sampling techniques. In our experiments below, we used algorithm 8 from (Neal, 2000).

The Gibbs sampler's success is due to its straightforward implementation. However, it suffers from one major drawback: sequential and time series data are likely to be strongly correlated. For example, if we know the value of a stock at time t then we can be reasonably sure that it will be similar at time $t+1$. As is well known, this is a situation which is far from ideal for the Gibbs sampler: strong correlations in the hidden states will make it unlikely that individual updates to s_t can cause large blocks within $\boldsymbol{s}$ to be changed. We will now introduce the beam sampler which does not suffer from this slow mixing behavior by sampling the whole sequence $\boldsymbol{s}$ in one go.

4. The Beam Sampler

The forward-backward algorithm does not apply to the iHMM because the number of states, and hence the number of potential state trajectories, are infinite. The idea of beam sampling is to introduce auxiliary variables $\boldsymbol{u}$ such that conditioned on $\boldsymbol{u}$ the number of trajectories with positive probability is finite. Now dynamic programming can be used to compute the conditional probabilities of each of these trajectories and thus sample *whole* trajectories efficiently. These

[1] Recall that we ignored the ordering of states in $\boldsymbol{\beta}$. In this representation the K distinct states in $\boldsymbol{s}$ are labeled $1 \ldots K$ and $K+1$ denotes a new state.

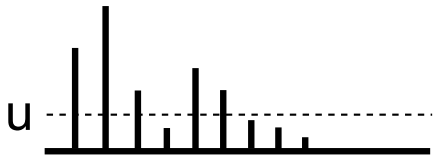

Figure 2. The auxiliary variable u partitions the probability distribution π (vertical bars) into a set of entries less than u and a set of entries larger than u.

auxiliary variables do not change the marginal distribution over other variables hence MCMC sampling will converge to the true posterior. This idea of using auxiliary variables to limit computation costs is inspired by (Walker, 2007), who applied it to limit the number of components in a DP mixture model that need be considered during sampling.

As opposed to the sampler in the previous section, the beam sampler does not marginalize out $\boldsymbol{\pi}$ nor $\boldsymbol{\phi}$. Specifically, the beam sampler iteratively samples the auxiliary variables $\boldsymbol{u}$, the trajectory $\boldsymbol{s}$, the transition probabilities $\boldsymbol{\pi}$, the shared DP parameters $\boldsymbol{\beta}$ and the hyperparameters α and γ conditioned on all other variables. In the following, we shall describe in more detail how to sample each set of variables, as well as how the auxiliary variables allow dynamic programming to be carried out over a finite number of trajectories without approximations.

Sampling $\boldsymbol{u}$: for each t we introduce an auxiliary variable u_t with conditional distribution $u_t \sim \mathsf{Uniform}(0, \pi_{s_{t-1}s_t})$ depending on $\boldsymbol{\pi}$, s_{t-1} and s_t.

Sampling $\boldsymbol{s}$: we sample the whole trajectory $\boldsymbol{s}$ given the auxiliary variables $\boldsymbol{u}$ and other variables using a form of forward filtering-backward sampling. The important observation here is that only trajectories $\boldsymbol{s}$ with $\pi_{s_{t-1}s_t} \geq u_t$ for all t will have non-zero probability given $\boldsymbol{u}$. There are only finitely many such trajectories[2] and as a result we can compute the conditional distribution over all such trajectories efficiently using dynamic programming.

First note that the probability density for u_t is $p(u_t|s_{t-1}, s_t, \boldsymbol{\pi}) = \frac{\mathbb{I}(0<u_t<\pi_{s_{t-1},s_t})}{\pi_{s_{t-1},s_t}}$, where $\mathbb{I}(C) = 1$ if condition C is true and 0 otherwise. We compute $p(s_t|y_{1:t}, u_{1:t})$ for all t as follows (we omitted the additional conditioning variables $\boldsymbol{\pi}$ and $\boldsymbol{\phi}$ for clarity):

$$\begin{aligned}
&p(s_t|y_{1:t}, u_{1:t}) \\
\propto &p(s_t, u_t, y_t|y_{1:t-1}, u_{1:t-1}), \\
= &\sum_{s_{t-1}} p(y_t|s_t)p(u_t|s_t, s_{t-1})p(s_t|s_{t-1}) \\
&\qquad p(s_{t-1}|y_{1:t-1}, u_{1:t-1}), \\
= &p(y_t|s_t) \sum_{s_{t-1}} \mathbb{I}(u_t < \pi_{s_{t-1},s_t}) p(s_{t-1}|y_{1:t-1}, u_{1:t-1}), \\
= &p(y_t|s_t) \sum_{s_{t-1}:u_t<\pi_{s_{t-1},s_t}} p(s_{t-1}|y_{1:t-1}, u_{1:t-1}). \qquad (4)
\end{aligned}$$

Note that we only need to compute (4) for the finitely many s_t values belonging to some trajectory with positive probability. Further, although the sum over s_{t-1} is technically a sum over an infinite number of terms, the auxiliary variable u_t truncates this summation to the finitely many s_{t-1}'s that satisfy both constraints $\pi_{s_{t-1},s_t} > u_t$ and $p(s_{t-1}|y_{1:t-1}, u_{1:t-1}) > 0$. Finally, to sample the whole trajectory $\boldsymbol{s}$, we sample s_T from $p(s_T|y_{1:T}, u_{1:T})$ and perform a backward pass where we sample s_t given the sample for s_{t+1}: $p(s_t|s_{t+1}, y_{1:T}, u_{1:T}) \propto p(s_t|y_{1:t}, u_{1:t})p(s_{t+1}|s_t, u_{t+1})$.

Sampling $\boldsymbol{\pi}$, $\boldsymbol{\phi}$, $\boldsymbol{\beta}$: these follow directly from the theory of HDPs (Teh et al., 2006), but we briefly describe these for completeness.

Let n_{ij} be the number of times state i transitions to state j in the trajectory $\boldsymbol{s}$, where $i, j \in \{1 \dots K\}$, K is the number of distinct states in $\boldsymbol{s}$, and these states have been relabeled $1 \dots K$. Merging the infinitely many states not represented in $\boldsymbol{s}$ into one state, the conditional distribution of $(\pi_{k1} \dots \pi_{kK}, \sum_{k'=K+1}^{\infty} \pi_{kk'})$ given its Markov blanket $\boldsymbol{s}, \boldsymbol{\beta}, \alpha$ is

$$\mathsf{Dirichlet}\left(n_{k1} + \alpha\beta_1 \dots n_{kK} + \alpha\beta_K, \alpha \textstyle\sum_{i=K+1}^{\infty} \beta_i\right),$$

To sample $\boldsymbol{\beta}$ we introduce a further set of auxiliary variables m_{ij} which are independent with conditional distributions

$$p(m_{ij} = m|\boldsymbol{s}, \boldsymbol{\beta}, \alpha) \propto S(n_{ij}, m)(\alpha\beta_j)^m,$$

where $S(\cdot, \cdot)$ denotes Stirling numbers of the first kind. The shared DP parameter $(\beta_1 \dots, \beta_K, \sum_{k'=K+1}^{\infty} \beta_{k'})$ has conditional distribution

$$\mathsf{Dirichlet}\left(m_{\cdot 1} \dots m_{\cdot K}, \gamma\right),$$

where $m_{\cdot k} = \sum_{k'=1}^{K} m_{k'k}$. (Teh et al., 2006; Antoniak, 1974) gives more details.

Finally, each ϕ_k is independent of others conditional on $\boldsymbol{s}$, $\boldsymbol{y}$ and their prior distribution H, i.e. $p(\boldsymbol{\phi}|\boldsymbol{s}, \boldsymbol{y}, H) =$

[2] To see this, note that $u_t > 0$ with probability 1 for each t, since each $\pi_{kk'} > 0$ with probability 1. Given the auxiliary variable u_t, note further that for each possible value of s_{t-1}, u_t partitions the set of transition probabilities out of state s_{t-1} into two sets: a finite set with $\pi_{s_{t-1}k} > u_t$ and an infinite set with $\pi_{s_{t-1}k} < u_t$, as illustrated in figure 2. Thus we can recursively show that for $t = 1, 2 \dots T$ the set of trajectories $s_{1:t}$ with all $\pi_{s_{t'-1}s_{t'}} > u_t$ is finite.

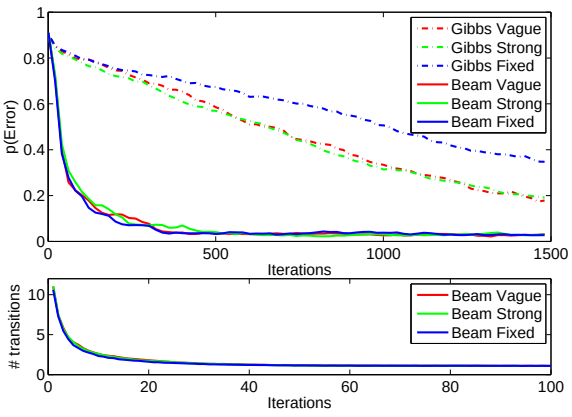

Figure 3. iHMM performance on strong negatively correlated data. The top plot shows the error of the Gibbs and beam sampler for the first 1500 iterations averaged over 20 runs. The bottom plot shows the average number of previous states considered in equation (4) for the first 100 iterations of the beam sampler.

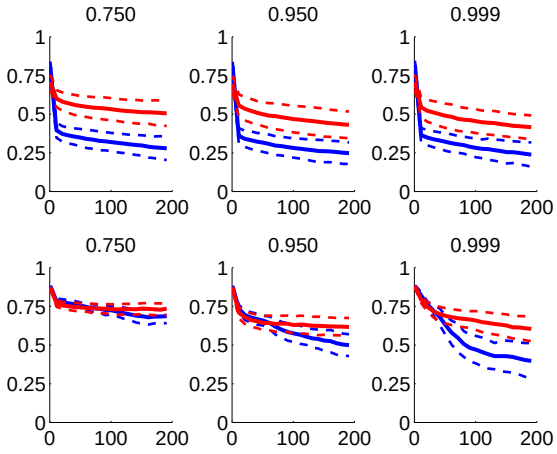

Figure 4. iHMM error on increasing positively correlated data. The blue curve shows the beam sampler while the red curve shows the Gibbs sampler performance. The dotted line show the one standard deviation error bars.

$\prod_k p(\phi_k|\boldsymbol{s},\boldsymbol{y},H)$. When the base distribution H is conjugate to the data distribution F each ϕ_k can be sampled efficiently. Otherwise we may resort to Metropolis-Hastings or other approaches. Note that in the non-conjugate case this is simpler than for Gibbs sampling. In the experimental section, we describe an application where the base distribution and likelihood are non-conjugate.

To conclude our discussion of the beam sampler, it is useful to point out that there is nothing special about sampling u_t from the uniform distribution on $[0, \pi_{s_{t-1},s_t}]$: by choosing a distribution over $[0, \pi_{s_t,s_{t-1}}]$ with higher mass near smaller values of u_t, we will allow more trajectories to have positive probability and hence considered by the forward filtering-backward sampling algorithm. Although this will typically improve mixing time, it also comes at additional computational cost. This brings us to the issue of the computational cost of the beam sampler: since for each timestep and each state assignment we need to sum over all represented previous states, the worst case complexity is $\mathcal{O}(TK^2)$. However, the sum in (4) is only over previous states for which the transition probability is larger than u_t; this means that in practice we might only need to sum over a few previous states. In our experiments below, we will give some empirical evidence for this "average case" behavior. Further, we have found that the drastically improved mixing of the beam sampler more than made up for the additional cost over Gibbs sampling. Finally, although we did not find any advantage doing so, it is certainly possible to interleave the beam sampler and the Gibbs sampler.

5. Experiments

We evaluate the beam sampler on two artificial and two real datasets to illustrate the following properties: (1) the beam sampler mixes in much fewer iterations than the Gibbs sampler; (2) the actual complexity per iteration of the beam sampler is only marginally more than the Gibbs sampler; (3) the beam sampler mixes well regardless of strong correlations in the data; (4) the beam sampler is more robust with respect to varying initialization and prior distribution; (5) the beam sampler handles non conjugate models naturally; (6) the iHMM is a viable alternative to the finite HMM. All datasets and a Matlab version of our software are available at *http://mlg.eng.cam.ac.uk/jurgen*.

5.1. Artificial Data

Our first experiment compares the performance of the iHMM on a sequence of length 800 generated by a 4 state HMM. The hidden state sequence was almost cyclic (1-2-3-4-1-2-3-...) with a 1% probability of self transition: i.o.w the true distribution of hidden states is strong negatively correlated. We use a multinomial output distribution with the following emission matrix

$$\begin{bmatrix} 0.0 & 0.5 & 0.5 \\ 0.6666 & 0.1666 & 0.1666 \\ 0.5 & 0.0 & 0.5 \\ 0.3333 & 0.3333 & 0.3333 \end{bmatrix}.$$

Next we run the Gibbs and beam sampler 20 times from a random initialization with every state randomly chosen between 1 and 20. We test the performance of both samplers using three different hyperparameter settings: (1) vague gamma hyperpriors for α and

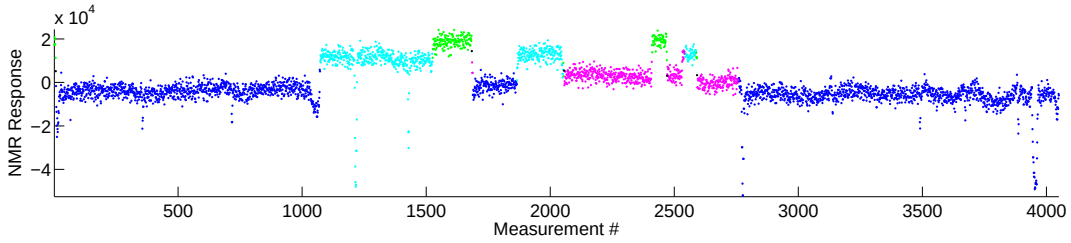

Figure 5. The 40'th sample of the beam sampler with every state represented by a different color on the well-log dataset.

γ (Gamma$(1,1)$ and Gamma$(2,1)$ respectively); (2) strong gamma hyperpriors for α and γ (Gamma$(6,15)$ and Gamma$(16,4)$ respectively); (3) fixed hyperparameters $\alpha = 0.4, \gamma = 3.8$. The latter were chosen using the values the beam and Gibbs samplers converged to. At every iteration, we greedily compute an assignment of sample states to true states to maximize overlap and use the resulting Hamming distance as our error measure. The top plot in figure 3 clearly shows that the beam sampler discovers the underlying structure much faster than the Gibbs sampler. Also, the beam sampler is insensitive to the prior while the performance of the Gibbs sampler becomes worse as we strengthen our prior beliefs. The bottom plot of figure 3 shows how many states are summed over in equation (4) averaged per timestep, per state. We find that after only about 20 iterations, the beam sampler on average considers a little more than one state. This implies that the actual complexity of the beam sampler is closer to $\mathcal{O}(TK)$ rather than the worst case complexity of $\mathcal{O}(TK^2)$. Although this behavior is dependent on the choice of distribution for the auxiliary variable u_t and the sparsity of the transition matrix, we have verified that this behavior is consistent also for larger iHMM's.

Our second experiment illustrates the performance of the beam sampler on data generated from HMM's with increasing positive correlation between the hidden states. We generated sequences of length 4000 from a 4 state HMM with self-transition probabilities increasing from 0.75 to 0.95 and finally 0.999. In one experiment (top plot of figure 4) we generated normal distributed observation from an informative output model with means $-2.0, 4.0, 1.0, -0.5$ and standard deviation 0.5, in another experiment (bottom plot of figure 4) we generated normal distributed observations from a less informative output model with means $-1.0, 0.5, -0.5, 0.0$ and standard deviation 0.5. We initialize the experiment as above and set the base distribution for the state means to be a 0 mean normal with 2.0 standard deviation. Then, we greedily compute the error compared to ground truth and average the results over 60 different random starting positions. The top row shows that with an informative prior, both the Gibbs and beam sampler can reduce the initial error by at least 50% independent of the correlation between hidden states. When the output model is less informative however and there is little correlation between the hidden states, the learning problem is hardest: the lower left plot shows that both the beam and Gibbs sampler discover structure only slowly. When the correlation increases, the learning problem should become easier. However, as the lower right plot shows, although the beam sampler mixes increasingly well, the Gibbs sampler suffers from slow random walk behavior.

5.2. Well Data

The next experiment illustrates the performance of the iHMM on a changepoint detection problem. The data consists of 4050 noisy measurements of nuclear-response of rock strata obtained via lowering a probe through a bore-hole. Figure 5 illustrates this datasets. The data has been previously analyzed in (Ruanaidh & Fitzgerald, 1996) by eliminating the forty greatest outliers and running a changepoint detection algorithm with a fixed number of changepoints. This approach works well as this one-dimensional dataset can be inspected visually to make a decision on whether to throw away datapoints and get a rough idea for the number of changepoints. However, we believe that with a nonparametric model, we can automatically adapt the number of changepoints. Moreover, by setting up a noise model with fat tails, we hope to automatically handle the outlier problem.

We model the mean of the nuclear-response for every segment. First we normalize the data to have zero mean; then we specify a zero mean normal distribution for the base distribution H. We choose the variance of this normal to be the empirical variance of the dataset. For the output model, we let F correspond to a Student-t distribution with $\nu = 1$, also known as the Cauchy distribution. We set the scale parameter for the Cauchy distribution to twice the empirical standard deviation for the dataset. Since the Cauchy likelihood is not conjugate with respect to the normal base distribution, we modified the Gibbs sampler based on algorithm 8 in (Neal, 2000). We use the aux-

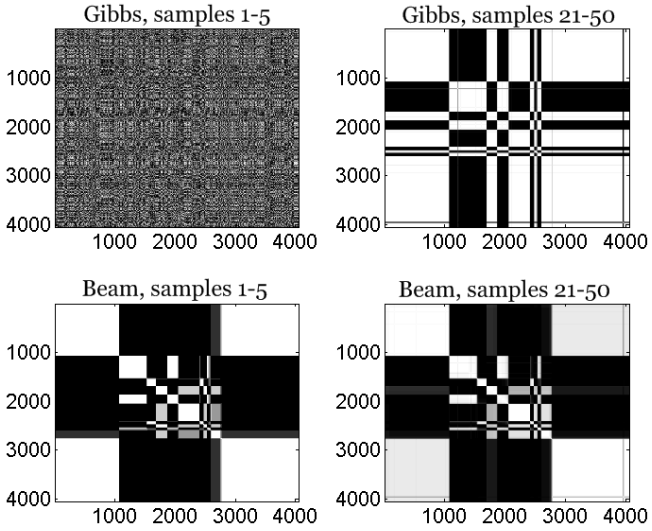

Figure 6. The left plots show how frequent two datapoints were in the same cluster averaged over the first 5 samples. The right plots show how frequently two datapoints were in the same cluster averaged over the last 30 samples.

iliary variable sampling scheme discussed in (Gelman et al., 2004) to resample the segment means.

Figure 5 shows the results of one sample from the beam sampler: the iHMM segments the dataset reasonably well and robustly handles the outliers. To compare the Gibbs and beam samplers, we compute 50 samples after a burnin of 5000 iterations with 1000 iterations in between each sample. For every pair of datapoints we compute the probability that they are in the same segment, averaged over the first five samples (left plots in figure 6) and the last thirty samples (right plots in figure 6). First, note that after the first 10000 iterations, the Gibbs sampler hasn't discovered any structure while the beam sampler has. This supports our claim that the beam sampler mixes faster than the Gibbs sampler. Moreover, we expect that the Gibbs sampler will have trouble to reassign the state assignment for whole segments because of slow random walk behavior. The beam sampler on the other hand resamples whole hidden state sequences and should be able to reassign whole segments more easily. The right plots of figure 6 confirm our expectation: a careful inspection of both plots shows that the Gibbs sampler is visually more black-white indicating that either two datapoints are always in the same cluster or never in the same cluster; the beam sampler, on the other hand, has gray areas which indicate that it averages over different assignments of the segments: e.g. the Gibbs plot (upper right) suggests that the leftmost segment and rightmost segment are *always* in the same state, while the beam sampler plot (bottom right) indicates that only part of the time, the left and rightmost segments are in the same state (90% of the time).

5.3. Alice in Wonderland

Another application domain for HMMs is the area of text prediction. One such task is that of predicting sequences of letters in text taken from *Alice's Adventures in Wonderland*. We compare the performance of a finite HMM trained using variational Bayes (as described in (MacKay, 1997)) with two iHMMs trained using beam sampling and Gibbs sampling. Both samplers had a burn-in of 1000 iterations and an additional 10000 iterations to collect 50 samples of hidden state sequences from the posterior (i.e. we sample every 200 iterations).

The training data for each HMM (whether finite or infinite) was taken to be a single sequence of 1000 characters from the first chapter of the book. There were 31 different observation symbols (26 letters ignoring case plus space and basic punctuation characters). The test data was taken to be the subsequent 4000 characters from the same chapter. For all finite HMMs we analyzed performance on models with the number of hidden states ranging from 1 to 50. For VB, we note that the true predictive distribution is intractable to compute. Therefore, we used the posterior parameter distributions to sample 50 candidate parameter settings, and used these to compute an approximate predictive log-likelihood. For the iHMMs, we sampled 50 hidden state sequences from the stationary distribution after convergence and used these samples to compute an approximate predictive log-likelihood. For the VB-HMM we set the prior pseudo-counts for the transition matrix to $4/K$ across all states and the prior pseudo-counts for the emission matrix to 0.3 across all symbols. Accordingly, we set the hyperprior for the iHMMs such that $a_\alpha = 4$ and $b_\alpha = 1$ and $H \sim \text{Dirichlet}\,(()\,0.3, \cdots 0.3)$. The results for VB and the iHMMs were averaged over 50 and 20 independent

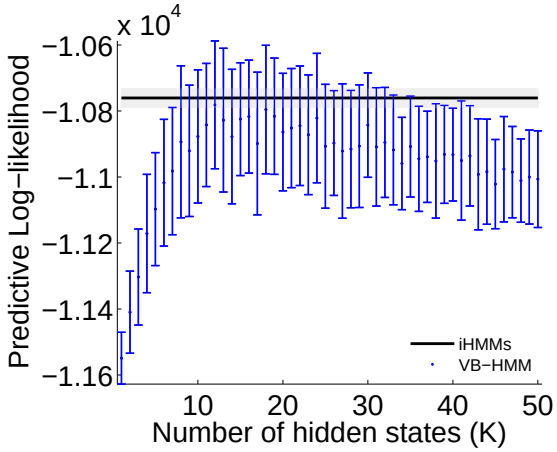

Figure 7. Comparing VB-HMM with the iHMM.

runs respectively. The plot includes error bars corresponding to 2 standard deviations.

Figure 7 illustrates the estimated predictive log-likelihoods for the finite VB-HMM and the two iHMMs trained using beam and Gibbs sampling. We find that the iHMMs have superior predictive power when compared to the VB-HMM, even when we select the best number of hidden states (around $K = 16$). Both the iHMMs converged to a posterior distribution over hidden state sequences with around 16 states, showing that nonparametric Bayesian techniques are an effective way to handle model selection. The final performance of the Gibbs and beam sampler were not found to be significantly different as we set the number of iterations high enough to ensure that both algorithms converge. Indeed, the aim of this experiment is not to compare the performance of individuals iHMM sampling schemes, rather, it is to further illustrate the relative effectiveness of using models of infinite capacity.

6. Conclusion

In this paper we introduced the beam sampler, a new inference algorithm for the iHMM that draws inspiration from slice sampling and dynamic programming to sample whole hidden state trajectories efficiently. We showed that the beam sampler is a more robust sampling algorithm than the Gibbs sampler. We believe that the beam sampler is the algorithm of choice for iHMM inference because it converges faster than the Gibbs sampler and is straightforward to implement. Moreover, it conveniently allows us to learn non-conjugate models. To encourage adoption of the iHMM as an alternative to HMM learning, we have made the software and datasets used in this paper available at *http://mlg.eng.cam.ac.uk/jurgen*.

The beam sampler idea is flexible enough to do inference for various extensions of the iHMM: our current work involves an adaptation of the beam sampler to an extension of the iHMM that handles inputs, effectively resulting in a nonparametric generalization of the input-output HMM (Bengio & Frasconi, 1995). We believe this is a promising model for nonparametric Bayesian learning of POMDPs. Another project currently underway is to use the beam sampler for efficiently learning finite, but very large hidden Markov models. Finally, we are exploring the possibilities of using the embedded HMM construction (Neal et al., 2004) as an alternative for the beam sampler for efficient inference in the iHMM.

Abstract

Previous work has shown that the difficulties in learning deep generative or discriminative models can be overcome by an initial unsupervised learning step that maps inputs to useful intermediate representations. We introduce and motivate a new training principle for unsupervised learning of a representation based on the idea of making the learned representations robust to partial corruption of the input pattern. This approach can be used to train autoencoders, and these denoising autoencoders can be stacked to initialize deep architectures. The algorithm can be motivated from a manifold learning and information theoretic perspective or from a generative model perspective. Comparative experiments clearly show the surprising advantage of corrupting the input of autoencoders on a pattern classification benchmark suite.

1. Introduction

Recent theoretical studies indicate that deep architectures (Bengio & Le Cun, 2007; Bengio, 2007) may be needed to *efficiently* model complex distributions and achieve better generalization performance on challenging recognition tasks. The belief that additional levels of functional composition will yield increased representational and modeling power is not new (McClelland et al., 1986; Hinton, 1989; Utgoff & Stracuzzi, 2002). However, in practice, learning in deep architectures has proven to be difficult. One needs only to ponder the difficult problem of inference in deep directed graphical models, due to "explaining away". Also looking back at the history of multi-layer neural networks, their difficult optimization (Bengio et al., 2007; Bengio, 2007) has long prevented reaping the expected benefits of going beyond one or two hidden layers. However this situation has recently changed with the successful approach of (Hinton et al., 2006; Hinton & Salakhutdinov, 2006; Bengio et al., 2007; Ranzato et al., 2007; Lee et al., 2008) for training Deep Belief Networks and stacked autoencoders.

One key ingredient to this success appears to be the use of an unsupervised training criterion to perform a layer-by-layer initialization: each layer is at first trained to produce a higher level (hidden) representation of the observed patterns, based on the representation it receives as input from the layer below, by optimizing a local unsupervised criterion. Each level produces a representation of the input pattern that is more abstract than the previous level's, because it is obtained by composing more operations. This initialization yields a starting point, from which a global fine-tuning of the model's parameters is then performed using another training criterion appropriate for the task at hand. This technique has been shown empirically to avoid getting stuck in the kind of poor solutions one typically reaches with random initializations. While unsupervised learning of a mapping that produces "good" intermediate representations of the input pattern seems to be key, little is understood regarding what constitutes "good" representations for initializing deep architectures, or what explicit criteria may guide learning such representations. We know of only a few algorithms that seem to work well for this purpose: Restricted Boltzmann Machines (RBMs) trained with contrastive divergence on one hand, and various types of autoencoders on the other.

The present research begins with the question of what

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

explicit criteria a good intermediate representation should satisfy. Obviously, it should at a minimum retain a certain amount of "information" about its input, while at the same time being constrained to a given form (e.g. a real-valued vector of a given size in the case of an autoencoder). A supplemental criterion that has been proposed for such models is sparsity of the representation (Ranzato et al., 2008; Lee et al., 2008). Here we hypothesize and investigate an additional specific criterion: **robustness to partial destruction of the input**, i.e., partially destroyed inputs should yield almost the same representation. It is motivated by the following informal reasoning: a good representation is expected to capture stable structures in the form of dependencies and regularities characteristic of the (unknown) distribution of its observed input. For high dimensional redundant input (such as images) at least, such structures are likely to depend on evidence gathered from a combination of many input dimensions. They should thus be recoverable from partial observation only. A hallmark of this is our human ability to recognize partially occluded or corrupted images. Further evidence is our ability to form a high level concept associated to multiple modalities (such as image and sound) and recall it even when some of the modalities are missing.

To validate our hypothesis and assess its usefulness as one of the guiding principles in learning deep architectures, we propose a modification to the autoencoder framework to explicitly integrate robustness to partially destroyed inputs. Section 2 describes the algorithm in details. Section 3 discusses links with other approaches in the literature. Section 4 is devoted to a closer inspection of the model from different theoretical standpoints. In section 5 we verify empirically if the algorithm leads to a difference in performance. Section 6 concludes the study.

2. Description of the Algorithm

2.1. Notation and Setup

Let X and Y be two random variables with joint probability density $p(X,Y)$, with marginal distributions $p(X)$ and $p(Y)$. Throughout the text, we will use the following notation: Expectation: $\mathbb{E}_{p(X)}[f(X)] = \int p(\mathbf{x})f(\mathbf{x})\mathrm{d}\mathbf{x}$. Entropy: $\mathbb{H}(X) = \mathbb{H}(p) = \mathbb{E}_{p(X)}[-\log p(X)]$. Conditional entropy: $\mathbb{H}(X|Y) = \mathbb{E}_{p(X,Y)}[-\log p(X|Y)]$. Kullback-Leibler divergence: $\mathbb{D}_{\mathsf{KL}}(p\|q) = \mathbb{E}_{p(X)}[\log \frac{p(X)}{q(X)}]$. Cross-entropy: $\mathbb{H}(p\|q) = \mathbb{E}_{p(X)}[-\log q(X)] = \mathbb{H}(p) + \mathbb{D}_{\mathsf{KL}}(p\|q)$. Mutual information: $\mathbf{I}(X;Y) = \mathbb{H}(X) - \mathbb{H}(X|Y)$. Sigmoid: $s(x) = \frac{1}{1+e^{-x}}$ and $s(\mathbf{x}) = (s(\mathbf{x}_1), \ldots, s(\mathbf{x}_d))^T$. Bernoulli distribution with mean μ: $\mathcal{B}_\mu(x)$. and by extension $\mathcal{B}_\mu(\mathbf{x}) = (\mathcal{B}_{\mu_1}(\mathbf{x}_1), \ldots, \mathcal{B}_{\mu_d}(\mathbf{x}_d))$.

The setup we consider is the typical supervised learning setup with a training set of n (input, target) pairs $D_n = \{(\mathbf{x}^{(1)}, t^{(1)}) \ldots, (\mathbf{x}^{(n)}, t^{(n)})\}$, that we suppose to be an i.i.d. sample from an unknown distribution $q(X,T)$ with corresponding marginals $q(X)$ and $q(T)$.

2.2. The Basic Autoencoder

We begin by recalling the traditional autoencoder model such as the one used in (Bengio et al., 2007) to build deep networks. An autoencoder takes an input vector $\mathbf{x} \in [0,1]^d$, and first maps it to a hidden representation $\mathbf{y} \in [0,1]^{d'}$ through a deterministic mapping $\mathbf{y} = f_\theta(\mathbf{x}) = s(\mathbf{W}\mathbf{x} + \mathbf{b})$, parameterized by $\theta = \{\mathbf{W}, \mathbf{b}\}$. $\mathbf{W}$ is a $d' \times d$ weight matrix and $\mathbf{b}$ is a bias vector. The resulting latent representation $\mathbf{y}$ is then mapped back to a "reconstructed" vector $\mathbf{z} \in [0,1]^d$ in input space $\mathbf{z} = g_{\theta'}(\mathbf{y}) = s(\mathbf{W}'\mathbf{y} + \mathbf{b}')$ with $\theta' = \{\mathbf{W}', \mathbf{b}'\}$. The weight matrix $\mathbf{W}'$ of the reverse mapping may optionally be constrained by $\mathbf{W}' = \mathbf{W}^T$, in which case the autoencoder is said to have *tied weights*. Each training $\mathbf{x}^{(i)}$ is thus mapped to a corresponding $\mathbf{y}^{(i)}$ and a reconstruction $\mathbf{z}^{(i)}$. The parameters of this model are optimized to minimize the *average reconstruction error*:

$$\begin{aligned}\theta^\star, \theta'^\star = &\quad \arg\min_{\theta,\theta'} \frac{1}{n}\sum_{i=1}^{n} L\left(\mathbf{x}^{(i)}, \mathbf{z}^{(i)}\right) \\ = &\quad \arg\min_{\theta,\theta'} \frac{1}{n}\sum_{i=1}^{n} L\left(\mathbf{x}^{(i)}, g_{\theta'}(f_\theta(\mathbf{x}^{(i)}))\right) \quad (1)\end{aligned}$$

where L is a loss function such as the traditional *squared error* $L(\mathbf{x},\mathbf{z}) = \|\mathbf{x} - \mathbf{z}\|^2$. An alternative loss, suggested by the interpretation of $\mathbf{x}$ and $\mathbf{z}$ as either bit vectors or vectors of bit probabilities (Bernoullis) is the *reconstruction cross-entropy*:

$$\begin{aligned}L_{\mathbf{H}}(\mathbf{x},\mathbf{z}) = &\quad \mathbb{H}(\mathcal{B}_{\mathbf{x}}\|\mathcal{B}_{\mathbf{z}}) \\ = &\quad -\sum_{k=1}^{d}[\mathbf{x}_k \log \mathbf{z}_k + (1-\mathbf{x}_k)\log(1-\mathbf{z}_k)] \quad (2)\end{aligned}$$

Note that if $\mathbf{x}$ is a binary vector, $L_{\mathbf{H}}(\mathbf{x},\mathbf{z})$ is a negative log-likelihood for the example $\mathbf{x}$, given the Bernoulli parameters $\mathbf{z}$. Equation 1 with $L = L_{\mathbf{H}}$ can be written

$$\theta^\star, \theta'^\star = \arg\min_{\theta,\theta'} \mathbb{E}_{q^0(X)}\left[L_{\mathbf{H}}\left(X, g_{\theta'}(f_\theta(X))\right)\right] \quad (3)$$

where $q^0(X)$ denotes the empirical distribution associated to our n training inputs. This optimization will typically be carried out by stochastic gradient descent.

2.3. The Denoising Autoencoder

To test our hypothesis and enforce robustness to partially destroyed inputs we modify the basic autoencoder we just described. We will now train it to reconstruct a clean "repaired" input from a *corrupted*, partially destroyed one. This is done by first corrupting the initial input $\mathbf{x}$ to get a partially destroyed version $\tilde{\mathbf{x}}$ by means of a stochastic mapping $\tilde{\mathbf{x}} \sim q_{\mathcal{D}}(\tilde{\mathbf{x}}|\mathbf{x})$. In our experiments, we considered the following corrupting process, parameterized by the desired proportion ν of "destruction": for each input $\mathbf{x}$, a fixed number νd of components are chosen at random, and their value is forced to 0, while the others are left untouched. All information about the chosen components is thus removed from that particuler input pattern, and the autoencoder will be trained to "fill-in" these artificially introduced "blanks". Note that alternative corrupting noises could be considered[1]. The corrupted input $\tilde{\mathbf{x}}$ is then mapped, as with the basic autoencoder, to a hidden representation $\mathbf{y} = f_\theta(\tilde{\mathbf{x}}) = s(\mathbf{W}\tilde{\mathbf{x}}+\mathbf{b})$ from which we reconstruct a $\mathbf{z} = g_{\theta'}(\mathbf{y}) = s(\mathbf{W}'\mathbf{y} + \mathbf{b}')$ (see figure 1 for a schematic representation of the process). As before the parameters are trained to minimize the average reconstruction error $L_{\mathsf{H}}(\mathbf{x}, \mathbf{z}) = \mathsf{H}(\mathcal{B}_{\mathbf{x}} \| \mathcal{B}_{\mathbf{z}})$ over a training set, i.e. to have $\mathbf{z}$ as close as possible to the uncorrupted input $\mathbf{x}$. But the key difference is that $\mathbf{z}$ is now a deterministic function of $\tilde{\mathbf{x}}$ rather than $\mathbf{x}$ and thus the result of a stochastic mapping of $\mathbf{x}$.

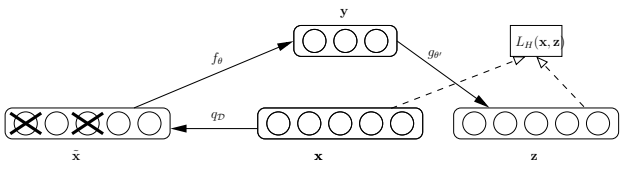

Figure 1. An example $\mathbf{x}$ is corrupted to $\tilde{\mathbf{x}}$. The autoencoder then maps it to $\mathbf{y}$ and attempts to reconstruct $\mathbf{x}$.

Let us define the joint distribution

$$q^0(X, \widetilde{X}, Y) = q^0(X) q_{\mathcal{D}}(\widetilde{X}|X) \delta_{f_\theta(\widetilde{X})}(Y) \qquad (4)$$

where $\delta_u(v)$ puts mass 0 when $u \neq v$. Thus Y is a deterministic function of $\widetilde{X}$. $q^0(X, \widetilde{X}, Y)$ is parameterized by θ. The objective function minimized by stochastic gradient descent becomes:

$$\arg\min_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X})} \left[L_{\mathsf{H}} \left(X, g_{\theta'}(f_\theta(\widetilde{X})) \right) \right]. \qquad (5)$$

So from the point of view of the stochastic gradient descent algorithm, in addition to picking an input sample from the training set, we will also produce a random corrupted version of it, and take a gradient step towards reconstructing the uncorrupted version from the corrupted version. Note that in this way, the autoencoder cannot learn the identity, unlike the basic autoencoder, thus removing the constraint that $d' < d$ or the need to regularize specifically to avoid such a trivial solution.

[1]The approach we describe and our analysis is not specific to a particular kind of corrupting noise.

2.4. Layer-wise Initialization and Fine Tuning

The basic autoencoder has been used as a building block to train deep networks (Bengio et al., 2007), with the representation of the k-th layer used as input for the $(k+1)$-th, and the $(k+1)$-th layer trained after the k-th has been trained. After a few layers have been trained, the parameters are used as initialization for a network optimized with respect to a supervised training criterion. This greedy layer-wise procedure has been shown to yield significantly better local minima than random initialization of deep networks , achieving better generalization on a number of tasks (Larochelle et al., 2007).

The procedure to train a deep network using the denoising autoencoder is similar. The only difference is how each layer is trained, i.e., to minimize the criterion in eq. 5 instead of eq. 3. Note that the corruption process $q_{\mathcal{D}}$ is only used during training, but not for propagating representations from the raw input to higher-level representations. Note also that when layer k is trained, it receives as input the uncorrupted output of the previous layers.

3. Relationship to Other Approaches

Our training procedure for the denoising autoencoder involves learning to recover a clean input from a corrupted version, a task known as *denoising*. The problem of image denoising, in particular, has been extensively studied in the image processing community and many recent developments rely on machine learning approaches (see e.g. Roth and Black (2005); Elad and Aharon (2006); Hammond and Simoncelli (2007)). A particular form of gated autoencoders has also been used for denoising in Memisevic (2007). Denoising using autoencoders was actually introduced much earlier (LeCun, 1987; Gallinari et al., 1987), as an alternative to Hopfield models (Hopfield, 1982). Our objective however is fundamentally different from that of developing a competitive image denoising algorithm. We investigate explicit robustness to corrupting noise as a novel criterion guiding the learning of suitable intermediate representations to initialize a deep network. Thus our corruption+denoising procedure is applied not only on the input, but also recursively to intermediate representations.

The approach also bears some resemblance to the well known technique of augmenting the training data with stochastically "transformed" patterns. E.g. augmenting a training set by transforming original bitmaps through small rotations, translations, and scalings is known to improve final classification performance. In contrast to this technique our approach does not use any prior knowledge of image topology, nor does it produce extra labeled examples for supervised training. We use corrupted patterns in a generic (i.e. *not* specific to images) *unsupervised* initialization step, while the supervised training phase uses the unmodified original data.

There is a well known link between "training with noise" and regularization: they are equivalent for small additive noise (Bishop, 1995). By contrast, our corruption process is a large, non-additive, destruction of information. We train autoencoders to "fill in the blanks", not merely be smooth functions (regularization). Also in our experience, regularized autoencoders (i.e. with weight decay) do not yield the quantitative jump in performance and the striking qualitative difference observed in the filters that we get with denoising autoencoders.

There are also similarities with the work of (Doi et al., 2006) on robust coding over noisy channels. In their framework, a linear encoder is to encode a clean input for optimal transmission over a noisy channel to a decoder that reconstructs the input. This work was later extended to robustness to noise in the input, in a proposal for a model of retinal coding (Doi & Lewicki, 2007). Though some of the inspiration behind our work comes from neural coding and computation, our goal is not to account for experimental data of neuronal activity as in (Doi & Lewicki, 2007). Also, the non-linearity of our denoising autoencoder is crucial for its use in initializing a deep neural network.

It may be objected that, if our goal is to handle *missing values* correctly, we could have more naturally defined a proper latent variable generative model, and infer the posterior over the latent (hidden) representation in the presence of missing inputs. But this usually requires a costly marginalization[2] which has to be carried out for each new example. By contrast, our approach tries to learn a fast and robust deterministic mapping f_θ from examples of *already corrupted* inputs. The burden is on learning such a constrained mapping during training, rather than on unconstrained inference at use time. We expect this may force the model to capture implicit invariances in the data, and result in interesting features. Also note that in section 4.2 we will see how our learning algorithm for the denoising autoencoder can be viewed as a form of variational inference in a particular generative model.

[2] as for RBMs, where it is exponential in the number of missing values

4. Analysis of Denoising Autoencoders

The above intuitive motivation for the denoising autoencoder was given with the perspective of discovering robust representations. In the following, which can be skipped without hurting the remainder of the paper, we propose alternative perspectives on the algorithm.

4.1. Manifold Learning Perspective

The process of mapping a corrupted example to an uncorrupted one can be visualized in Figure 2, with a low-dimensional manifold near which the data concentrate. We learn a stochastic operator $p(X|\widetilde{X})$ that maps an $\widetilde{X}$ to an X, $p(X|\widetilde{X}) = \mathcal{B}_{g_{\theta'}(f_\theta(\widetilde{X}))}(X)$. The corrupted examples will be much more likely to be outside and farther from the manifold than the uncorrupted ones. Hence the stochastic operator $p(X|\widetilde{X})$ learns a map that tends to go from lower probability points $\widetilde{X}$ to high probability points X, generally on or near the manifold. Note that when $\widetilde{X}$ is farther from the manifold, $p(X|\widetilde{X})$ should learn to make bigger steps, to reach the manifold. At the limit we see that the operator should map even far away points to a small volume near the manifold.

The denoising autoencoder can thus be seen as a way to define and learn a manifold. The intermediate representation $Y = f(X)$ can be interpreted as a coordinate system for points on the manifold (this is most clear if we force the dimension of Y to be smaller than the dimension of X). More generally, one can think of $Y = f(X)$ as a representation of X which is well suited to capture the main variations in the data, i.e., on the manifold. When additional criteria (such as sparsity) are introduced in the learning model, one can no longer directly view $Y = f(X)$ as an explicit low-dimensional coordinate system for points on the manifold, but it retains the property of capturing the main factors of variation in the data.

4.2. Top-down, Generative Model Perspective

In this section we recover the training criterion for our denoising autoencoder (eq. 5) from a generative model perspective. Specifically we show that training the denoising autoencoder as described in section 2.3 is equivalent to maximizing a variational bound on a particular generative model.

Consider the generative model $p(X, \widetilde{X}, Y) = p(Y)p(X|Y)p(\widetilde{X}|X)$ where $p(X|Y) = \mathcal{B}_{s(\mathbf{W}'Y+\mathbf{b}')}$ and

$p(\widetilde{X}|X) = q_{\mathcal{D}}(\widetilde{X}|X)$. $p(Y)$ is a uniform prior over $Y \in [0,1]^{d'}$. This defines a generative model with parameter set $\theta' = \{\mathbf{W}', \mathbf{b}'\}$. We will use the previously defined $q^0(X, \widetilde{X}, Y) = q^0(X) q_{\mathcal{D}}(\widetilde{X}|X) \delta_{f_\theta(\widetilde{X})}(Y)$ (equation 4) as an auxiliary model in the context of a variational approximation of the log-likelihood of $p(\widetilde{X})$. Note that we abuse notation to make it lighter, and use the same letters X, $\widetilde{X}$ and Y for different sets of random variables representing the same quantity under different distributions: p or q^0. Keep in mind that whereas we had the dependency structure $X \to \widetilde{X} \to Y$ for q or q^0, we have $Y \to X \to \widetilde{X}$ for p.

Since p contains a corruption operation at the last generative stage, we propose to fit $p(\widetilde{X})$ to corrupted training samples. Performing maximum likelihood fitting for samples drawn from $q^0(\widetilde{X})$ corresponds to minimizing the cross-entropy, or maximizing

$$\begin{aligned}\mathcal{H} &= \max_{\theta'}\{-\mathbb{H}(q^0(\widetilde{X}) \| p(\widetilde{X}))\} \\ &= \max_{\theta'}\{\mathbb{E}_{q^0(\widetilde{X})}[\log p(\widetilde{X})]\}. \end{aligned} \tag{6}$$

Let $q^\star(X, Y|\widetilde{X})$ be a conditional density, the quantity $\mathcal{L}(q^\star, \widetilde{X}) = \mathbb{E}_{q^\star(X,Y|\widetilde{X})}\left[\log \frac{p(X,\widetilde{X},Y)}{q^\star(X,Y|\widetilde{X})}\right]$ is a lower bound on $\log p(\widetilde{X})$ since the following can be shown to be true for any $q^\star$:

$$\log p(\widetilde{X}) = \mathcal{L}(q^\star, \widetilde{X}) + \mathbb{D}_{\mathsf{KL}}(q^\star(X, Y|\widetilde{X}) \| p(X, Y|\widetilde{X}))$$

Also it is easy to verify that the bound is tight when $q^\star(X, Y|\widetilde{X}) = p(X, Y|\widetilde{X})$, where the $\mathbb{D}_{\mathsf{KL}}$ becomes 0. We can thus write $\log p(\widetilde{X}) = \max_{q^\star} \mathcal{L}(q^\star, \widetilde{X})$, and consequently rewrite equation 6 as

$$\begin{aligned}\mathcal{H} &= \max_{\theta'}\{\mathbb{E}_{q^0(\widetilde{X})}[\max_{q^\star} \mathcal{L}(q^\star, \widetilde{X})]\} \\ &= \max_{\theta', q^\star}\{\mathbb{E}_{q^0(\widetilde{X})}[\mathcal{L}(q^\star, \widetilde{X})]\} \end{aligned} \tag{7}$$

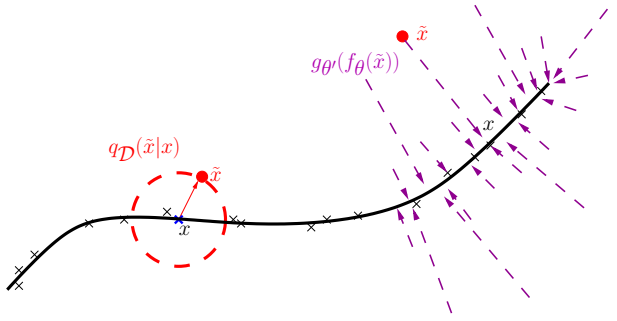

Figure 2. **Manifold learning perspective.** Suppose training data (×) concentrate near a low-dimensional manifold. Corrupted examples (•) obtained by applying corruption process $q_{\mathcal{D}}(\widetilde{X}|X)$ will lie farther from the manifold. The model learns with $p(X|\widetilde{X})$ to "project them back" onto the manifold. Intermediate representation Y can be interpreted as a coordinate system for points on the manifold.

where we moved the maximization outside of the expectation because an unconstrained $q^\star(X, Y|\widetilde{X})$ can in principle perfectly model the conditional distribution needed to maximize $\mathcal{L}(q^\star, \widetilde{X})$ for any $\widetilde{X}$. Now if we replace the maximization over an unconstrained $q^\star$ by the maximization over the parameters θ of our q^0 (appearing in f_θ that maps an $\mathbf{x}$ to a $\mathbf{y}$), we get a lower bound on $\mathcal{H}$: $\mathcal{H} \geq \max_{\theta',\theta}\{\mathbb{E}_{q^0(\widetilde{X})}[\mathcal{L}(q^0, \widetilde{X})]\}$ Maximizing this lower bound, we find

$$\begin{aligned}&\arg\max_{\theta,\theta'}\{\mathbb{E}_{q^0(\widetilde{X})}[\mathcal{L}(q^0, \widetilde{X})]\} \\ &= \arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X},Y)}\left[\log \frac{p(X,\widetilde{X},Y)}{q^0(X,Y|\widetilde{X})}\right] \\ &= \arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X},Y)}\Big[\log p(X,\widetilde{X},Y)\Big] \\ &\qquad + \mathbb{E}_{q^0(\widetilde{X})}\left[\mathbb{H}[q^0(X,Y|\widetilde{X})]\right] \\ &= \arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X},Y)}\left[\log p(X,\widetilde{X},Y)\right]. \end{aligned}$$

Note that θ only occurs in $Y = f_\theta(\widetilde{X})$, and θ' only occurs in $p(X|Y)$. The last line is therefore obtained because $q^0(X|\widetilde{X}) \propto q_{\mathcal{D}}(\widetilde{X}|X) q^0(X)$ (none of which depends on (θ, θ')), and $q^0(Y|\widetilde{X})$ is deterministic, i.e., its entropy is constant, irrespective of (θ, θ'). Hence the entropy of $q^0(X, Y|\widetilde{X}) = q^0(Y|\widetilde{X}) q^0(X|\widetilde{X})$, does not vary with (θ, θ'). Finally, following from above, we obtain our training criterion (eq. 5):

$$\begin{aligned}&\arg\max_{\theta,\theta'} \mathbb{E}_{q^0(\widetilde{X})}[\mathcal{L}(q^0, \widetilde{X})] \\ &= \arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X},Y)}[\log[p(Y)p(X|Y)p(\widetilde{X}|X)]] \\ &= \arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X},Y)}[\log p(X|Y)] \\ &= \arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X})}[\log p(X|Y = f_\theta(\widetilde{X}))] \\ &= \arg\min_{\theta,\theta'} \mathbb{E}_{q^0(X,\widetilde{X})}\left[L_{\mathbf{H}}\left(X, g_{\theta'}(f_\theta(\widetilde{X}))\right)\right] \end{aligned}$$

where the third line is obtained because (θ, θ') have no influence on $\mathbb{E}_{q^0(X,\widetilde{X},Y)}[\log p(Y)]$ because we chose $p(Y)$ uniform, i.e. constant, nor on $\mathbb{E}_{q^0(X,\widetilde{X})}[\log p(\widetilde{X}|X)]$, and the last line is obtained by inspection of the definition of $L_{\mathbf{H}}$ in eq. 2, when $p(X|Y = f_\theta(\widetilde{X}))$ is a $\mathcal{B}_{g_{\theta'}(f_\theta(\widetilde{X}))}$.

4.3. Other Theoretical Perspectives

Information Theoretic Perspective: Consider $X \sim q(X)$, q unknown, $Y = f_\theta(\widetilde{X})$. It can easily be shown (Vincent et al., 2008) that minimizing the expected reconstruction error amounts to *maximizing*

a lower bound on mutual information $\mathbf{I}(X;Y)$. Denoising autoencoders can thus be justified by the objective that Y captures as much information as possible about X *even as* Y *is a function of corrupted input.*

Stochastic Operator Perspective: Extending the manifold perspective, the denoising autoencoder can also be seen as corresponding to a semi-parametric model from which we can sample (Vincent et al., 2008):

$$p(X) = \frac{1}{n}\sum_{i=1}^{n}\sum_{\tilde{\mathbf{x}}} p(X|\widetilde{X}=\tilde{\mathbf{x}})q_{\mathcal{D}}(\tilde{\mathbf{x}}|\mathbf{x}_i),$$

where $\mathbf{x}_i$ is one of the n training examples.

5. Experiments

We performed experiments with the proposed algorithm on the same benchmark of classification problems used in (Larochelle et al., 2007)[3]. It contains different variations of the MNIST digit classification problem (input dimensionality $d = 28 \times 28 = 784$), with added factors of variation such as rotation (*rot*), addition of a background composed of random pixels (*bg-rand*) or made from patches extracted from a set of images (*bg-img*), or combinations of these factors (*rot-bg-img*). These variations render the problems particularly challenging for current generic learning algorithms. Each problem is divided into a training, validation, and test set (10000, 2000, 50000 examples respectively). A subset of the original MNIST problem is also included with the same example set sizes (problem *basic*). The benchmark also contains additional binary classification problems: discriminating between convex and non-convex shapes (*convex*), and between wide and long rectangles (*rect*, *rect-img*).

Neural networks with 3 hidden layers initialized by stacking *denoising autoencoders* (SdA-3), and fine tuned on the classification tasks, were evaluated on all the problems in this benchmark. Model selection was conducted following a similar procedure as Larochelle et al. (2007). Several values of hyper parameters (destruction fraction ν, layer sizes, number of unsupervised training epochs) were tried, combined with early stopping in the fine tuning phase. For each task, the best model was selected based on its classification performance on the validation set.

Table 1 reports the resulting classification error on the test set for the new model (SdA-3), together with the performance reported in Larochelle et al. (2007)[4] for SVMs with Gaussian and polynomial kernels, 1 and 3 hidden layers deep belief network (DBN-1 and DBN-3) and a 3 hidden layer deep network initialized by stacking basic autoencoders (SAA-3). Note that SAA-3 is equivalent to a SdA-3 with $\nu = 0\%$ destruction. As can be seen in the table, the corruption+denoising training works remarkably well as an initialization step, and in most cases yields significantly better classification performance than basic autoencoder stacking with no noise. On all but one task the SdA-3 algorithm performs on par or better than the best other algorithms, including deep belief nets. Due to space constraints, we do not report all selected hyper-parameters in the table (only showing ν). But it is worth mentioning that, for the majority of tasks, the model selection procedure chose best performing models with an *overcomplete first hidden layer representation* (typically of size 2000 for the 784-dimensional MNIST-derived tasks). This is very different from the traditional "bottleneck" autoencoders, and made possible by our denoising training procedure. All this suggests that the proposed procedure was indeed able to produce more useful feature detectors.

Next, we wanted to understand qualitatively the effect of the corruption+denoising training. To this end we display the filters obtained after initial training of the first denoising autoencoder on MNIST digits. Figure 3 shows a few of these filters as little image patches, for different noise levels. Each patch corresponds to a row of the learnt weight matrix $\mathbf{W}$, i.e. the incoming weights of one of the hidden layer neurons. The beneficial effect of the denoising training can clearly be seen. Without the denoising procedure, many filters appear to have learnt no interesting feature. They look like the filters obtained after random initialization. But when increasing the level of destructive corruption, an increasing number of filters resemble sensible feature detectors. As we move to higher noise levels, we observe a phenomenon that we expected: filters become less local, they appear sensitive to larger structures spread out across more input dimensions.

6. Conclusion and Future Work

We have introduced a very simple training principle for autoencoders, based on the objective of undoing a corruption process. This is motivated by the goal of learning representations of the input that are robust to small irrelevant changes in input. We also motivated it from a manifold learning perspective and gave an interpretation from a generative model perspective.

This principle can be used to train and stack autoencoders to initialize a deep neural network. A series

[3] All the datasets for these problems are available at http://www.iro.umontreal.ca/∼lisa/icml2007.

[4] Except that *rot* and *rot-bg-img*, as reported on the website from which they are available, have been regenerated since Larochelle et al. (2007), to fix a problem in the initial data generation process. We used the updated data and corresponding benchmark results given on this website.

Table 1. **Comparison of stacked denoising autoencoders (SdA-3) with other models.**
Test error rate on all considered classification problems is reported together with a 95% confidence interval. Best performer is in bold, as well as those for which confidence intervals overlap. SdA-3 appears to achieve performance superior or equivalent to the best other model on all problems except *bg-rand*. For SdA-3, we also indicate the fraction ν of destroyed input components, as chosen by proper model selection. Note that SAA-3 is equivalent to SdA-3 with $\nu = 0\%$.

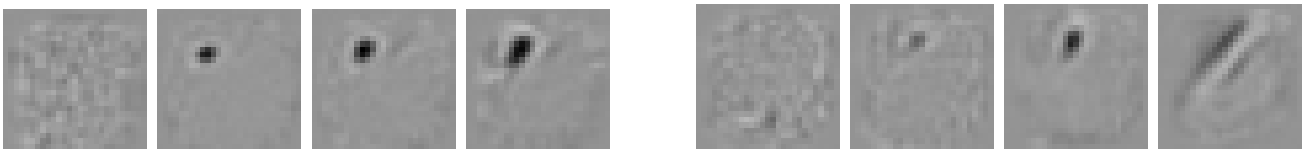
(a) No destroyed inputs (b) 25% destruction (c) 50% destruction



(d) Neuron A (0%, 10%, 20%, 50% destruction) (e) Neuron B (0%, 10%, 20%, 50% destruction)

Figure 3. **Filters obtained after training the first denoising autoencoder.**
(a-c) show some of the filters obtained after training a denoising autoencoder on MNIST samples, with increasing destruction levels ν. The filters at the same position in the three images are related only by the fact that the autoencoders were started from the same random initialization point.
(d) and **(e)** zoom in on the filters obtained for two of the neurons, again for increasing destruction levels.
As can be seen, with no noise, many filters remain similarly uninteresting (undistinctive almost uniform grey patches). As we increase the noise level, denoising training forces the filters to differentiate more, and capture more distinctive features. Higher noise levels tend to induce less local filters, as expected. One can distinguish different kinds of filters, from local blob detectors, to stroke detectors, and some full character detectors at the higher noise levels.

of image classification experiments were performed to evaluate this new training principle. The empirical results support the following conclusions: unsupervised initialization of layers with an explicit denoising criterion helps to capture interesting structure in the input distribution. This in turn leads to intermediate representations much better suited for subsequent learning tasks such as supervised classification. It is possible that the rather good experimental performance of Deep Belief Networks (whose layers are initialized as RBMs) is partly due to RBMs encapsulating a similar form of robustness to corruption in the representations they learn, possibly because of their stochastic nature which introduces noise in the representation during training. Future work inspired by this observation should investigate other types of corruption process, not only of the input but of the representation itself as well.

Acknowledgments

We thank the anonymous reviewers for their useful comments that helped improved the paper. We are also very grateful for financial support of this work by NSERC, MITACS and CIFAR.

Prediction with Expert Advice for the Brier Game

Vladimir Vovk VOVK@CS.RHUL.AC.UK

Computer Learning Research Centre, Department of Computer Science, Royal Holloway, University of London, Egham, Surrey TW20 0EX, UK

Abstract

We show that the Brier game of prediction is mixable and find the optimal learning rate and substitution function for it. The resulting prediction algorithm is applied to predict results of football and tennis matches. The theoretical performance guarantee turns out to be rather tight on these data sets, especially in the case of the more extensive tennis data.

1. Introduction

The paradigm of prediction with expert advice was introduced in the late 1980s (see, e.g., Littlestone & Warmuth, 1994, Cesa-Bianchi et al., 1997) and has been applied to various loss functions; see Cesa-Bianchi and Lugosi (2006) for a recent book-length review. An especially important class of loss functions is that of "mixable" ones, for which the learner's loss can be made as small as the best expert's loss plus a constant (depending on the number of experts). It is known (Haussler et al., 1998; Vovk, 1998) that the optimal additive constant is attained by the "strong aggregating algorithm" proposed in Vovk (1990) (we use the adjective "strong" to distinguish it from the "weak aggregating algorithm" of Kalnishkan & Vyugin, 2005).

There are several important loss functions that have been shown to be mixable and for which the optimal additive constant has been found. The prime examples in the case of binary observations are the log loss function and the square loss function. The log loss function, whose mixability is obvious, has been explored extensively, along with its important generalizations, the Kullback–Leibler divergence and Cover's loss function.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

In this paper we concentrate on the square loss function. In the binary case, its mixability was demonstrated in Vovk (1990). There are two natural directions in which this result could be generalized:

Regression: observations are real numbers (square-loss regression is a standard problem in statistics).

Classification: observations take values in a finite set (this leads to the "Brier game", to be defined below, a standard way of measuring the quality of predictions in meteorology and other applied fields: see, e.g., Dawid, 1986).

The mixability of the square loss function in the case of observations belonging to a bounded interval of real numbers was demonstrated in Haussler et al. (1998); Haussler et al.'s algorithm was simplified in Vovk (2001). Surprisingly, the case of square-loss non-binary classification has never been analysed in the framework of prediction with expert advice. The purpose of this paper is to fill this gap. The full version (Vovk & Zhdanov, 2008) of this paper is available on arXiv.

2. Prediction Algorithm and Loss Bound

A game of prediction consists of three components: the observation space Ω, the decision space Γ, and the loss function $\lambda : \Omega \times \Gamma \to \mathbb{R}$. In this paper we are interested in the following *Brier game* (Brier, 1950): Ω is a finite and non-empty set, $\Gamma := \mathcal{P}(\Omega)$ is the set of all probability measures on Ω, and

$$\lambda(\omega, \gamma) = \sum_{o \in \Omega} \left(\gamma\{o\} - \delta_\omega\{o\}\right)^2,$$

where $\delta_\omega \in \mathcal{P}(\Omega)$ is the probability measure concentrated at ω: $\delta_\omega\{\omega\} = 1$ and $\delta_\omega\{o\} = 0$ for $o \neq \omega$. (For example, if $\Omega = \{1, 2, 3\}$, $\omega = 1$, $\gamma\{1\} = 1/2$, $\gamma\{2\} = 1/4$, and $\gamma\{3\} = 1/4$, $\lambda(\omega, \gamma) = (1/2 - 1)^2 + (1/4 - 0)^2 + (1/4 - 0)^2 = 3/8$.)

The game of prediction is being played repeatedly by a learner having access to decisions made by a pool of experts, which leads to the following prediction protocol:

Protocol 1 Prediction with expert advice

$L_0 := 0$.
$L_0^k := 0$, $k = 1, \dots, K$.
for $N = 1, 2, \dots$ **do**
  Expert k announces $\gamma_N^k \in \Gamma$, $k = 1, \dots, K$.
  Learner announces $\gamma_N \in \Gamma$.
  Reality announces $\omega_N \in \Omega$.
  $L_N := L_{N-1} + \lambda(\omega_N, \gamma_N)$.
  $L_N^k := L_{N-1}^k + \lambda(\omega_N, \gamma_N^k)$, $k = 1, \dots, K$.
end for

At each step of Protocol 1 Learner is given K experts' advice and is required to come up with his own decision; L_N is his cumulative loss over the first N steps, and L_N^k is the kth expert's cumulative loss over the first N steps. In the case of the Brier game, the decisions are probability forecasts for the next observation.

An optimal (in the sense of Theorem 1 below) strategy for Learner in prediction with expert advice for the Brier game is given by the strong aggregating algorithm. For each expert k, the algorithm maintains its weight w^k, constantly slashing the weights of less successful experts.

Algorithm 1 Strong aggregating algorithm for the Brier game

$w_0^k := 1$, $k = 1, \dots, K$.
for $N = 1, 2, \dots$ **do**
  Read the Experts' predictions γ_N^k, $k = 1, \dots, K$.
  Set $G_N(\omega) := -\ln \sum_{k=1}^K w_{N-1}^k e^{-\lambda(\omega, \gamma_N^k)}$, $\omega \in \Omega$.
  Solve $\sum_{\omega \in \Omega} (s - G_N(\omega))^+ = 2$ in $s \in \mathbb{R}$.
  Set $\gamma_N\{\omega\} := (s - G_N(\omega))^+/2$, $\omega \in \Omega$.
  Output prediction $\gamma_N \in \mathcal{P}(\Omega)$.
  Read observation ω_N.
  $w_N^k := w_{N-1}^k e^{-\lambda(\omega_N, \gamma_N^k)}$.
end for

The algorithm will be derived in Section 5. The following result (to be proved in Section 4) gives a performance guarantee for it that cannot be improved by any other prediction algorithm.

Theorem 1. *Using Algorithm 1 as Learner's strategy in Protocol 1 for the Brier game guarantees that*

$$L_N \le \min_{k=1,\dots,K} L_N^k + \ln K \tag{1}$$

for all $N = 1, 2, \dots$. If $A < \ln K$, Learner does not have a strategy guaranteeing

$$L_N \le \min_{k=1,\dots,K} L_N^k + A \tag{2}$$

for all $N = 1, 2, \dots$.

3. Experimental Results

In our first empirical study of Algorithm 1 we use historical data about 6416 matches in various English football league competitions, namely: the Premier League (the pinnacle of the English football system), the Football League Championship, Football League One, Football League Two, the Football Conference. Our data, provided by Football-Data, cover two full seasons, 2005/2006 and 2006/2007, and part of the 2007/2008 season (which ends in May shortly after the paper submission deadline). The matches are sorted first by date and then by league. In the terminology of our prediction protocol, the outcome of each match is the observation, taking one of three possible values, "home win", "draw", or "away win"; we will encode the possible values as 1, 2, and 3.

For each match we have forecasts made by a range of bookmakers. We chose eight bookmakers for which we have enough data over a long period of time, namely Bet365, Bet&Win, Gamebookers, Interwetten, Ladbrokes, Sportingbet, Stan James, and VC Bet. (And the seasons mentioned above were chosen because the forecasts of these bookmakers are available for them.)

A probability forecast for the next observation is essentially a vector (p_1, p_2, p_3) consisting of positive numbers summing to 1. The bookmakers do not announce these numbers directly; instead, they quote three betting odds, a_1, a_2, and a_3. Each number a_i is the amount which the bookmaker undertakes to pay out to a client betting on outcome i per unit stake in the event that i happens (the stake itself is never returned to the bettor, which makes all betting odds greater than 1; i.e., the odds are announced according to the "continental" rather than "traditional" system). The inverse value $1/a_i$, $i \in \{1, 2, 3\}$, can be interpreted as the bookmaker's quoted probability for the observation i. The bookmaker's quoted probabilities are usually slightly (because of the competition with other bookmakers) in his favour: the sum $1/a_1 + 1/a_2 + 1/a_3$ exceeds 1 by the amount called the *overround* (at most 0.15 in the vast majority of cases). We used

$$p_i := \frac{1/a_i}{1/a_1 + 1/a_2 + 1/a_3}, \quad i = 1, 2, 3, \tag{3}$$

as the bookmaker's forecasts; it is clear that $p_1 + p_2 + p_3 = 1$.

The results of applying Algorithm 1 to the football data, with 8 experts and 3 possible observations, are shown in Figure 1. Let L_N^k be the cumulative loss of Expert k, $k = 1, \dots, 8$, over the first N matches and L_N be the corresponding number for Algorithm 1 (i.e., we essentially continue to use the notation of Theorem 1). The dashed line corresponding to Expert k shows the excess loss $N \mapsto L_N^k - L_N$ of Expert k over Algorithm 1. The excess loss can be negative, but from Theorem 1 we know that it cannot be less than $-\ln 8$; this lower bound is also shown in Figure 1. Finally, the thick line (the positive part of the x axis) is drawn for comparison: this is the excess loss of Algorithm 1 over itself. We can see that at each moment in time the algorithm's cumulative loss is fairly close to the cumulative loss of the best expert (at that time; the best expert keeps changing over the time).

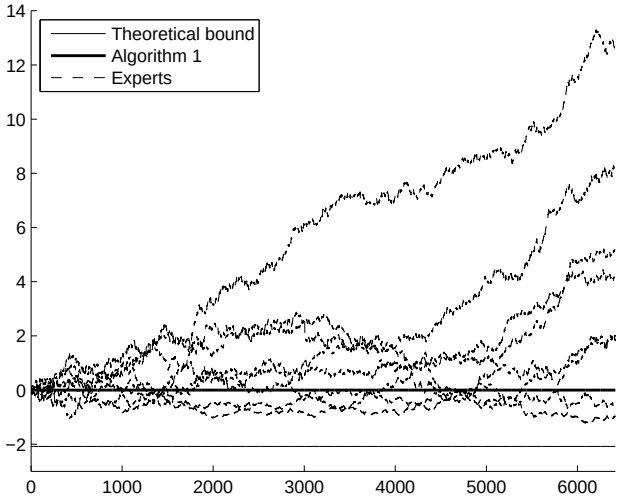

Figure 1. The difference between the cumulative loss of each of the 8 bookmakers (experts) and of Algorithm 1 on the football data. The theoretical lower bound $-\ln 8$ from Theorem 1 is also shown.

Figure 2 shows the results of another empirical study, involving data about a large number of tennis tournaments in 2004, 2005, 2006, and 2007, with the total number of matches 10,087. The tournaments include, e.g., Australian Open, French Open, Wimbledon, and US Open; the data is provided by Tennis-Data. The matches are sorted by date, then by tournament. The data contain information about the winner of each match and the betting odds of 4 bookmakers for his/her win and for the opponent's win. Therefore, now there are two possible observations (player 1's win and player 2's win). There are four bookmakers: Bet365, Centrebet, Expekt, and Pinnacle Sports. The results in Figure 2 are presented in the same way as in Figure 1. Typical values of the overround are below 0.1.

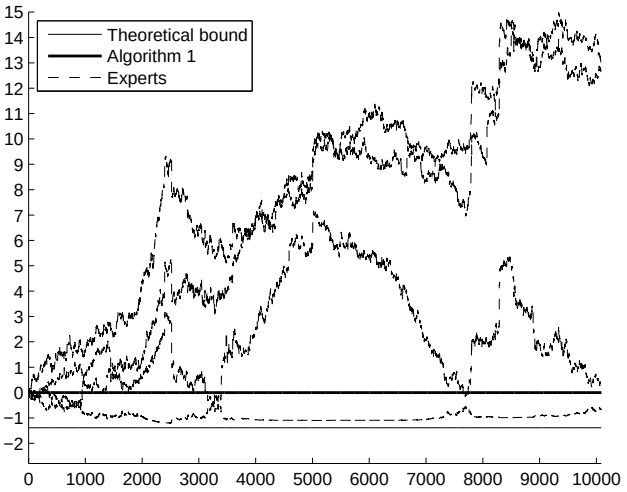

Figure 2. The difference between the cumulative loss of each of the 4 bookmakers and of Algorithm 1 on the tennis data. Now the theoretical bound is $-\ln 4$.

In both Figure 1 and Figure 2 the cumulative loss of Algorithm 1 is close to the cumulative loss of the best expert, despite the fact that some of the experts perform poorly. The theoretical bound is not hopelessly loose for the football data and is rather tight for the tennis data. The pictures look exactly the same when Algorithm 1 is applied in the more realistic manner where the weights w^k are not updated over the matches that are played simultaneously.

Our second empirical study (Figure 2) is about binary prediction, and so the algorithm of Vovk (1990) could have also been used (and would have given similar results). We included it since we are not aware of any empirical studies even for the binary case.

Other popular algorithms for prediction with expert advice that could be used instead of Algorithm 1 in our empirical studies are Kivinen and Warmuth's (1999) Weighted Average Algorithm (WAA) and Freund and Schapire's (1997) Hedge algorithm (HA). The performance guarantees for these two algorithms are much weaker than the optimal (1), especially in the case of the HA (even if the loss bound given in Freund & Schapire, 1997, is replaced by the stronger bound given in Vovk, 1998, Example 7). The weak performance guarantees show in the empirical performance of the algorithms. For the football data the maximal difference between the cumulative loss of both the WAA and the HA and the cumulative loss of the best

expert is about twice as large as that for Algorithm 1 (and so is approximately equal to the optimal bound $\ln K$ given by (1)). For the tennis data the maximal difference for the WAA is about three times as large as for Algorithm 1, and for the HA it is about twice as large; therefore, both algorithms violate the optimal bound $\ln K$. For further details, see Vovk and Zhdanov (2008).

The data used for producing Figures 1 and 2 can be downloaded from `http://vovk.net/ICML2008`.

4. Proof of Theorem 1

This proof will use some basic notions of elementary differential geometry, especially those connected with the Gauss–Kronecker curvature of surfaces. (The use of curvature in this kind of results is standard: see, e.g., Vovk, 1990, and Haussler et al., 1998.) All definitions that we will need can be found in, e.g., Thorpe, 1979.

A vector $f \in \mathbb{R}^\Omega$ (understood to be a function $f : \Omega \to \mathbb{R}$) is a *superprediction* if there is $\gamma \in \Gamma$ such that, for all $\omega \in \Omega$, $\lambda(\omega, \gamma) \le f(\omega)$; the set Σ of all superpredictions is the *superprediction set*. For each *learning rate* $\eta > 0$, let $\Phi_\eta : \mathbb{R}^\Omega \to (0,\infty)^\Omega$ be the homeomorphism defined by

$$\Phi_\eta(f) : \omega \in \Omega \mapsto e^{-\eta f(\omega)}, \quad f \in \mathbb{R}^\Omega.$$

The image $\Phi_\eta(\Sigma)$ of the superprediction set will be called the *η-exponential superprediction set*. It is known that

$$L_N \le \min_{k=1,\dots,K} L_N^k + \frac{\ln K}{\eta}$$

can be guaranteed if and only if the η-exponential superprediction set is convex (part "if" for all K and part "only if" for $K \to \infty$ are proved in Vovk, 1998; part "only if" for all K is proved by Chris Watkins, and the details can be found in, e.g., Vovk, 2007, Appendix). Comparing this with (1) and (2) we can see that we are required to prove that

- $\Phi_\eta(\Sigma)$ is convex when $\eta \le 1$;
- $\Phi_\eta(\Sigma)$ is not convex when $\eta > 1$.

Define the *η-exponential superprediction surface* to be the part of the boundary of the η-exponential superprediction set $\Phi_\eta(\Sigma)$ lying inside $(0,\infty)^\Omega$. The idea of the proof is to check that, for all $\eta < 1$, the Gauss–Kronecker curvature of this surface is nowhere vanishing. Even when this is done, however, there is still uncertainty as to in which direction the surface is bulging (towards the origin or away from it). The standard argument (as in Thorpe, 1979, Chapter 12, Theorem 6) based on the continuity of the smallest principal curvature shows that the η-exponential superprediction set is bulging away from the origin for small enough η: indeed, since it is true at some point, it is true everywhere on the surface. By the continuity in η this is also true for all $\eta < 1$. Now, since the η-exponential superprediction set is convex for all $\eta < 1$, it is also convex for $\eta = 1$.

Let us now check that the Gauss–Kronecker curvature of the η-exponential superprediction surface is always positive when $\eta < 1$ and is sometimes negative when $\eta > 1$ (the rest of the proof, an elaboration of the above argument, will be easy). Set $n := |\Omega|$; without loss of generality we assume $\Omega = \{1, \dots, n\}$.

A convenient parametric representation of the η-exponential superprediction surface is

$$\begin{pmatrix} x^1 \\ x^2 \\ \vdots \\ x^{n-1} \\ x^n \end{pmatrix} = \begin{pmatrix} e^{-\eta((u^1-1)^2+(u^2)^2+\dots+(u^n)^2)} \\ e^{-\eta((u^1)^2+(u^2-1)^2+\dots+(u^n)^2)} \\ \vdots \\ e^{-\eta((u^1)^2+\dots+(u^{n-1}-1)^2+(u^n)^2)} \\ e^{-\eta((u^1)^2+\dots+(u^{n-1})^2+(u^n-1)^2)} \end{pmatrix}, \quad (4)$$

where $u^1, \dots, u^{n-1}$ are the coordinates on the surface, $u^1, \dots, u^{n-1} \in (0,1)$ subject to $u^1 + \dots u^{n-1} < 1$, and u^n is a shorthand for $1 - u^1 - \dots - u^{n-1}$. The derivative of (4) in u^1 is

$$\frac{\partial}{\partial u^1} \begin{pmatrix} x^1 \\ x^2 \\ \vdots \\ x^{n-1} \\ x^n \end{pmatrix} = 2\eta \times$$

$$\begin{pmatrix} (u^n - u^1 + 1)e^{-\eta((u^1-1)^2+(u^2)^2+\dots+(u^{n-1})^2+(u^n)^2)} \\ (u^n - u^1)e^{-\eta((u^1)^2+(u^2-1)^2+\dots+(u^{n-1})^2+(u^n)^2)} \\ \vdots \\ (u^n - u^1)e^{-\eta((u^1)^2+(u^2)^2+\dots+(u^{n-1}-1)^2+(u^n)^2)} \\ (u^n - u^1 - 1)e^{-\eta((u^1)^2+(u^2)^2+\dots+(u^{n-1})^2+(u^n-1)^2)} \end{pmatrix}$$

$$\propto \begin{pmatrix} (u^n - u^1 + 1)e^{2\eta u^1} \\ (u^n - u^1)e^{2\eta u^2} \\ \vdots \\ (u^n - u^1)e^{2\eta u^{n-1}} \\ (u^n - u^1 - 1)e^{2\eta u^n} \end{pmatrix},$$

the derivative in u^2 is

$$\frac{\partial}{\partial u^2}\begin{pmatrix} x^1 \\ x^2 \\ \vdots \\ x^{n-1} \\ x^n \end{pmatrix} \propto \begin{pmatrix} (u^n-u^2)e^{2\eta u^1} \\ (u^n-u^2+1)e^{2\eta u^2} \\ \vdots \\ (u^n-u^2)e^{2\eta u^{n-1}} \\ (u^n-u^2-1)e^{2\eta u^n} \end{pmatrix},$$

and so on, up to

$$\frac{\partial}{\partial u^{n-1}}\begin{pmatrix} x^1 \\ x^2 \\ \vdots \\ x^{n-1} \\ x^n \end{pmatrix} \propto \begin{pmatrix} (u^n-u^{n-1})e^{2\eta u^1} \\ (u^n-u^{n-1})e^{2\eta u^2} \\ \vdots \\ (u^n-u^{n-1}+1)e^{2\eta u^{n-1}} \\ (u^n-u^{n-1}-1)e^{2\eta u^n} \end{pmatrix},$$

all coefficients of proportionality being equal and positive.

Let us set $v^{i,j} := (u^n - u^i)e^{2\eta u^j}$ and $w^i := (u^n - u^i)$, for purely typographical reasons. A normal vector to the surface can be found as

$$Z := \begin{vmatrix} e_1 & \cdots & e_{n-1} & e_n \\ v^{1,1}+e^{2\eta u^1} & \cdots & v^{1,n-1} & v^{1,n}-e^{2\eta u^n} \\ \vdots & \ddots & \vdots & \vdots \\ v^{n-1,1} & \cdots & v^{n-1,n-1} & v^{n-1,n}-e^{2\eta u^n} \\ & & +e^{2\eta u^{n-1}} & \end{vmatrix}.$$

The coefficient in front of e_1 is the $(n-1)\times(n-1)$ determinant

$$\begin{vmatrix} v^{1,2} & \cdots & v^{1,n-1} & v^{1,n}-e^{2\eta u^n} \\ v^{2,2}+e^{2\eta u^2} & \cdots & v^{2,n-1} & v^{2,n}-e^{2\eta u^n} \\ \vdots & \ddots & \vdots & \vdots \\ v^{n-1,2} & \cdots & v^{n-1,n-1} & v^{n-1,n}-e^{2\eta u^n} \\ & & +e^{2\eta u^{n-1}} & \end{vmatrix}$$

$$\propto e^{-2\eta u^1}\begin{vmatrix} w^1 & \cdots & w^1 & w^1-1 \\ w^2+1 & \cdots & w^2 & w^2-1 \\ \vdots & \ddots & \vdots & \vdots \\ w^{n-1} & \cdots & w^{n-1}+1 & w^{n-1}-1 \end{vmatrix}$$

$$= e^{-2\eta u^1}\begin{vmatrix} 1 & 1 & \cdots & 1 & w^1-1 \\ 2 & 1 & \cdots & 1 & w^2-1 \\ 1 & 2 & \cdots & 1 & w^3-1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & 1 & \cdots & 2 & w^{n-1}-1 \end{vmatrix}$$

$$= e^{-2\eta u^1}\begin{vmatrix} 1 & 1 & \cdots & 1 & u^n-u^1-1 \\ 1 & 0 & \cdots & 0 & u^1-u^2 \\ 0 & 1 & \cdots & 0 & u^1-u^3 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & u^1-u^{n-1} \end{vmatrix}$$

$$= e^{-2\eta u^1}\big((-1)^n(u^n-u^1-1)+(-1)^{n+1}(u^1-u^2) + (-1)^{n+1}(u^1-u^3)+\cdots+(-1)^{n+1}(u^1-u^{n-1})\big)$$

$$= e^{-2\eta u^1}(-1)^n\times \big((u^2+u^3+\cdots+u^n)-(n-1)u^1-1\big)$$

$$= -e^{-2\eta u^1}(-1)^n n u^1 \propto u^1 e^{-2\eta u^1} \quad (5)$$

(with a positive coefficient of proportionality, $e^{2\eta}$, in the first $\propto$; the third equality follows from the expansion of the determinant along the last column and then along the first row).

Similarly, the coefficient in front of e_i is proportional (with the same coefficient of proportionality) to $u^i e^{-2\eta u^i}$ for $i = 2,\dots,n-1$; indeed, the $(n-1)\times(n-1)$ determinant representing the coefficient in front of e_i can be reduced to the form analogous to (5) by moving the ith row to the top.

The coefficient in front of e_n is proportional to

$$e^{-2\eta u^n}\begin{vmatrix} w^1+1 & w^1 & \cdots & w^1 & w^1 \\ w^2 & w^2+1 & \cdots & w^2 & w^2 \\ \vdots & \vdots & \ddots & \vdots & \\ w^{n-2} & w^{n-2} & \cdots & w^{n-2}+1 & w^{n-2} \\ w^{n-1} & w^{n-1} & \cdots & w^{n-1} & w^{n-1}+1 \end{vmatrix}$$

$$= e^{-2\eta u^n}\begin{vmatrix} 1 & 0 & \cdots & 0 & w^1 \\ 0 & 1 & \cdots & 0 & w^2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & w^{n-2} \\ -1 & -1 & \cdots & -1 & w^{n-1}+1 \end{vmatrix}$$

$$= e^{-2\eta u^n}\begin{vmatrix} 1 & 0 & \cdots & 0 & u^n-u^1 \\ 0 & 1 & \cdots & 0 & u^n-u^2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & u^n-u^{n-2} \\ 0 & 0 & \cdots & 0 & nu^n \end{vmatrix} = nu^n e^{-2\eta u^n}$$

(with the coefficient of proportionality $e^{2\eta}(-1)^{n-1}$).

The Gauss–Kronecker curvature at the point with coordinates $(u^1,\dots,u^{n-1})$ is proportional (with a positive coefficient of proportionality, possibly depending on the point) to

$$\begin{vmatrix} \frac{\partial Z^{\mathrm{T}}}{\partial u^1} \\ \vdots \\ \frac{\partial Z^{\mathrm{T}}}{\partial u^{n-1}} \\ Z^{\mathrm{T}} \end{vmatrix} \quad (6)$$

(Thorpe, 1979, Chapter 12, Theorem 5, with $^{\mathrm{T}}$ standing for transposition).

Set $v^i := (1-2\eta u^i)e^{-2\eta u^i}$ and $w^i = u^i e^{-2\eta u^i}$, again for typographical reasons. A straightforward calculation allows us to rewrite determinant (6) (ignoring the

positive coefficient $((-1)^{n-1}ne^{2\eta})^n$) as

$$\begin{vmatrix} v^1 & 0 & \cdots & 0 & -v^n \\ 0 & v^2 & \cdots & 0 & -v^n \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & v^{n-1} & -v^n \\ w^1 & w^2 & \cdots & w^{n-1} & w^n \end{vmatrix} \propto$$

$$\begin{vmatrix} 1-2\eta u^1 & 0 & \cdots & 0 & -1+2\eta u^n \\ 0 & 1-2\eta u^2 & \cdots & 0 & -1+2\eta u^n \\ \vdots & \ddots & \vdots & \vdots & \\ 0 & 0 & \cdots & 1-2\eta u^{n-1} & -1+2\eta u^n \\ u^1 & u^2 & \cdots & u^{n-1} & u^n \end{vmatrix}$$

$$\begin{aligned} &= u^1(1-2\eta u^2)(1-2\eta u^3)\cdots(1-2\eta u^n) \\ &+ u^2(1-2\eta u^1)(1-2\eta u^3)\cdots(1-2\eta u^n)+\cdots \\ &+ u^n(1-2\eta u^1)(1-2\eta u^2)\cdots(1-2\eta u^{n-1}) \end{aligned} \quad (7)$$

(with a positive coefficient of proportionality; to avoid calculation of the parities of various permutations, the reader might prefer to prove the last equality by induction in n, expanding the last determinant along the first column). Our goal is to show that the last expression in (7) is positive when $\eta < 1$ but can be negative when $\eta > 1$.

If $\eta > 1$, set $u^1 = u^2 := 1/2$ and $u^3 = \cdots = u^n := 0$. The last expression in (7) becomes negative. Therefore, the η-exponential superprediction set is not convex (Thorpe, 1979, Chapter 13, Theorem 1).

It remains to consider the case $\eta < 1$. Set $t_i := 1 - 2\eta u^i$, $i = 1, \dots, n$; the constraints on the t_i are

$$\begin{aligned} -1 < 1-2\eta < t_i < 1, \quad i = 1, \dots, n, \\ t_1 + \cdots + t_n = n - 2\eta > n-2. \end{aligned} \quad (8)$$

Our goal is to prove

$$(1-t_1)t_2t_3\cdots t_n + \cdots + (1-t_n)t_1t_2\cdots t_{n-1} > 0,$$

i.e.,

$$t_2t_3\cdots t_n + \cdots + t_1t_2\cdots t_{n-1} > nt_1\cdots t_n. \quad (9)$$

This reduces to

$$\frac{1}{t_1} + \cdots + \frac{1}{t_n} > n \quad (10)$$

if $t_1 \cdots t_n > 0$, and to

$$\frac{1}{t_1} + \cdots + \frac{1}{t_n} < n \quad (11)$$

if $t_1 \cdots t_n < 0$. The remaining case is where some of the t_i are zero; for concreteness, let $t_n = 0$. By (8) we have $t_1 + \cdots + t_{n-1} > n-2$, and so all of $t_1, \dots, t_{n-1}$ are positive; this shows that (9) is indeed true.

Let us prove (10). Since $t_1 \cdots t_n > 0$, all of $t_1, \dots, t_n$ are positive (if two of them were negative, the sum $t_1 + \cdots + t_n$ would be less than $n-2$; cf. (8)). Therefore,

$$\frac{1}{t_1} + \cdots + \frac{1}{t_n} > \underbrace{1 + \cdots + 1}_{n \text{ times}} = n.$$

To establish (9) it remains to prove (11). Suppose, without loss of generality, that $t_1 > 0$, $t_2 > 0, \dots$, $t_{n-1} > 0$, and $t_n < 0$. Since the function $t \in (0,1] \mapsto 1/t$ is convex, we can also assume, without loss of generality, $t_1 = \cdots = t_{n-2} = 1$. Then $t_{n-1} + t_n > 0$, and so

$$\frac{1}{t_{n-1}} + \frac{1}{t_n} < 0;$$

therefore,

$$\frac{1}{t_1} + \cdots + \frac{1}{t_{n-2}} + \frac{1}{t_{n-1}} + \frac{1}{t_n} < n-2 < n.$$

Finally, let us check that the positivity of the Gauss–Kronecker curvature implies the convexity of the η-exponential superprediction set, for $\eta \le 1$. Because of the continuity of the η-exponential superprediction surface in η we can and will assume, without loss of generality, that $\eta < 1$. The η-exponential superprediction surface will be oriented by choosing the normal vector field directed towards the origin; this can be done since

$$\begin{pmatrix} x^1 \\ \vdots \\ x^n \end{pmatrix} \propto \begin{pmatrix} e^{2\eta u^1} \\ \vdots \\ e^{2\eta u^n} \end{pmatrix}, \quad Z \propto \begin{pmatrix} -u^1 e^{-2\eta u^1} \\ \vdots \\ -u^n e^{-2\eta u^n} \end{pmatrix}, \quad (12)$$

with the first coefficient of proportionality positive (cf. (4) and the bottom row of the first determinant in (7)), and the scalar product of the two vectors in (12) is always negative.

Let us first check that the smallest principal curvature

$$k_1 = k_1(u^1, \dots, u^{n-1}, \eta)$$

of the η-exponential superprediction surface is always positive (among the arguments of k_1 we list not only the coordinates $u^1, \dots, u^{n-1}$ of a point on the surface (4) but also the learning rate $\eta \in (0,1)$). At least at some $(u^1, \dots, u^{n-1}, \eta)$ the value of $k_1(u^1, \dots, u^{n-1}, \eta)$ is positive: take a sufficiently small η and the point on the surface (4) at which the maximum of $x^1 + \cdots + x^n$ is attained (the point of the η-exponential superprediction set at which the maximum is attained will

lie on the surface since the maximum is attained at $(x^1,\dots,x^n)=(1,\dots,1)$ when $\eta=0$). Therefore, for all $(u^1,\dots,u^{n-1},\eta)$ the value of $k_1(u^1,\dots,u^{n-1},\eta)$ is positive: if k_1 had different signs at two points in the set

$$\left\{(u^1,\dots,u^{n-1},\eta)\,|\,u^1\in(0,1),\dots,u^{n-1}\in(0,1),\right.$$
$$\left.u^1+\dots+u^{n-1}<1,\eta\in(0,1)\right\},\quad(13)$$

we could connect these points by a continuous curve lying completely inside (13); at some point on the curve, k_1 would be zero, in contradiction to the positivity of the Gauss–Kronecker curvature $k_1\cdots k_{n-1}$.

Now it is easy to show that the η-exponential superprediction set is convex. Suppose there are two points A and B on the η-exponential superprediction surface such that the interval $[A,B]$ contains points outside the η-exponential superprediction set. The intersection of the plane OAB, where O is the origin, with the η-exponential superprediction surface is a planar curve; the curvature of this curve at the point between A and B closest to the origin will be negative (with the curve oriented by directing the normal vector field towards the origin), contradicting the positivity of k_1 at that point and Meusnier's theorem (cf. (12)).

5. Derivation of the Prediction Algorithm

To achieve the loss bound (1) in Theorem 1 Learner can use, as discussed earlier, the strong aggregating algorithm (see, e.g., Vovk, 2001, Section 2.1, (15)) with $\eta=1$. In this section we will find a substitution function for the strong aggregating algorithm for the Brier game with $\eta\le1$, which is the only component of the algorithm not described explicitly in Vovk (2001). Our substitution function will not require that its input, the generalized prediction, should be computed from the normalized distribution $(w^k)_{k=1}^K$ on the experts; this is a valuable feature for generalizations to an infinite number of experts (as demonstrated in, e.g., Vovk, 2001, Appendix A.1).

Suppose that we are given a generalized prediction $(l_1,\dots,l_n)^{\mathrm T}$ computed by the aggregating pseudo-algorithm from a normalized distribution on the experts. Since $(l_1,\dots,l_n)^{\mathrm T}$ is a superprediction (remember that we are assuming $\eta\le1$), we are only required to find a permitted prediction

$$\begin{pmatrix}\lambda_1\\ \lambda_2\\ \vdots\\ \lambda_n\end{pmatrix}=\begin{pmatrix}(u^1-1)^2+(u^2)^2+\dots+(u^n)^2\\ (u^1)^2+(u^2-1)^2+\dots+(u^n)^2\\ \vdots\\ (u^1)^2+(u^2)^2+\dots+(u^n-1)^2\end{pmatrix}\quad(14)$$

(cf. (4)) satisfying

$$\lambda_1\le l_1,\dots,\lambda_n\le l_n.\quad(15)$$

Now suppose we are given a generalized prediction $(L_1,\dots,L_n)^{\mathrm T}$ computed by the APA from an unnormalized distribution on the experts; in other words, we are given

$$\begin{pmatrix}L_1\\ \vdots\\ L_n\end{pmatrix}=\begin{pmatrix}l_1+c\\ \vdots\\ l_n+c\end{pmatrix}$$

for some $c\in\mathbb R$. To find (14) satisfying (15) we can first find the largest $t\in\mathbb R$ such that $(L_1-t,\dots,L_n-t)^{\mathrm T}$ is still a superprediction and then find (14) satisfying

$$\lambda_1\le L_1-t,\dots,\lambda_n\le L_n-t.\quad(16)$$

Since $t\ge c$, it is clear that $(\lambda_1,\dots,\lambda_n)^{\mathrm T}$ will also satisfy the required (15).

Proposition 1. *Define $s\in\mathbb R$ by the requirement*

$$\sum_{i=1}^n(s-L_i)^+=2.\quad(17)$$

The unique solution to the optimization problem $t\to\max$ under the constraints (16) with $\lambda_1,\dots,\lambda_n$ as in (14) will be

$$u^i=\frac{(s-L_i)^+}{2},\ \ i=1,\dots,n,\quad(18)$$
$$t=s-1-(u^1)^2-\dots-(u^n)^2.\quad(19)$$

There exists a unique s satisfying (17) since the left-hand side of (17) is a continuous, increasing (strictly increasing when positive) and unbounded above function of s. The substitution function is given by (18).

Proof of Proposition 1. Let us denote the u^i and t defined by (18) and (19) as $\overline{u}^i$ and $\overline{t}$, respectively. To see that they satisfy the constraints (16), notice that the ith constraint can be spelt out as

$$(\overline{u}^1)^2+\dots+(\overline{u}^n)^2-2\overline{u}^i+1\le L_i-\overline{t},$$

which immediately follows from (18) and (19). As a by-product, we can see that the inequality becomes an equality, i.e.,

$$\overline{t}=L_i-1+2\overline{u}^i-(\overline{u}^1)^2-\dots-(\overline{u}^n)^2,\quad(20)$$

for all i with $\overline{u}^i>0$.

We can rewrite (16) as

$$\begin{cases}t\le L_1-1+2u^1-(u^1)^2-\dots-(u^n)^2,\\ \qquad\vdots\\ t\le L_n-1+2u^n-(u^1)^2-\dots-(u^n)^2,\end{cases}\quad(21)$$

and our goal is to prove that these inequalities imply $t < \bar{t}$ (unless $u^1 = \overline{u}^1, \dots, u^n = \overline{u}^n$). Choose $\overline{u}^i$ (necessarily $\overline{u}^i > 0$ unless $u^1 = \overline{u}^1, \dots, u^n = \overline{u}^n$; in the latter case, however, we can, and will, also choose $\overline{u}^i > 0$) for which $\epsilon_i := \overline{u}^i - u^i$ is maximal. Then every value of t satisfying (21) will also satisfy

$$\begin{aligned} t &\le L_i - 1 + 2u^i - \sum_{j=1}^n (u^j)^2 \\ &= L_i - 1 + 2\overline{u}^i - 2\epsilon_i - \sum_{j=1}^n (\overline{u}^j)^2 + 2\sum_{j=1}^n \epsilon_j \overline{u}^j - \sum_{j=1}^n \epsilon_j^2 \\ &\le L_i - 1 + 2\overline{u}^i - \sum_{j=1}^n (\overline{u}^j)^2 - \sum_{j=1}^n \epsilon_j^2 \le \bar{t}, \end{aligned}$$

with the last $\le$ following from (20) and becoming $<$ when not all u^j coincide with $\overline{u}^j$. □

The detailed description of the resulting prediction algorithm was given as Algorithm 1 in Section 2. As discussed, that algorithm uses the generalized prediction $G_N(\omega)$ computed from unnormalized weights.

6. Conclusion

In this paper we only considered the simplest prediction problem for the Brier game: competing with a finite pool of experts. In the case of square-loss regression, it is possible to find efficient closed-form prediction algorithms competitive with linear functions (see, e.g., Cesa-Bianchi & Lugosi, 2006, Chapter 11). Such algorithms can often be "kernelized" to obtain prediction algorithms competitive with reproducing kernel Hilbert spaces of prediction rules. This would be an appealing research programme in the case of the Brier game as well.

Acknowledgments

We are grateful to Football-Data and Tennis-Data for providing access to the data used in this paper. This work was partly supported by EPSRC (grant EP/F002998/1). Comments by Alexey Chernov, Alex Gammerman, Yuri Kalnishkan, and anonymous referees have helped us improve the presentation.

Abstract

Most existing sparse Gaussian process (g.p.) models seek computational advantages by basing their computations on a set of m basis functions that are the covariance function of the g.p. with one of its two inputs fixed. We generalise this for the case of Gaussian covariance function, by basing our computations on m Gaussian basis functions with arbitrary diagonal covariance matrices (or length scales). For a fixed number of basis functions and any given criteria, this additional flexibility permits approximations no worse and typically better than was previously possible. We perform gradient based optimisation of the marginal likelihood, which costs $O(m^2n)$ time where n is the number of data points, and compare the method to various other sparse g.p. methods. Although we focus on g.p. regression, the central idea is applicable to all kernel based algorithms, and we also provide some results for the support vector machine (s.v.m.) and kernel ridge regression (k.r.r.). Our approach outperforms the other methods, particularly for the case of very few basis functions, *i.e.* a very high sparsity ratio.

1. Introduction

The Gaussian process (g.p.) is a popular non-parametric model for supervised learning problems. Although g.p.'s have been shown to perform well on a wide range of tasks, their usefulness is severely limited by the $O(n^3)$ time and $O(n^2)$ storage requirements where n is the number of data points. A large amount of work has been done to alleviate this problem, either by approximating the posterior distribution, or constructing degenerate covariance functions for which the exact posterior is less expensive to evaluate (Smola & Bartlett, 2000; Csató & Opper, 2002; Lawrence et al., 2002; Seeger et al., 2003; Snelson & Ghahramani, 2006) — for a unifying overview see (Quiñonero-Candela & Rasmussen, 2005). The majority of such methods achieve an $O(m^2n)$ time complexity for training where $m \ll n$ is the number of points on which the computations are based.

The g.p. can be interpreted as a linear (in the parameters) model which, due to its non-parametric nature, has potentially as many parameters to estimate as there are training points. An exception is the case where the covariance function has finite rank, such as the linear covariance function on $\mathbb{R}^d \times \mathbb{R}^d$ given by $k(\boldsymbol{x}, \boldsymbol{x}') = \boldsymbol{x}^\top \boldsymbol{x}'$, which has rank d. In this case the g.p. collapses to a parametric method and it is possible to derive algorithms with $O(d^2n)$ time complexity by basing the computations on d basis functions.

For non-degenerate covariance functions, most existing sparse g.p. algorithms all have in common that they base their computations on m basis functions of the form $k(\boldsymbol{v}_i, \cdot)$. Typically the set $\mathcal{V} = \{\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_m\}$ is taken to be a subset of the training set (Smola & Bartlett, 2000; Csató & Opper, 2002; Seeger et al., 2003). For example Seeger *et al.* (Seeger et al., 2003) employ a highly efficient approximate information gain criteria to incrementally select points from the training set in a greedy manner.

More recently Snelson and Ghahramani (2006) have shown that further improvements in the quality of the model for a given m can be made — especially for small m — by removing the restriction that $\mathcal{V}$ be a subset of the training set. For this they introduced a new sparse g.p. model which has the advantage of being closer to the full g.p., and also of being more amenable to gradient based optimisation of the marginal likelihood with respect to the set $\mathcal{V}$. A further advantage of their con-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

tinuous optimisation of $\mathcal{V}$ is that the hyper-parameters of the model can be optimised at the same time — this is more difficult when $\mathcal{V}$ is taken to be a subset of the training set, since choosing such a subset is a hard combinatoric problem.

In this paper we take a logical step forward in the development of sparse g.p. algorithms. We also base our computations on a finite set of basis functions, but remove the restriction that the basis functions be of the form $k(\boldsymbol{v}_i, \cdot)$ where k is the covariance of the g.p. This will require computing integrals involving the basis and covariance functions, and so cannot always be done in closed form. Fortunately however, closed form expressions can be obtained for arguably the most useful scenario, namely that of Gaussian covariance function (with arbitrary diagonal covariance matrix) along with Gaussian basis functions (again each with their own arbitrary diagonal covariance matrix).

The central idea is that, under some mild restrictions, we can compute the prior probability density — under the g.p. model with Gaussian covariance — of arbitrary Gaussian mixtures. Our analysis is new, but there is a precedent for it in the literature. In particular, Walder et al. (2006) employ a similar idea, but from an reproducing kernel Hilbert space (r.k.h.s.) rather than a g.p. perspective, and for a different basis and covariance function. Also related is (Gehler & Franz, 2006), which analyses from a g.p. perspective with arbitrary basis and covariance function, but with the difference that they do not take infinite limits.

Our idea has a direct r.k.h.s. analogy. Indeed the main idea is applicable to any kernel machine, but in this paper we focus on the g.p. framework. The main reason for this is that it allows us to build on the sparse g.p. model of Snelson and Ghahramani (2006), which has been shown to be amenable to gradient based optimisation of the marginal likelihood. Nonetheless we do provide some experimental results for the kernel ridge regression (k.r.r.) case, as well as an animated toy example of the support vector machine (s.v.m.), in the accompanying video.

The paper is structured as follows. Section 2 provides an introduction to g.p. regression. In Section 3 we derive the likelihood of arbitrary Gaussian mixtures under the g.p. model with Gaussian covariance, and clarify the link to r.k.h.s.'s. In Section 4 we discuss and motivate the precise probabilistic model which we use to make practical use of our theoretical results. Experimental results and conclusions are presented in Sections 5 and 6, respectively.

2. Gaussian Process Regression

We assume that we are given an independent and identically distributed (i.i.d.) sample

$$\mathcal{S} = \{(\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_n, y_n)\} \subset \mathbb{R}^d \times \mathbb{R}$$

drawn from an unknown distribution, and the goal is to estimate $p(y|\boldsymbol{x})$. We introduce a latent variable $u \in \mathbb{R}$, and make the assumption that $p(y|u, \boldsymbol{x}) = p(y|u)$. Hence we can think of y as a noisy realisation of u, which we model by $p(y|u) = \mathcal{N}(y|u, \sigma_n^2)$ where σ_n is a hyper-parameter.[1]

The relationship $\boldsymbol{x} \to u$ is a random process $u(\cdot)$, namely a zero mean g.p. with covariance function $k : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$. Typically k will be defined in terms of further hyper-parameters. We shall denote such a g.p. as $\mathcal{G}(k)$, which is defined by the fact that its joint evaluation at a finite number of input points is a zero mean Gaussian random variable with covariance

$$\mathbb{E}_{f\sim\mathcal{G}(k)}\left[f(\boldsymbol{x})f(\boldsymbol{z})\right] = k(\boldsymbol{x}, \boldsymbol{z}).$$

One can show that given the hyper-parameters, the posterior $p(\boldsymbol{u}|\mathcal{S})$, where[2] $[\boldsymbol{u}]_i = u(\boldsymbol{x}_i)$, is

$$\begin{aligned} p(\boldsymbol{u}|\mathcal{S}) &\propto p(\boldsymbol{u})\mathcal{N}(\boldsymbol{y}|\boldsymbol{u}, \sigma_n^2 I) \\ &\propto \mathcal{N}\left(\boldsymbol{u}|K_{xx}(K_{xx}+\sigma_n^2 I)^{-1}y, \sigma_n^2 K_{xx}(K_{xx}+\sigma_n^2 I)^{-1}\right), \end{aligned} \tag{1}$$

where $[K_{xx}]_{ij} = k(\boldsymbol{x}_i, \boldsymbol{x}_j)$. Like many authors we neglect to notate the conditioning upon the hyper-parameters, both in the above expression and for the remainder of the paper. Now, it can also be shown that the latent function $u_* = u(\boldsymbol{x}_*)$ at an arbitrary test point $\boldsymbol{x}_*$ is distributed according to $p(u_*|\boldsymbol{x}_*, \mathcal{S}) = \int p(u_*|\boldsymbol{x}_*, \mathcal{S}, \boldsymbol{u})p(\boldsymbol{u}|\boldsymbol{x}_*, \mathcal{S})\,\mathrm{d}\boldsymbol{u} = \mathcal{N}(u_*|\mu_*, \sigma_*^2)$, where

$$\mu_* = \boldsymbol{y}^\top (K_{xx} + \sigma_n^2 I)^{-1}\boldsymbol{k}_*, \tag{2}$$

$$\sigma_*^2 = k(\boldsymbol{x}_*, \boldsymbol{x}_*) - \boldsymbol{k}_*^\top (K_{xx} + \sigma_n^2 I)^{-1}\boldsymbol{k}_*, \tag{3}$$

and we have defined $[\boldsymbol{k}_*]_i = k(\boldsymbol{x}_*, \boldsymbol{x}_i)$.

In a Bayesian setting, one places priors over the hyper-parameters and computes the hyper-posterior, but this usually involves costly numerical integration techniques. Alternatively one may fix the hyper-parameters to those obtained by maximising some criteria such as the marginal likelihood conditioned upon them, $p(\boldsymbol{y}|\mathcal{X}) = \mathcal{N}(\boldsymbol{y}|\boldsymbol{0}, K_y)$, where $\mathcal{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$

[1] We adopt the common convention of writing $\mathcal{N}(x|\mu, \sigma)$ for the probability density at x of the Gaussian random variable with mean μ and variance σ.

[2] Square brackets with subscripts denote elements of matrices and vectors, and a colon subscript denotes an entire row or column of a matrix.

and $K_{yy} = K_{xx} + \sigma_n^2 I$ is the covariance matrix for $\boldsymbol{y}$. This can be computed using the result that

$$\log\left(p(\boldsymbol{y}|\mathcal{X})\right) \propto -\boldsymbol{y}^\top K_{yy}^{-1}\boldsymbol{y} - \log|K_{yy}| + c, \quad (4)$$

where c is a term independent of the hyper-parameters. Even when one neglects the cost of choosing the hyper-parameters however, it typically costs $O(n)$ and $O(n^2)$ time to evaluate the posterior mean and variance respectively, after an initial setup cost of $O(n^3)$.

3. Sparse Multiscale Gaussian Process Regression

In this section we – loosely speaking – derive the likelihood of a mixture of Gaussians with arbitrary diagonal covariance matrices, under a g.p. prior with a covariance function that is also a Gaussian with arbitrary diagonal covariance matrix. Let u be drawn from $\mathcal{G}(k)$. As we mentioned previously, this means that the vector of joint evaluations at an arbitrary ordered set of points $\mathcal{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ is a random variable, call it $\boldsymbol{u}_\mathcal{X}$, distributed according to

$$p_{\boldsymbol{u}_\mathcal{X}}(\boldsymbol{u}) = \mathcal{N}\left(\boldsymbol{u}|\boldsymbol{0}, K_{xx}\right). \quad (5)$$

Hence by definition

$$p_{\boldsymbol{u}_\mathcal{X}}(\textstyle\sum_{i=1}^m c_i\boldsymbol{u}_i) = \left|2\pi K_{xx}^{-1}\right|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}\sum_{i,j=1}^m c_i c_j \boldsymbol{u}_i^\top K_{xx}^{-1}\boldsymbol{u}_j\right),$$

where $|\cdot|$ denotes the matrix determinant. Note that this is simply the probability density function (p.d.f.) of $\boldsymbol{u}_\mathcal{X}$ where we have set the argument to be $\sum_{i=1}^m c_i\boldsymbol{u}_i$, for some $c_i \in \mathbb{R}$. We have done this because later we will wish to determine the likelihood of a function expressed as a summation of fixed basis functions. To this end we now consider an infinite limit of the above case. Taking the limit $n \to \infty$ of uniformly distributed points[3] $\boldsymbol{x}_i$ leads to the following p.d.f. for $\mathcal{G}(k)$,

$$p_{\mathcal{G}(k)}(\textstyle\sum_{i=1}^m c_i u_i) = \left|2\pi k^{-1}\right|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}\sum_{i,j=1}^m c_i c_j \Psi_k(u_i, u_j)\right), \quad (6)$$

where

$$\Psi_k(u_i, u_j) \triangleq \int\int k^{-1}(\boldsymbol{x}, \boldsymbol{y}) u_i(\boldsymbol{x}) u_j(\boldsymbol{y})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{y}. \quad (7)$$

We will discuss the factor of $\left|2\pi k^{-1}\right|^{-\frac{1}{2}}$ shortly. Note that in the previous case of finite n, if we let $\boldsymbol{u} = K_{xx}\boldsymbol{\alpha}$ and assume that K_{xx} is invertible, then $\boldsymbol{\alpha} = K_{xx}^{-1}\boldsymbol{u}$. Following this finite analogy, by k^{-1} we now intend a sloppy notation for the function which, for $u = \int \alpha(\boldsymbol{x}) k(\boldsymbol{x}, \cdot)\,\mathrm{d}\boldsymbol{x}$, satisfies $\int u(\boldsymbol{x}) k^{-1}(\boldsymbol{x}, \cdot)\,\mathrm{d}\boldsymbol{x} = \alpha(\cdot)$. Hence if we define

$$M_k : \alpha \mapsto M_k\alpha = \int \alpha(\boldsymbol{x}) k(\boldsymbol{x}, \cdot)\,\mathrm{d}\boldsymbol{x},$$

then k^{-1} is by definition the Green's function (Roach, 1970) of M_k, as it satisfies

$$\int \big(M_k\alpha\big)(\boldsymbol{x}) k^{-1}(\boldsymbol{x}, \cdot)\,\mathrm{d}\boldsymbol{x} = \alpha(\cdot). \quad (8)$$

Let us now consider the covariance function given by $k(\boldsymbol{x}, \boldsymbol{y}) = cg(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{\sigma})$, where $c > 0$, $\boldsymbol{\sigma} > \boldsymbol{0} \in \mathbb{R}^d$ and g is a normalised Gaussian on $\mathbb{R}^d \times \mathbb{R}^d$ with diagonal covariance matrix, that is[4]

$$g(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{\sigma}) \triangleq |2\pi\mathrm{diag}\,(\boldsymbol{\sigma})|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}\sum_{i=1}^d \frac{([\boldsymbol{x} - \boldsymbol{y}]_i)^2}{[\boldsymbol{\sigma}]_i}\right). \quad (9)$$

If we assume furthermore that our function is an arbitrary mixture of such Gaussians, so that

$$u_i(\boldsymbol{x}) = g(\boldsymbol{x}, \boldsymbol{v}_i, \boldsymbol{\sigma}_i), \quad (10)$$

then the well known integral (for the convolution of two Gaussians)

$$\int g(\boldsymbol{x}, \boldsymbol{v}_i, \boldsymbol{\sigma}_i) g(\boldsymbol{x}, \boldsymbol{v}_j, \boldsymbol{\sigma}_j)\,\mathrm{d}\boldsymbol{x} = g(\boldsymbol{v}_i, \boldsymbol{v}_j, \boldsymbol{\sigma}_i + \boldsymbol{\sigma}_j), \quad (11)$$

leads to

$$\left(\frac{1}{c} M_{cg(\cdot,\cdot,\boldsymbol{\sigma})} g(\cdot, \boldsymbol{v}_i, \boldsymbol{\sigma}_i - \boldsymbol{\sigma})\right)(\boldsymbol{x}) = g(\boldsymbol{x}, \boldsymbol{v}_i, \boldsymbol{\sigma}_i) = u_i(\boldsymbol{x}). \quad (12)$$

As the covariance function and the basis functions are all Gaussian we can obtain in closed form

$$\begin{aligned}\Psi_k(u_i, u_j) &\overset{(7,10,12)}{=} \int\int k^{-1}(\boldsymbol{x}, \boldsymbol{y}) g(\boldsymbol{x}, \boldsymbol{v}_i, \boldsymbol{\sigma}_i) \\ &\quad \cdot \left(\frac{1}{c} M_{cg(\cdot,\cdot,\boldsymbol{\sigma})} g(\cdot, \boldsymbol{v}_j, \boldsymbol{\sigma}_j - \boldsymbol{\sigma})\right)(\boldsymbol{y})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{y} \\ &\overset{(8)}{=} \frac{1}{c}\int g(\boldsymbol{x}, \boldsymbol{v}_i, \boldsymbol{\sigma}_i) g(\boldsymbol{x}, \boldsymbol{v}_j, \boldsymbol{\sigma}_j - \boldsymbol{\sigma})\,\mathrm{d}\boldsymbol{x} \\ &\overset{(11)}{=} \frac{1}{c}\, g(\boldsymbol{v}_i, \boldsymbol{v}_j, \boldsymbol{\sigma}_i + \boldsymbol{\sigma}_j - \boldsymbol{\sigma}).\end{aligned}$$

[3] Although any non-vanishing distribution leads to the same result.

[4] We use diag in a sloppy fashion with two meanings — for $\boldsymbol{a} \in \mathbb{R}^n$, $\mathrm{diag}(\boldsymbol{a}) \in \mathbb{R}^{n\times n}$ is a diagonal matrix satisfying $[\mathrm{diag}(\boldsymbol{a})]_{ii} = [\boldsymbol{a}]_i$. But for $A \in \mathbb{R}^{n\times n}$, $\mathrm{diag}(A) \in \mathbb{R}^n$ is a column vector with $[\mathrm{diag}(A)]_i = [A]_{ii}$

For clarity we have noted above each equals sign the number of the equation which implies the corresponding logical step. The following expression summarises the main idea of the present section

$$p_{\mathcal{G}(cg(\cdot,\cdot,\boldsymbol{\sigma}))}\Big(\sum_{i=1}^{m} c_i g(\cdot,\boldsymbol{v}_i,\boldsymbol{\sigma}_i)\Big)$$
$$\propto \exp\Big(-\frac{1}{2}\sum_{i,j=1}^{m}\frac{1}{c}c_i c_j g(\boldsymbol{v}_i,\boldsymbol{v}_j,\boldsymbol{\sigma}_i+\boldsymbol{\sigma}_j-\boldsymbol{\sigma})\Big). \quad (13)$$

We give only an unnormalised form by neglecting the factor $\left|2\pi k^{-1}\right|^{-\frac{1}{2}}$ in (6). The neglected factor is equal to the inverse of the integral of the right hand side of the above expression with respect to all functions $\sum_{i=1}^{m} c_i g(\cdot,\boldsymbol{v}_i,\boldsymbol{\sigma}_i)$. We need not concern ourselves with choosing a measure with respect to which this integral is finite, due to the fact that, since we will be working only with ratios of the above likelihood (*i.e.* for *maximum a posteriori* (m.a.p.) estimation and marginal likelihood maximisation), we need only the unnormalised form. Note that this peculiarity is not particular to our proposed sparse approximation to the g.p., but is a property of g.p.'s in general.

Interpretation We now make two remarks regarding the expression (13). **i)** If $\boldsymbol{\sigma}_1=\boldsymbol{\sigma}_2=\cdots=\boldsymbol{\sigma}_n=\boldsymbol{\sigma}$ and we reparameterise $c_i=cc_i'$ then it simplifies to (5). **ii)** Let $c=1$ and $h(\boldsymbol{x})=\exp\left(-\frac{1}{2}\boldsymbol{x}^\top \mathrm{diag}\left(\boldsymbol{\sigma}_1\right)^{-1}\boldsymbol{x}\right)$, an unnormalised Gaussian. Using (9) and (13) we can derive the log-likelihood of h under the g.p. prior,

$$\log\Big(p_{\mathcal{G}(g(\cdot,\cdot,\boldsymbol{\sigma}))}\big(h(\cdot)\big)\Big)\propto -\sqrt{\frac{|\mathrm{diag}\left(\boldsymbol{\sigma}_1\right)|}{|\mathrm{diag}\left(2\boldsymbol{\sigma}_1-\boldsymbol{\sigma}\right)|}}. \quad (14)$$

Simple analysis of this expression shows that the most likely such function h is that with $\boldsymbol{\sigma}_1=\boldsymbol{\sigma}$. From this extremal point, as any component of $\boldsymbol{\sigma}_1$ increases, the log likelihood of h decreases without bound. Similarly decreasing any component of $\boldsymbol{\sigma}_1$ also decreases the log likelihood, and as any component of $\boldsymbol{\sigma}_1$ approaches half the value of the corresponding component of $\boldsymbol{\sigma}$, then the log likelihood decreases without bound. To be more precise, we have for all $j=1,2,\ldots,d$ that

$$\lim_{[\boldsymbol{\sigma}_1]_j\to\left(\frac{1}{2}[\boldsymbol{\sigma}]_j\right)^+}\log\Big(p_{\mathcal{G}(g(\cdot,\cdot,\boldsymbol{\sigma}))}\big(h(\cdot)\big)\Big)=-\infty.$$

An interesting consequence of the second remark is that, roughly speaking, it is not possible to recover a Gaussian function using a g.p. with Gaussian covariance, if the covariance function is more than twice as broad as the function to be recovered. Although this may at first appear to contradict proven consistency results for the Gaussian covariance function (for example (Steinwart, 2002)), this is not the case. On the contrary, such results hold only for compact domains, and our analysis is for $\mathbb{R}^d$.

An r.k.h.s. Analogy We note that (13) has a direct analogy in the theory of r.k.h.s.'s, as made clear by the following lemma. The lemma follows from (13) and the well understood relationship between every g.p. and the corresponding r.k.h.s. of functions.

Lemma 3.1. *Let $\mathcal{H}$ be the r.k.h.s. with reproducing kernel $g(\cdot,\cdot,\boldsymbol{\sigma})$. If the conditions $\boldsymbol{\sigma}_i>\frac{1}{2}\boldsymbol{\sigma}$ and $\boldsymbol{\sigma}_j>\frac{1}{2}\boldsymbol{\sigma}$ are satisfied component-wise, then*

$$\langle g(\cdot,\boldsymbol{v}_i,\boldsymbol{\sigma}_i),g(\cdot,\boldsymbol{v}_j,\boldsymbol{\sigma}_j)\rangle_{\mathcal{H}}=g(\boldsymbol{v}_i,\boldsymbol{v}_j,\boldsymbol{\sigma}_i+\boldsymbol{\sigma}_j-\boldsymbol{\sigma}). \quad (15)$$

If either condition is not satisfied, then the corresponding function on the left hand side is not in $\mathcal{H}$.

Naturally this can also be proven directly, but doing so for the general case is more involved and we omit the details due to space limitations.[5] However, by assuming that the conditions $\boldsymbol{\sigma}_i>\boldsymbol{\sigma}$ and $\boldsymbol{\sigma}_j>\boldsymbol{\sigma}$ are satisfied component-wise, then it is straightforward to obtain the main result. The basic idea is as follows. Using (11) we substitute $g(\cdot,\boldsymbol{v}_p,\boldsymbol{\sigma}_p)=\int g(\cdot,\boldsymbol{x}_p,\boldsymbol{\sigma})g(\boldsymbol{x}_p,\boldsymbol{v}_p,\boldsymbol{\sigma}_p-\boldsymbol{\sigma})\,\mathrm{d}\boldsymbol{x}_p$ for $p=i,j$ into the l.h.s. of (15). By linearity we can write the two integrals outside the inner product. Next we use the r.k.h.s. reproducing property — the fact that $\langle f(\cdot),g(\cdot,\boldsymbol{x},\boldsymbol{\sigma})\rangle_{\mathcal{H}}=f(\boldsymbol{x}),\forall f\in\mathcal{H},\boldsymbol{x}\in\mathbb{R}^d$ — to evaluate the inner product. Using (11) we integrate to obtain the r.h.s. of (15).

4. Inference with the Sparse Model

4.1. A Simple Approach

In the previous section we derived the g.p. likelihood over a certain restricted function space. This likelihood defines a distribution over functions of the form $\sum_{i=1}^{m} c_i g(\cdot,\boldsymbol{v}_i,\boldsymbol{\sigma}_i)$ where g as given previously is deterministic and the c_i are, by inspection of (13), normally distributed according to

$$\boldsymbol{c}\sim\mathcal{N}\left(\boldsymbol{0},U_\Psi^{-1}\right), \quad (16)$$

where $[U_\Psi]_{i,j}=\Psi_k(u_i,u_j)$. Let us write $\mathcal{U}=\{u_1,\ldots,u_m\}$ (which we refer to as the basis) and refer to the random process thus defined as $\mathcal{G}_{\mathcal{U}}(k)$. This new random process is equivalent to a full g.p. with

[5] For ICML reviewing, we can provide proof on request.

covariance function of rank at most m given by

$$\mathbb{E}_{f\sim\mathcal{G}_{\mathcal{U}}(k)}\left[f(\boldsymbol{x})f(\boldsymbol{z})\right] = \mathbb{E}_{\boldsymbol{c}\sim\mathcal{N}\left(\boldsymbol{0},U_\Psi^{-1}\right)}\left[\left(\boldsymbol{u}_{vx}^\top\boldsymbol{c}\right)\left(\boldsymbol{u}_{vz}^\top\boldsymbol{c}\right)^\top\right] = \boldsymbol{u}_{vx}^\top U_\Psi^{-1}\boldsymbol{u}_{vz}, \tag{17}$$

where $[\boldsymbol{u}_{vx}]_i = g(\boldsymbol{x},\boldsymbol{v}_i,\boldsymbol{\sigma}_i)$ and $[\boldsymbol{u}_{vz}]_i = g(\boldsymbol{z},\boldsymbol{v}_i,\boldsymbol{\sigma}_i)$.

As an aside, note that if we choose as the basis $\mathcal{U} = \{g(\cdot,\boldsymbol{x},\boldsymbol{\sigma}), g(\cdot,\boldsymbol{z},\boldsymbol{\sigma})\}$, then it is easy to verify using (17) that $\mathbb{E}_{f\sim\mathcal{G}_{\mathcal{U}}(g(\cdot,\cdot,\boldsymbol{\sigma}))}\left[f(\boldsymbol{x})f(\boldsymbol{z})\right] = \mathbb{E}_{f\sim\mathcal{G}(k)}\left[f(\boldsymbol{x})f(\boldsymbol{z})\right]$. This is analogous to a special case of the representer theorem from the theory of r.k.h.s.'s, and agrees with the interpretation that (16) is such that $\mathcal{G}_{\mathcal{U}}(k)$ approximates $\mathcal{G}(k)$ well in some sense, for the given basis $\mathcal{U}$.

Returning to the main thread, the new posterior can be derived as it was at the end of Section 2 for the exact g.p., but using the new covariance function (17). Hence after some algebra we have from (2) and (3) that, conditioned again upon the hyper-parameters, the latent function $u_* = u(\boldsymbol{x}_*)$ at an arbitrary test point is distributed according to $p_{u\sim\mathcal{G}_{\mathcal{U}}(k)}(u_*|\boldsymbol{x}_*,\mathcal{S}) = \mathcal{N}(u_*|\mu_*,\sigma_*^2)$, where

$$\mu_* = \left(U_{vx}\boldsymbol{y}\right)^\top\left(U_{vx}U_{vx}^\top + \sigma_n^2 U_\Psi\right)^{-1}\boldsymbol{u}_{v*}, \tag{18}$$

$$\sigma_*^2 = \sigma_n^2\boldsymbol{u}_{v*}^\top\left(U_{vx}U_{vx}^\top + \sigma_n^2 U_\Psi\right)^{-1}\boldsymbol{u}_{v*}, \tag{19}$$

and we have defined $[U_{vx}]_{i,j} = g(\boldsymbol{x}_j,\boldsymbol{v}_i,\boldsymbol{\sigma}_i)$, *etc.* Note that these expressions can be evaluated in $O(m)$ and $O(m^2)$ time respectively, after an initial setup or training cost of $O(m^2n)$. This is the usual improvement over the full g.p. obtained by such sparse approximation schemes. It turns out however that by employing an idea introduced by Snelson and Ghahramani (2006), we can retain these computational advantages while switching to a different model that is closer to the full g.p.

4.2. Inference with Improved Variance

A fair criticism of the previous model is that the predictive variance approaches zero far away from the basis function centres $\boldsymbol{v}_i$, as can be seen from (19). It turns out that this is particularly problematic to gradient based methods for choosing the basis (the $\boldsymbol{v}_i$ and $\boldsymbol{\sigma}_i$) by maximising the marginal likelihood (Snelson & Ghahramani, 2006). An effective but still computationally attractive way of healing the model is to switch to a different g.p. — which we denote $\tilde{\mathcal{G}}_{\mathcal{U}}(k)$ — whose covariance function satisfies

$$\mathbb{E}_{\tilde{\mathcal{G}}_{\mathcal{U}}(k)}\left[f(\boldsymbol{x})f(\boldsymbol{z})\right] = \delta_{\boldsymbol{x},\boldsymbol{z}}k(\boldsymbol{x},\boldsymbol{z}) + \overline{\delta}_{\boldsymbol{x},\boldsymbol{z}}\boldsymbol{u}_{vx}^\top U_\Psi^{-1}\boldsymbol{u}_{vz}, \tag{20}$$

where $\delta_{\boldsymbol{a},\boldsymbol{b}}$ is the Kronecker delta function and $\overline{\delta}_{\boldsymbol{a},\boldsymbol{b}} = 1 - \delta_{\boldsymbol{a},\boldsymbol{b}}$. Note that if $\boldsymbol{x} = \boldsymbol{z}$ then the covariance is that of the original g.p. $\mathcal{G}(k)$, otherwise it is that of $\mathcal{G}_{\mathcal{U}}(k)$. Unlike (17), the prior variance in this case is the same as that of the full g.p., even though in general the covariance is not. Once again the posterior can be found as before by replacing the covariance function in (2) and (3) with the right hand side of (20). In this case we obtain after some algebra the expression $p_{u\sim\tilde{\mathcal{G}}_{\mathcal{U}}(k)}(u_*|\boldsymbol{x}_*,\mathcal{S}) = \mathcal{N}(u_*|\mu_*,\sigma_*^2)$, where

$$\mu_* = \boldsymbol{u}_{v*}^\top Q^{-1}U_{vx}\left(\Lambda + \sigma_n^2 I\right)^{-1}\boldsymbol{y}, \tag{21}$$

$$\sigma_*^2 = k(\boldsymbol{x}_*,\boldsymbol{x}_*) - \boldsymbol{u}_{v*}^\top\left(U_\Psi^{-1} - Q^{-1}\right)\boldsymbol{u}_{v*}, \tag{22}$$

$\Lambda = \operatorname{diag}(\boldsymbol{\lambda})$, and

$$[\boldsymbol{\lambda}]_i = k(\boldsymbol{v}_i,\boldsymbol{v}_i) - [U_{vv}]_{:,i}^\top U_\Psi^{-1}[U_{vv}]_{:,i},$$
$$Q = U_\Psi + U_{vx}\left(\Lambda + \sigma_n^2 I\right)^{-1}U_{vx}^\top.$$

To compute the marginal likelihood we can use the expression (4). Note that it can be computed efficiently using Cholesky decompositions. In order to optimize the marginal likelihood, we also need its gradients with respect to the various parameters. Our derivation of the gradients (which closely follows (Seeger et al., 2003)) is long and tedious, and has been omitted due to space limitations. Note that by factorising appropriately, all of the required gradients can be obtained in $O(m^2n + mnd)$.

4.3. A Unifying View

We now briefly outline how the method of the previous section fits into the unifying framework of sparse g.p.'s provided by Quiñonero-Candela and Rasmussen (2005). Using Bayes rule and marginalising out the training set latent variables $\boldsymbol{u}$, we obtain the posterior

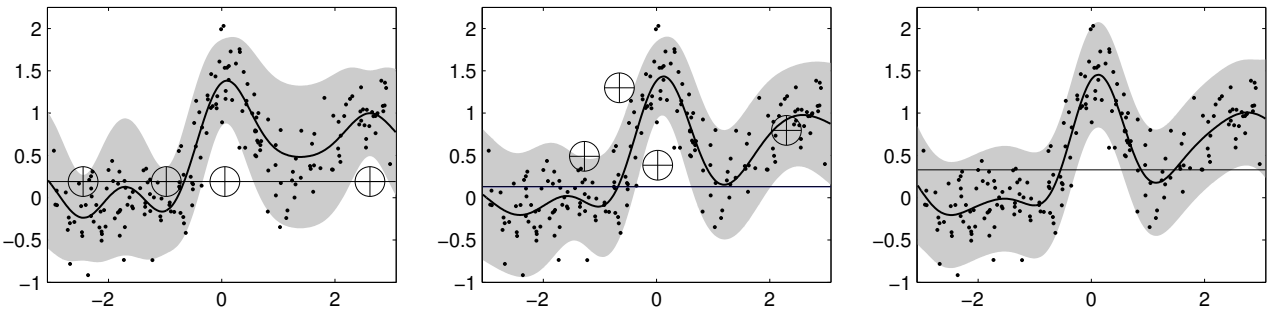
$$p(u_*|\boldsymbol{y}) = \frac{1}{p(\boldsymbol{y})}\int p(\boldsymbol{y}|\boldsymbol{u})p(\boldsymbol{u},u^*)\,\mathrm{d}\boldsymbol{u}.$$

Here we have neglected to notate conditioning on $\boldsymbol{x}^*$ and $\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n$, and have written p instead of the more precise $p_{u\sim\mathcal{G}(k)}$. Our algorithm can be interpreted as employing two separate approximations. The first is conditional independence of $\boldsymbol{u}$ and u^* given $\boldsymbol{a}$, *i.e.*

$$p(\boldsymbol{u},u^*) = \int p(\boldsymbol{u},u^*|\boldsymbol{a})p(\boldsymbol{a})\,\mathrm{d}\boldsymbol{a} \approx \int p(\boldsymbol{u}|\boldsymbol{a})p(u^*|\boldsymbol{a})p(\boldsymbol{a})\,\mathrm{d}\boldsymbol{a},$$

where $\boldsymbol{a}$ (which is marginalised out) is taken to be

$$\left(\langle u_1,u\rangle_{\mathcal{H}}\ \ \langle u_2,u\rangle_{\mathcal{H}}\ \ \cdots\ \ \langle u_m,u\rangle_{\mathcal{H}}\right)^\top,$$



(a) *spgp-full* (b) Our *vsgp-full* (c) Exact g.p.

Figure 1. Predictive distributions (mean curve with ± two standard deviations shaded). For the *spgp-full* and *vsgp-full* algorithms, we plot the $(\boldsymbol{v}_i, \boldsymbol{\sigma}_i) \in \mathbb{R} \times \mathbb{R}$ of the basis as crossed circles. The horizontal lines denote the resulting $\boldsymbol{\sigma} \in \mathbb{R}$ of the covariance function $cg(\cdot, \cdot, \boldsymbol{\sigma})$.

the vector of inner products between the basis functions u_i and the latent function u, in the r.k.h.s. $\mathcal{H}$ associated with $k(\cdot, \cdot)$. The second approximation is

$$p(\boldsymbol{u}|\boldsymbol{a}) = \mathcal{N}\left(U_{xv}U_\Psi^{-1}\boldsymbol{v}, K_{xx} - U_{xv}U_\Psi^{-1}U_{xv}^\top\right) \approx \mathcal{N}\left(U_{xv}U_\Psi^{-1}\boldsymbol{v}, \mathrm{diag}'\left(K_{xx} - U_{xv}U_\Psi^{-1}U_{xv}^\top\right)\right).$$

where $\mathrm{diag}'(A)$ is a diagonal matrix matching A on the diagonal, and $[K_{xv}]_{i,j} = k(\boldsymbol{x}_i, \boldsymbol{v}_j)$, *etc.* Note that the first line can be shown with some algebra, whereas the second is an approximation. One can show that this leads to the result of Section 4.2, but we omit the details for brevity. Of the algorithms considered in (Quiñonero-Candela & Rasmussen, 2005), ours is closest to that of Snelson and Ghahramani (2006), however there the basis functions take the form $u_i = k(\boldsymbol{v}_i, \cdot)$, which has two implications. Firstly, $\boldsymbol{a}$ simplifies to

$$\left(u(\boldsymbol{v}_1)\ u(\boldsymbol{v}_2)\ \cdots\ u(\boldsymbol{v}_m)\right)^\top,$$

the vector of the values of u at $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_m$. Secondly, U_Ψ and U_{xv} simplify to K_{vv} and K_{xv}, respectively.

5. Experiments

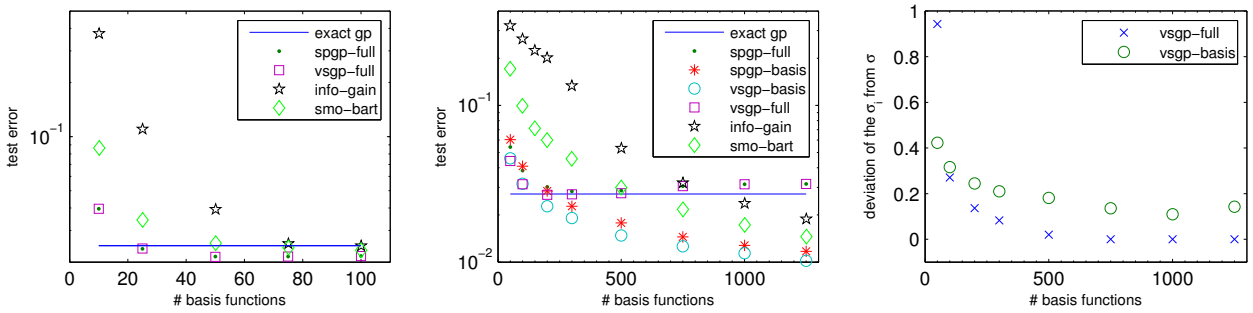
Our main goal is to demonstrate the value of being able to vary the $\boldsymbol{\sigma}_i$ individually. Note that the chief advantage of our method is in producing highly sparse solutions, and the results represent the state of the art in this respect. As such, and since the prediction cost is $O(md)$, we analyse the predictive performance of the model as a function of the number of basis functions m. Note that neither our method nor the most closely related method of Snelson and Ghahramani (2006) are particularly competitive in terms of training time. Nonetheless, there is a demand for algorithms which sacrifice training speed for testing speed, such as real-time vision and control systems, and web services in which the number of queries is large.

Let us clarify the terminology we use to refer to the various algorithms under comparison. Our new method is the variable sigma Gaussian process (v.s.g.p.). The *vsgp-full* variant consists of optimising the marginal likelihood with respect to the m basis centers $\boldsymbol{v}_i \in \mathbb{R}^d$ and length scales $\boldsymbol{\sigma}_i \in \mathbb{R}^d$ of our basis functions $u_i = g(\cdot, \boldsymbol{v}_i, \boldsymbol{\sigma}_i)$ where g is defined in (9). Also optimised are the following hyper parameters — the noise variance $\sigma_n \in \mathbb{R}$ of (1), and the parameters $c \in \mathbb{R}$ and $\boldsymbol{\sigma} \in \mathbb{R}^d$ of our original covariance function $cg(\cdot, \cdot, \boldsymbol{\sigma})$. The *vsgp-basis* variant is identical to *vsgp-full* except that σ_n, c and $\boldsymbol{\sigma}$ are determined by optimising the marginal likelihood of a full g.p. trained on a subset of the training data, and then held fixed while the $\boldsymbol{\sigma}_i$ and $\boldsymbol{v}_i$ are optimised as before. Both v.s.g.p. variants use the $\tilde{\mathcal{G}}_{\mathcal{U}}(k)$ probabilistic model of Section 4.2, where $k = cg(\cdot, \cdot, \boldsymbol{\sigma})$. For the optimisation of the sparse pseudo-input Gaussian process (s.p.g.p.) and v.s.g.p. methods we used a standard conjugate gradient type optimiser.[6]

spgp-full and *spgp-basis* correspond to the work of Snelson and Ghahramani (2006), and are identical to their v.s.g.p. counterparts except that — as with all sparse g.p. methods prior to the present work — they are forced to satisfy the constraints $\boldsymbol{\sigma}_i = \boldsymbol{\sigma}, i = 1 \ldots m$. To initialise the marginal likelihood optimisation we take the $\boldsymbol{v}_i$ to be a *k-means* clustering of the training data. The other parameters are always initialised to the same sensible starting values, which is reasonable due to the preprocessing we employ (which is identical to that of (Seeger et al., 2003)) in order to standardise the data sets.

Figure 1 demonstrates the basic idea on a one dimensional toy problem. Using $m = 4$ basis functions is not

[6] Carl Rasmussen's `minimize.m`, which is freely available from `http://www.kyb.mpg.de/~carl`.



(a) *pumadyn-32nm* test error (b) *kin-40k* test error (c) *kin-40k* $\boldsymbol{\sigma}_i$ deviation

Figure 2. Plots (a) and (b) depict the test error as a function of basis size m. In (c) we plot against m the deviation of the $\boldsymbol{\sigma}_i$ from $\boldsymbol{\sigma}$, measured by the mean squared difference (see the text), for the *kin-40k* data set.

enough for *spgp-full* to infer a posterior similar to that of the full g.p. trained on the depicted $n = 200$ training points. The v.s.g.p. achieves a posterior closer to that of the full g.p. by employing — in comparison to the full g.p. — larger $\boldsymbol{\sigma}_i$'s and a smaller $\boldsymbol{\sigma}$. This leads to an effective covariance function — that of $\tilde{\mathcal{G}}_{\mathcal{U}}(k)$ as given by (17) — which better matches that of the full g.p. depicted in Figure 1 (c). In addition to merely observing the similarity between Figures 1 (b) and (c), we verified this last statement directly by visualising $\mathbb{E}_{\tilde{\mathcal{G}}_{\mathcal{U}}(k)}[f(\boldsymbol{x})f(\boldsymbol{z})]$ of (20) as a function of $\boldsymbol{x}$ and $\boldsymbol{z}$, but we omit the plot due to space limitations.

Figure 2 shows our experiments which, as in (Seeger et al., 2003) and (Snelson & Ghahramani, 2006), were performed on the *pumadyn-32nm* and *kin-40k* data sets.[7] Optimising the v.s.g.p. methods from a random initialisation tended to lead to inferior local optima, so we used the s.p.g.p. to find a starting point for the optimisation. This is possible because both methods optimise the same criteria, while the s.p.g.p. merely searches a subset of the space permitted by the v.s.g.p. framework. To ensure a fair comparison, we optimised the s.p.g.p. for 4000 iterations, whereas for the v.s.g.p. we optimised first the s.p.g.p. for 2000 iterations (*i.e.* fixing $\boldsymbol{\sigma}_i = \boldsymbol{\sigma}, i = 1 \dots m$), took the result as a starting point, and optimised the v.s.g.p. for a further 2000 iterations (with the $\boldsymbol{\sigma}_i$ unconstrained).

We have also reproduced with kind permission the results of Seeger *et al.* (Seeger et al., 2003), and hence have used exactly the experimental methodology described therein. The results we reproduce are from the *info-gain* and *smo-bart* methods. *info-gain* is their own method which is extremely cheap to train for a given set of hyper parameters. The method uses greedy subset selection based on a criteria which can be evaluated efficiently. *smo-bart* is similar but is based on a criteria which is more expensive to compute (Smola & Bartlett, 2000). We also show the result of training a full g.p. on a subset of the data of size 2000 and 1024 for *kin-40k* and *pumadyn-32nm*, respectively.

Neither *info-gain* nor *smo-bart* estimate the hyper-parameters, but rather fix them to the values determined by optimising the marginal likelihood of the full g.p. Hence they are most directly comparable to *spgp-basis* and *vsgp-basis*. However, *spgp-full* and *vsgp-full* correspond to the more difficult task of estimating the hyper parameters at the same time as the basis.

For *pumadyn-32nm* we do not plot *spgp-basis* and *vsgp-basis* as the results are practically identical to *spgp-full* and *vsgp-full*. This differs from (Snelson & Ghahramani, 2006), where local minima problems with *spgp-full* on the *pumadyn-32nm* data set are reported. It is unclear why our experiments did not suffer in this way — possible explanations are the choice of initial starting point, as well as the choice of optimisation algorithm. The results of the s.p.g.p. and v.s.g.p. methods on the *pumadyn-32nm* data set very similar, but both outperform the *info-gain* and *smo-bart* approaches.

The *kin-40k* results are rather different. While the $\boldsymbol{\sigma}_i$ deviated little from $\boldsymbol{\sigma}$ on the *pumadyn-32nm* data set, this was not the case for *kin-40k*, particularly for small m, as seen in Figure 2 (c) where we plot $\frac{1}{md}\sum_{i=1}^{m}\sum_{j=1}^{d}([\boldsymbol{\sigma}_i - \boldsymbol{\sigma}]_j)^2$. Our results are in agreement with those of (Snelson & Ghahramani, 2006) — our *vsgp-full* outperforms *spgp-full* for small m, which in turn outperforms both *info-gain* and *smo-bart*. However for large m both *spgp-full* and *vsgp-full*

[7] *kin-40k*: 10000 training, 30000 test, 9 attributes, see www.igi.tugraz.at/aschwaig/data.html.
pumadyn-32nm: 7168 training, 1024 test, 33 attributes, see www.cs.toronto/delve.

tend to over-fit. This is to be expected due to the use of marginal likelihood optimisation, as the choice of basis $\mathcal{U}$ is equivalent to the choice of the order of md hyper parameters for the covariance function of $\tilde{\mathcal{G}}_{\mathcal{U}}(k)$. Happily, and somewhat surprisingly, the *vsgp-full* method tends not to over-fit more than the *spgp-full*, in spite of its having roughly twice as many basis parameters. Neither *vsgp-basis* nor *spgp-basis* suffered from over-fitting however, and while they both outperform *info-gain* and *smo-bart*, our *vsgp-basis* clearly demonstrates the advantage of our new s.p.g.p. framework by consistently outperforming *spgp-basis*.

Finally, to emphasise the applicability of our idea to other kernel algorithms, we provide an accompanying video which visualises the optimisation of an s.v.m. using multiscale gaussian basis functions.

6. Conclusions

Sparse g.p. regression is an important topic which has received a lot of attention in recent years. Previous methods have based their computations on subsets of the data or pseudo input points. To relate this to our method, this is analogous to basing the computations on a set of basis functions of the form $k(\boldsymbol{v}_i, \cdot)$ where k is the covariance function and the $\boldsymbol{v}_i$ are for example the pseudo input points. We have generalised this for the case of Gaussian covariance function, by basing our computations on a set of Gaussian basis functions whose bandwidth parameters may vary independently.

This provides a new avenue for approximations, applicable to all kernel based algorithms, including g.p.'s and the s.v.m., for example. To demonstrate the utility of this new degree of freedom, we have constructed sparse g.p. and k.r.r. algorithms which outperform previous methods, particularly for very sparse solutions. As such, our approach yields state of the art performance as a function of prediction time.

Manifold Alignment using Procrustes Analysis

Chang Wang CHWANG@CS.UMASS.EDU

Computer Science Department, University of Massachusetts, Amherst, MA 01003 USA

Abstract

In this paper we introduce a novel approach to manifold alignment, based on Procrustes analysis. Our approach differs from "semi-supervised alignment" in that it results in a mapping that is defined everywhere – when used with a suitable dimensionality reduction method – rather than just on the training data points. We describe and evaluate our approach both theoretically and experimentally, providing results showing useful knowledge transfer from one domain to another. Novel applications of our method including cross-lingual information retrieval and transfer learning in Markov decision processes are presented.

1. Introduction

Manifold alignment is very useful in a variety of applications since it provides knowledge transfer between two seemingly disparate data sets. Sample applications include automatic machine translation, representation and control transfer between different Markov decision processes (MDPs), image comparison, and bioinformatics. More precisely, suppose we have two data sets $\mathcal{S}_1 = \{x_1, \cdots, x_m\}$ and $\mathcal{S}_2 = \{y_1, \cdots, y_n\}$ for which we want to find a correspondence. Working with the data in its original form can be very difficult as the data might be in high dimensional spaces and the two sets might be represented by different features. For example, $\mathcal{S}_1$ could be a collection of English documents, whereas $\mathcal{S}_2$ is a collection of Arabic documents. Thus, it may be difficult to directly compare documents from the two collections.

Even though the processing of high-dimensional data sets is challenging, for many cases, the data source may only have a limited number of degrees of freedom, implying the data set has a low intrinsic dimensionality. Similar to current work in the field, we assume kernels for computing the similarity between data points in the original space are already given. In the first step, we map the data sets to low dimensional spaces reflecting their intrinsic geometries using a standard (nonlinear or linear) dimensionality reduction approach. For example, using a graph-based nonlinear dimensionality reduction method provides a discretized approximation to the manifolds, so the new representations characterize the relationships between points but not the original features. By doing this, we can compare the embeddings of the two sets instead of their original representations. Generally speaking, if two data sets $\mathcal{S}_1$ and $\mathcal{S}_2$ have similar intrinsic geometry structures, they have similar embeddings. In our second step, we apply Procrustes analysis to align the two low dimensional embeddings of the data sets based on a number of landmark points. Procrustes analysis, which has been used for statistical shape analysis and image registration of 2D/3D data (Luo et al., 1999), removes the translational, rotational and scaling components from one set so that the optimal alignment between the two sets can be achieved.

There is a growing body of work on manifold alignment. Ham et al. (Ham et al., 2005) align the manifolds leveraging a set of correspondences. In their approach, they map the points of the two data sets to the same space by solving a constrained embedding problem, where the embeddings of the corresponding points from different sets are constrained to be identical. The work of Lafon et al. (Lafon et al., 2006) is based on a similar framework as ours. They use Diffusion Maps to embed the nodes of the graphs corresponding to the aligned sets, and then apply affine matching to align the resulting clouds of points.

Our approach differs from semi-supervised alignment (Ham et al., 2005) in that it results in a mapping that is defined everywhere rather than just on the known data points (provided a suitable dimensionality

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

reduction method like LPP (He et al., 2003) or PCA is used). Recall that semi-supervised alignment is defined only on the known data points and it is hard to handle the new test points (Bengio et al., 2004). Our method is also faster, since it requires computing eigendecompositions of much smaller matrices. Compared to affine matching, which changes the shape of one given manifold to achieve alignment, our approach keeps the manifold shape untouched. This property preserves the relationship between any two data points in each individual manifold in the process of alignment. The computation times for affine matching and Procrustes analysis are similar, both run in $O(N^3)$ (where N is the number of instances).

Given the fact that dimensionality reduction approaches play a key role in our approach, we provide a theoretical bound for the difference between subspaces spanned by low dimensional embeddings of the two data sets. This bound analytically characterizes when the two data sets can be aligned well. In addition to the theoretical analysis of our algorithm, we also report on several novel applications of our alignment approach.

The rest of this paper is as follows. In Section 2 we describe the main algorithm. In Section 3 we explain the rationale underlying our approach, and prove a bound on the difference between the subspaces spanned by low dimensional embeddings of the two data sets being aligned. We describe some novel applications and summarize our experimental results in Section 4. Section 5 provides some concluding remarks.

2. Manifold Alignment

2.1. The Problem

Given two data sets along with additional pairwise correspondences between a subset of the training instances, we want to determine a correspondence between the remaining instances in the two data sets. Formally speaking, we have two sets: $\mathcal{S}_1 = \mathcal{S}_1^l \bigcup \mathcal{S}_1^u = \{x_1, \cdots, x_m\}$, $\mathcal{S}_2 = \mathcal{S}_2^l \bigcup \mathcal{S}_2^u = \{y_1, \cdots, y_n\}$, and the subsets $\mathcal{S}_1^l$ and $\mathcal{S}_2^l$ are in pairwise alignment. We want to find a mapping f, which is more precisely defined in Section 3.1, to optimally match the points between $\mathcal{S}_1^u$ and $\mathcal{S}_2^u$.

2.2. The Algorithm

Assume the kernel K_i for computing the similarity between data points in each of the two data sets is already given. The algorithmic procedure is stated below. For the sake of concreteness, in the procedure, Laplacian eigenmap (Belkin et al., 2003) is used for dimensionality reduction.

1. **Constructing the relationship matrices:**
   - Construct the weight matrices W_1 for $\mathcal{S}_1$ and W_2 for $\mathcal{S}_2$ using K_i, where $W_1(i,j) = K_1(x_i, x_j)$ and $W_2(i,j) = K_2(y_i, y_j)$.
   - Compute Laplacian matrices $\mathcal{L}_1 = I - D_1^{-0.5} W_1 D_1^{-0.5}$ and $\mathcal{L}_2 = I - D_2^{-0.5} W_2 D_2^{-0.5}$, where D_k is a diagonal matrix ($D_k(i,i) = \sum_j W_k(i,j)$) and I is the identity matrix.
2. **Learning low dimensional embeddings of the data sets:**
   - Compute selected eigenvectors of $\mathcal{L}_1$ and $\mathcal{L}_2$ as the low dimensional embeddings of the data sets $\mathcal{S}_1$ and $\mathcal{S}_2$. Let X, X_U be the d dimensional embeddings of $\mathcal{S}_1^l$ and $\mathcal{S}_1^u$, Y, Y_U be the d dimensional embeddings of $\mathcal{S}_2^l$ and $\mathcal{S}_2^u$, where $\mathcal{S}_1^l$, $\mathcal{S}_2^l$ are in pairwise alignment and $|\mathcal{S}_1^l| = |\mathcal{S}_2^l|$.
3. **Finding the optimal alignment of X and Y:**
   - Translate the configurations in X, X_U, Y and Y_U, so that X, Y have their centroids $(\sum_{i=1}^{|\mathcal{S}_1^l|} X_i/|\mathcal{S}_1^l|, \sum_{i=1}^{|\mathcal{S}_2^l|} Y_i/|\mathcal{S}_2^l|)$ at the origin.
   - Compute the singular value decomposition (SVD) of $Y^T X$, that is $U\Sigma V^T = SVD(Y^T X)$.
   - $Y^* = kYQ$ is the optimal mapping result that minimizes $\|X - Y^*\|_F$, where $\|.\|_F$ is Frobenius norm, $Q = UV^T$ and $k = trace(\Sigma)/trace(Y^T Y)$.
4. **Apply Q and k to find correspondences between $\mathcal{S}_1^u$ and $\mathcal{S}_2^u$.**
   - $Y_U^* = kY_U Q$.
   - For each element x in X_U, its correspondence in $Y_U^* = \arg\min_{y^* \in Y_U^*} \|y^* - x\|$.

Depending on the approach that we want to use, there are several variations of Step 1. For example, if we are using PCA, then we use the covariance matrices instead of Laplacian matrices; similarly, if we are using LPP (He et al., 2003), then we construct the weight matrices W_1^l for $\mathcal{D}_1^l$, W_2^l for $\mathcal{D}_2^l$ using K_i and then learn the projections. Note that when PCA or LPP is used, then the low dimensional embedding will be defined everywhere rather than just on the training points.

3. Justification

In this section, we prove two theorems. Theorem 1 shows why the algorithm is valid. Given the fact that dimensionality reduction approaches play a key role in our approach, Theorem 2 provides a theoretical bound for the difference between subspaces spanned by low dimensional embeddings of the two data sets. This bound analytically characterizes when the two data sets can be aligned well.

3.1. Optimal Manifold Alignment

Procrustes analysis seeks the isotropic dilation and the rigid translation, reflection and rotation needed to best match one data configuration to another (Cox et al., 2001). Given low dimensional embeddings X and Y (defined in Section 2), the most convenient way to do translation is to translate the configurations in X and Y so that their centroids are at the origin. Then the problem is simplified as: finding Q and k so that $\|X - kYQ\|_F$ is minimized, where $\|\cdot\|_F$ is Frobenius norm. The matrix Q is orthonormal, giving a rotation and possibly a reflection, k is a re-scale factor to either stretch or shrink Y. Below, we show that the optimal solution is given by the *SVD* of Y^TX. A detailed review of Procrustes analysis can be found in (Cox et al., 2001).

Theorem 1: Let X and Y be low dimensional embeddings of the points with known correspondences in data set $\mathcal{S}_1$, $\mathcal{S}_2$, and X_i matches Y_i for each i. If Singular Value Decomposition (*SVD*) of Y^TX is $U\Sigma V^T$, then $Q = UV^T$ and $k = trace(\Sigma)/trace(Y^TY)$ minimize $\|X - kYQ\|_F$.
Proof:
The problem is formalized as:
$\{k_{opt}, Q_{opt}\} = \arg\min_{k,Q} \|X - kYQ\|_F$. (1.1)

It is easy to verify that
$\|X - kYQ\|_F^2 = trace(X^TX) + k^2 \cdot trace(Y^TY) - 2k \cdot trace(Q^TY^TX)$. (1.2)

Since $trace(X^TX)$ is a constant, the minimization problem is equivalent to $\{k_{opt}, Q_{opt}\} = \arg\min_{k,Q}(k^2 \cdot trace(Y^TY) - 2k \cdot trace(Q^TY^TX))$. (1.3)

Differentiating with respect to k, we have
$2k \cdot trace(Y^TY) = 2 \cdot trace(Q^TY^TX)$,
i.e. $k = trace(Q^TY^TX)/trace(Y^TY)$. (1.4)

(1.3) and (1.4) show that the minimization problem reduces to $Q_{opt} = \arg\max_Q (trace(Q^TY^TX))^2$. (1.5)

Case 1:
If $trace(Q^TY^TX) \geq 0$, then the problem becomes $Q_{opt} = \arg\max_Q \ trace(Q^TY^TX)$. (1.6)

Using Singular Value Decomposition, we have $Y^TX = U\Sigma V^T$, where U and V are orthonormal, and Σ is a diagonal matrix having as its main diagonal all the positive singular values of Y^TX. So $\max_Q trace(Q^TY^TX) = \max_Q trace(Q^TU\Sigma V^T)$. (1.7)

It is well known that for two matrices A and B, $trace(AB) = trace(BA)$, so $\max_Q trace(Q^TU\Sigma V^T) = \max_Q trace(V^TQ^TU\Sigma)$. (1.8)

For simplicity, we use Z to represent V^TQ^TU. We know Q, U and V are all orthonormal matrices, so Z is also orthonormal. It is well known that any element in an orthonormal matrix, say B, is in [-1,1] (otherwise B^TB is not an identity matrix). So we know $trace(Z\Sigma) = Z_{1,1}\Sigma_{1,1} + \cdots + Z_{c,c}\Sigma_{c,c} \leq \Sigma_{1,1} + \cdots + \Sigma_{c,c}$ (1.9) , which implies $Z = I$ maximizes $trace(Z\Sigma)$, where I is an identity matrix. (1.10)

Obviously, the solution to $Z = I$ is $Q = UV^T$. (1.11)

Case 2:
If $trace(Q^TY^TX) < 0$, then the problem becomes $Q_{opt} = \arg\min_Q \ trace(Q^TY^TX)$. (1.12)

Following the similar procedure shown above, we have $trace(Z\Sigma) = Z_{1,1}\Sigma_{1,1} + \cdots + Z_{c,c}\Sigma_{c,c} \geq -\Sigma_{1,1} - \cdots - \Sigma_{c,c}$ (1.13) , which implies that $Z = -I$ minimizes $trace(Z\Sigma)$. (1.14)

Obviously, the solution to $Z = -I$ is $Q = -UV^T$. (1.15)

Considering (1.5), it is easy to verify that $Q = UV^T$ and $Q = -UV^T$ return the same results, so $Q = UV^T$ is always the optimal solution to (1.5), no matter whether $trace(Q^TY^TX)$ is positive or not. Further, we can simplify (1.4), and have $k = trace(\Sigma)/trace(Y^TY)$. (1.16) □

3.2. Theoretical Analysis

Many dimensionality reduction approaches first compute a relationship matrix, and then project the data onto a subspace spanned by the "top" eigenvectors of the matrix. The "top" eigenvectors mean some subset of eigenvectors that are of interest. They might be eigenvectors corresponding to largest, smallest, or

A is a $N \times N$ relationship matrix computed from $\mathcal{S}_1$.
B is a $N \times N$ relationship matrix computed from $\mathcal{S}_2$.
$E = B - A$.

$\mathcal{X}$ denotes a subspace of the column space of A spanned by top M eigenvectors of A.
$\mathcal{Y}$ denotes a subspace of the column space of B spanned by top M eigenvectors of B.
X is a matrix whose columns are an orthonormal basis of $\mathcal{X}$.
Y is a matrix whose columns are an orthonormal basis of $\mathcal{Y}$.

δ_A^1 is the set of top M eigenvalues of A, δ_A^2 includes all eigenvalues of A except those in δ_A^1.
δ_B^1 is the set of top M eigenvalues of B, δ_B^2 includes all eigenvalues of B except those in δ_B^1.

d_1 is the eigengap between δ_A^1 and δ_A^2, i.e. $d_1 = \min_{\lambda_i \in \delta_A^1, \lambda_j \in \delta_A^2} |\lambda_i - \lambda_j|$.
$d = \delta_A^1 - \delta_B^2$.

P denotes the orthogonal projection onto subspace $\mathcal{X}$.
Q denotes the orthogonal projection onto subspace $\mathcal{Y}$.

$\| \cdot \|$ denotes *Operator Norm*, i.e. $\|L\|_{\mu,\nu} = \max_{\nu(x)=1} \mu(Lx)$, where μ, ν are simply $\| \cdot \|_2$.

Figure 1. Notation used in Theorem 2.

even arbitrary eigenvalues. One example is Laplacian eigenmap, where we project the data onto the subspace spanned by the "smoothest" eigenvectors of the graph Laplacian. Another example is PCA, where we project the data onto the subspace spanned by the "largest" eigenvectors of the covariance matrix. In this section, we study the general approach, which provides a general framework for each individual algorithm such as Laplacian eigenmap. We assume the two given data sets $\mathcal{S}_1$ and $\mathcal{S}_2$ do not differ significantly, so the related relationship matrices A and B are "very similar". We study the difference between the embedding subspaces corresponding to the two relationship matrices. Notation used in the proof is in Figure 1. The difference between orthogonal projections $\|Q-P\|$ characterizes the distance between the two subspaces. The proof of the theorem below is based on the perturbation theory of spectral subspaces, where $E = B-A$ can be thought as the perturbation to A. The only assumption we need to make is for any i and j, $|E_{i,j}| = |B_{i,j} - A_{i,j}| \leq \tau$.

Theorem 2: If the absolute value of each element in E is bounded by τ, and $\tau \leq 2\varepsilon d_1/(N(\pi + 2\varepsilon))$, then the difference between the two embedding subspaces $\|Q - P\|$ is at most ε.

Proof:
From the definition of operator norm, we know $\|E\| = \max_{k_1,k_2,\cdots,k_N} \sqrt{\sum_i (\sum_j k_j E_{i,j})^2}$, given $\sum_i k_i^2 = 1$. (2.1)

We can verify the following inequality always holds: $\sum_i (\sum_j k_j E_{i,j})^2 \leq N \sum_j k_j^2 \sum_i E_{i,j}^2$. (2.2)

From (2.1) and (2.2), we have $\sum_i (\sum_j k_j E_{i,j})^2 \leq N^2\tau^2 \sum_j k_j^2 = N^2\tau^2$. (2.3)

Combining (2.1) and (2.3), we have: $\|E\| \leq N\tau$. (2.4)

It can be shown that if A and E are bounded self-adjoint operators on a separable Hilbert space, then the spectrum of $A+E$ is in the closed $\|E\|$-neighborhood of the spectrum of A (Kostrykin et al., 2003). From (Kostrykin et al., 2003), we also have the following inequality: $\|Q^\perp P\| \leq \pi\|E\|/2d$. (2.5)

We know A has an isolated part δ_A^1 of the spectrum separated from its remainder δ_A^2 by gap d_1. To guarantee $A + E$ also has separated components, we need to assume $\|E\| < d_1/2$. Thus (2.5) becomes $\|Q^\perp P\| \leq \pi\|E\|/2(d_1 - \|E\|)$. (2.6)

Interchanging the roles of δ_A^1 and δ_A^2, we have the analogous inequality: $\|QP^\perp\| \leq \pi\|E\|/2(d_1 - \|E\|)$. (2.7)

Since $\|Q - P\| = max\{\|Q^\perp P\|, \|QP^\perp\|\}$ (2.8), we have $\|Q - P\| \leq \pi\|E\|/2(d_1 - \|E\|)$. (2.9)

We define $R = Q - P$, and from (2.9), we get $\|R\| \leq \pi\|E\|/2(d_1 - \|E\|)$. (2.10)

(2.10) implies that if $\|E\| \leq 2d_1\varepsilon/(2\varepsilon + \pi)$, then $\|R\| \leq \varepsilon$. (2.11)

So we have the following conclusion: if the absolute value of each element in E is bounded by τ, and $\tau \leq 2\varepsilon d_1/(N(\pi + 2\varepsilon))$, then the difference of the subspaces spanned by top M eigenvectors of A and B is at most ε. □

Theorem 2 tells us that if the eigengap (between δ_A^1 and δ_A^2) is large, then the subspace corresponding to the top M eigenvectors of A is insensitive to perturbations. In other words, the algorithm can tolerate larger differences between A and B. So when we are selecting eigenvectors to form a subspace, the eigengap is an important factor to be considered. The reasoning behind this is that if the magnitudes of the relevant eigenval-

ues do not change too much, the top M eigenvectors will not be overtaken by other eigenvectors, thus the related space is more stable. Our result in essence connects the difference between the two relationship matrices to the difference between the subspaces spanned by their low dimensional embeddings.

4. Applications and Results

In this section, we first use a toy example to illustrate how our algorithm works, then we apply our approach to transfer knowledge from one domain to another. We present results applying our approach to two real world problems: cross-lingual information retrieval and transfer learning in Markov decision processes (MDPs).

4.1. A Toy Example

In this example, we directly align two manifolds and use some pictures to illustrate how our algorithm works. The two manifolds come from real protein tertiary structure data.

Protein 3D structure reconstruction is an important step in Nuclear Magnetic Resonance (NMR) protein structure determination. Basically, it finds a map from distances to coordinates. A protein 3D structure is a chain of amino acids. Let n be the number of amino acids in a given protein and $C_1, \cdots, C_n$ be the coordinate vectors for the amino acids, where $C_i = (C_{i,1}, C_{i,2}, C_{i,3})^T$ and $C_{i,1}, C_{i,2}$, and $C_{i,3}$ are the x, y, z coordinates of amino acid i (in biology, one usually uses atom but not amino acid as the basic element in determining protein structure. Since the number of atoms is huge, for simplicity, we use amino acid as the basic element). Then the distance $d_{i,j}$ between amino acids i and j can be defined as $d_{i,j} = \|C_i - C_j\|$. Define $A = \{d_{i,j}, i, j = 1, \cdots, n\}$, and $C = \{C_i, i = 1, \cdots, n\}$. It is easy to see that if C is given, then we can immediately compute A. However, if A is given, it is non-trivial to compute C. The latter problem is called Protein 3D structure reconstruction. In fact, the problem is even more tricky, since only the distances between neighbors are reliable, and this makes A an incomplete distance matrix. The problem has been proved to be NP-complete for general sparse distance matrices (Hogben, 2006). In real life, people use other techniques, such as angle constraints and human experience, together with the partial distance matrix to determine protein structures.

With the information available to us, NMR techniques might find multiple estimations (models), since more than one configuration can be consistent with the distance matrix and the constraints. Thus, the result is an ensemble of models, rather than a single structure. Most usually, the ensemble of structures, with perhaps 10 - 50 members, all of which fit the NMR data and retain good stereochemistry is deposited with the Protein Data Bank (PDB) (Berman et al., 2000). Models related to the same protein should be similar and comparisons between the models in this ensemble provides some information on how well the protein conformation was determined by NMR.

In this test, we study a Glutaredoxin protein PDB-1G7O (this protein has 215 amino acids in total), whose 3D structure has 21 models. Since such models are already low dimensional (3D) embeddings of the distance matrices, we skip Step 1 and 2 in our algorithm. We pick up Model 1 and Model 21 for test. These two models are related to the same protein, so it makes sense to treat them as manifolds to test our techniques. We denote Model 1 by Manifold A, which is represented by matrix S_1. We denote Model 21 by Manifold B, which is represented by matrix S_2. Obviously, both S_1 and S_2 are 215×3 matrices. To evaluate our re-scale factor, we manually stretch manifold A by letting $S_1 = 4 \cdot S_1$. Manifold A and B (row vectors of S_1 and S_2 represent points in the 3D space) are shown in Figure 2(A) and Figure 2(B). In biology, such chains are called protein backbones. For the purpose of comparison, we also plot both manifolds on the same graph (Figure 2(C)). It is clear that manifold A is much larger than B, and the orientations of A and B are quite different.

To align the two manifolds, we uniformly selected 1/4 amino acids as correspondence resulting in matrix X and Y, where row i of X (from S_1) matches row i of Y (from S_2) and both X and Y are 54×3 matrices. We run our algorithm from Step 3. Our algorithm identifies the re-scale factor k as 4.2971, and the rotation matrix Q as

$$\mathbf{Q} = \begin{pmatrix} 0.56151 & -0.53218 & 0.63363 \\ 0.65793 & 0.75154 & 0.048172 \\ -0.50183 & 0.38983 & 0.77214 \end{pmatrix}.$$

S_2^*, the new representation of S_2, is computed as $S_2^* = kS_2Q$. We plot S_2^* and S_1 in the same graph (Figure 2(D)). The result shows that Manifold B is rotated and enlarged to the similar size as A, and now the two manifolds are aligned very well.

4.2. Cross-lingual Information Retrieval

In information retrieval, manifold alignment can be used to find correspondences between documents. One example is finding the exact correspondences between documents in different languages. Such systems are quite useful, since they allow users to query a docu-

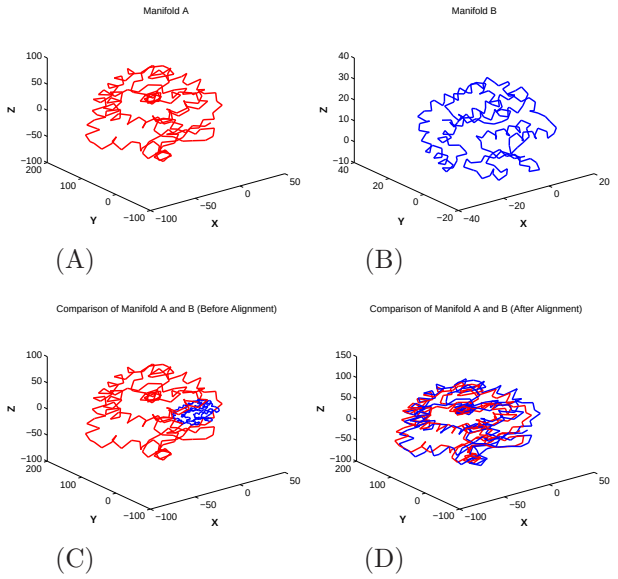

Figure 2. (A): Manifold A; (B): Manifold B; (C): Comparison of Manifold A(red) and B(blue) before alignment; (D): Comparison of Manifold A(red) and B(blue) after alignment.

ment in their native language and retrieve documents in a foreign language. Assume that we are given two document collections. For example, one in English and one in Arabic. We are also given some training correspondences between documents that are exact translations of each other. The task is: for each English or Arabian document in the untranslated set, to find the most similar document in the other corpus.

We apply our manifold alignment approach to this problem. The topical structure of each collection can be thought as a manifold over documents. Each document is a sample from the manifold. We are interested in the case where the underlying topical manifolds of two languages are similar. Our procedure for aligning collections consists of two steps: learning low dimensional embeddings of the two manifolds and aligning the low dimensional embeddings. To compute similarity of two documents in the same collection, we assume that document vectors are language models (multinomial term distributions) estimated using the document text. By treating documents as probability distributions, we can use distributional affinity to detect topical relatedness between documents. More precisely, a multinomial diffusion kernel is used for this particular application. The kernel used here is the same as the one used in (Diaz et al., 2007), where more detailed description is provided. Dimensionality reduction approaches are then used to learn the low dimensional embeddings. After shifting the centroids of the documents in each collection to the origin point, we apply our approach to learn the re-scale factor k and rotation Q from the training correspondences and then apply them to the untranslated set.

In our experiments, we used two document collections (one in English, one in Arabic, manually translated), each of which has 2119 documents. Correspondences between 25% of them were given and used to learn the mapping between them. The remaining 75% were used for testing. We used Laplacian eigenmap and LPP (the projection was learned from the data points in the correspondence) to learn the low dimensional embeddings, where top 100 eigenvectors were used to construct the embeddings. Our testing scheme is as follows: for each given Arabic document, we retrieve its top j most similar English documents. The probability that the true match is among this top j documents is used to show the goodness of the method. We also used the same data set to test the semi-supervised manifold alignment method proposed in (Ham et al., 2005), where top 100 eigenvectors were used for low dimensional embeddings. A fourth method (called baseline method) was also tested. The baseline method is as follows: assume that we have m correspondences in the training set, then document x is represented by a vector V with length m, where $V(i)$ is the similarity of x and the i^{th} document in the training correspondences. The baseline method maps the documents from different collections to the same embedding space - $\mathcal{R}^m$. Experiment results are shown in Figure 3.

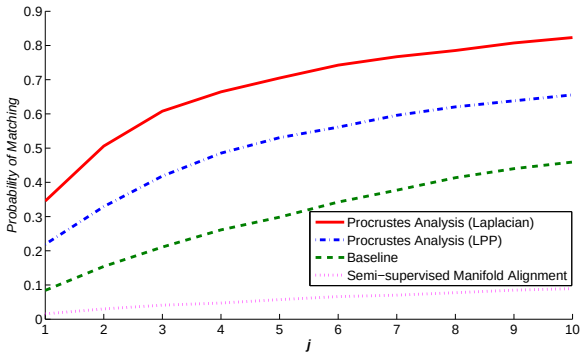

Figure 3. Cross-lingual information retrieval test.

Compared to semi-supervised manifold alignment method, the performance of Prucrustes (with Laplacian eigenmap) is significantly better. For each given Arabic document, if we retrieve 3 most relevant English documents, then the true match has a 60% probability of being among the 3. If we retrieve 10 most relevant English documents, then we have about 80% probability of getting the true match. Further, our method is much faster. Semi-supervised manifold

alignment method requires solving an eigenvalue problem over a $(n_1 + n_2 - m) \times (n_1 + n_2 - m)$ matrix, where n_i is the total number of the documents in collection i, and m is the number of training correspondences. Using our approach, the most time consuming step is finding the low dimensional embeddings with Laplacian eigenmap, which requires solving eigenvalue problems over a $n_1 \times n_1$ matrix and a $n_2 \times n_2$ matrix. We also compute the *SVD* over a $d \times d$ matrix, where d is the dimension of the low dimensional embeddings and is usually much smaller than n. In the experiments, Procrustes (with Laplacian eigenmap) is roughly 2 times faster than semi-supervised manifold alignment. Procrustes (with LPP) also returns reasonably good results: if we retrieve 10 most relevant English documents, then we have a 60% probability of getting the true match. Procrustes (with LPP) results in a mapping that is defined everywhere rather than just on the training data points and it also requires less time. Another interesting result is that the baseline algorithm also performs quite well, and better than semi-supervised alignment method. One reason that semi-supervised manifold alignment method is not working well is that mappings of the corresponding points are constrained to be identical. This might lead to "over fitting" problems for some applications.

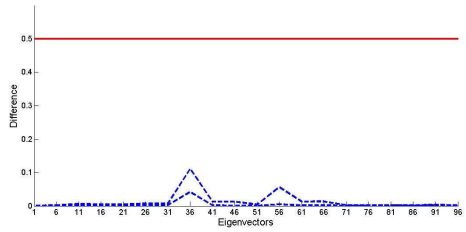
4.3. Transfer Learning in Markov Decision Process

Transfer learning studies how to re-use knowledge learned from one domain or task to a related domain or task. In this section, we investigate transfer learning in Markov decision processes (MDPs) following the approach of "proto-value functions" (PVFs), where the Laplacian eigenmap method is used to construct basis functions (Mahadevan, 2005). In a MDP, a value function is a mapping from states to real numbers, where the value of a state represents the long-term reward achieved starting from that state, and executing a particular policy. PVFs are an orthonormal basis spanning all value functions of an MDP on a state space manifold. They are computed as follows: First, create a weight matrix that reflects the topology of the state space using a series of random walks; Second, compute the graph Laplacian of the weight matrix; Third, select the smoothest k eigenvectors of this graph Laplacian as PVFs. If the state space is the same and only the reward function is changed, then the PVFs can be directly transferred to the new domain. One interesting question related to PVFs is how to transfer the old PVFs to a new domain when the new state space is only slightly different from the old one. In this section, we answer this question with our techniques.

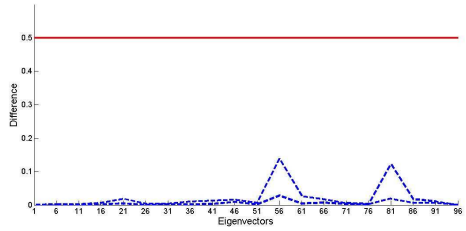
Let columns of Y denote PVFs of the current MDP. Given the procedure on how to generate PVFs, we know the rows of Y are also the low dimensional representations of the data points on the current state space manifold. Let rows of X represent the low dimensional embedding of the new manifold. Assume centroids of both X and Y are at the origin. By using isotropic dilation, reflection and rotation to align the two state space manifolds, we may find the optimal k and Q such that the two manifolds are aligned well. Our argument is that the new PVFs are YQ. The reason is as follows: suppose we have already found the optimal k and Q that minimize $\|X - kYQ\|_F$, then Y will be changed to kYQ in the process of alignment. k can be skipped, since it is well known that kYQ and YQ span the same space. The only thing that we need to show is the columns of YQ are orthonormal to each other (a requirement of PVFs). The proof is quite simple: $(YQ)^T YQ = Q^T Y^T YQ = Q^T IQ = I$, where I is an identity matrix. This means different columns of YQ are orthogonal to each other and norm of each column is 1, so YQ is orthonormal.

The conclusion shown above works when two state space manifolds are similar. Here, we still need to answer one more question: "under what conditions are the two manifolds similar?". Theorem 2 provides an answer to this question. Theorem 2 numerically bounds the difference between two spaces given the difference between the relevant relationship matrices. For this case, the relationship matrices are the Laplacian matrices used to model the state spaces. In this test, we run experiments to verify the bound. We investigate two reinforcement learning tasks. The inverted pendulum task requires balancing a pendulum of unknown mass and length by applying force to a cart attached to the pendulum. The state space is defined by two variables: the vertical angle of the pendulum, and the angular velocity of the pendulum. The mountain car task is to get a simulated car to the top of a hill as quickly as possible. The car does not have enough power to get there immediately, and so must oscillate on the hill to build up the necessary momentum. The state space is the position and velocity of the car.

We first generate two different sets of sampled states for the pendulum task and compute their related normalized graph Laplacian matrices A and B. We compute the top i non-trivial eigenvectors of A and B, and directly compute the difference between the spaces spanned by them. Theorem 2 says if the absolute value of each element in $A - B$ is bounded by τ, and $\tau \leq 2\varepsilon d_1/(N(\pi+2\varepsilon))$, then the difference of the spaces spanned by top i eigenvectors of A and B is at most



(A) Pendulum Task



(B) Mountain Car Task

Figure 4. (A): Bound for Pendulum task. (B): Bound for Mountain car task. For both tasks, ε is 0.5, true values (Max and Min in 5 tests) of the difference between two spaces are in dotted lines.

ε. We set ε be 0.5, and let τ be $\varepsilon d_1/(N(\pi+2\varepsilon))$. Here d_1 is the eigengap between top i eigenvectors and the other eigenvetors, N is 500. Based on our theorem, the difference between spaces should not be larger than ε. In our experiments, we tried 20 different values for i=1, 6, 11, $\cdots$, 96. For each i, we ran 5 tests. We carried out the same experiment on the Mountain Car task. Figure 4(A) and 4(B) respectively show the results from Pendulum task and Mountain car task. For each figure, we plot ε and the maximum and minimum difference values of the 5 tests for various values of i. For this application, the bound is loose, but the bound given in Theorem 2 is a general theoretical bound and for other applications, it might be tight. We also empirically evaluate the PVFs transfer performance. The results (not included) show that we can learn a good policy by using PVFs from a similar domain.

5. Conclusions

In this paper we introduce a novel approach to manifold alignment based on Procrustes Analysis. When used with a suitable dimensionality reduction method, our approach results in a mapping defined everywhere rather than just on the training data points. We also study the conditions under which low dimensional embeddings of two data sets can be aligned well. We presented novel applications of our approach, including cross-lingual information retrieval and transfer learning in Markov decision processes.

Abstract

We consider feature extraction (dimensionality reduction) for compositional data, where the data vectors are constrained to be positive and constant-sum. In real-world problems, the data components (variables) usually have complicated "correlations" while their total number is huge. Such scenario demands feature extraction. That is, we shall de-correlate the components and reduce their dimensionality. Traditional techniques such as the Principle Component Analysis (PCA) are not suitable for these problems due to unique statistical properties and the need to satisfy the constraints in compositional data. This paper presents a novel approach to feature extraction for compositional data. Our method first identifies a family of dimensionality reduction projections that preserve all relevant constraints, and then finds the optimal projection that maximizes the estimated Dirichlet precision on projected data. It reduces the compositional data to a given lower dimensionality while the components in the lower-dimensional space are de-correlated as much as possible. We develop theoretical foundation of our approach, and validate its effectiveness on some synthetic and real-world datasets.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

1. Introduction

Compositional data (positive constant-sum real vectors) are frequently encountered in various scientific disciplines and industrial applications. They quantitatively describe the parts that comprise the entire entity. In geology, scientists investigate relative proportion of different minerals in rocks. In microeconomics, household expenditure in different commodity/service groups is recorded as relative proportion. In information retrieval, documents are usually represented as relative frequencies of words in a prescribed vocabulary. Generally, compositional data are natural representations when the variables (features) are essentially probabilities of complementary and mutually exclusive events. The variables (features) in compositional data are referred to as *components* in this paper.

Feature extraction is often applied in machine learning when the datasets are large and complex. The same is needed for compositional data. The need for feature extraction arises from four aspects. First, prediction performance in classification and regression can benefit from a lower dimensional representation with de-correlated *components* to avoid the curse of dimensionality. Second, feature extraction may improve overall domain understanding, e.g., we could expect the learned *components* to represent latent independent sources from which the data are generated. Third, the computational expense of subsequent data processing can be reduced with a lower dimensionality. Finally, reducing data to two or three dimensions facilitates visualization and further analysis by domain experts.

However, traditional feature extraction techniques are

not suitable for compositional data due to several reasons. First, the traditional measurement of "correlation"[1] implicated by multivariate Gaussian and PCA only captures a linear relationship between two random variables. In contrast, the "curved" nature (Aitchison, 1983) of compositional data and the "spurious correlation" (Pearson, 1896) induced by the constant-sum constraint make it problematic to interpret correlation as merely a linear relationship. We thus need a new concept of "correlation" for compositional data. Second, the positive and constant-sum constraints for compositional data are not considered in most dimensionality reduction techniques, and simply modifying them to accommodate these constraints may induce biases.

PCA is one of the most widely used techniques for feature extraction. Given a target dimension k, PCA identifies an orthogonal projection to a k dimensional subspace that maximizes the estimated Gaussian variance of the projected data. Moreover, the covariance matrix is diagonalized such that the variables are decorrelated. Our approach adapts this framework for compositional data. In particular, we first identify a family of projections that preserve a simplex constraint as substitutes for the orthogonal projections in PCA. Then, we find an optimal projection that minimizes the "Dirichlet correlation" among the projected *components*, as a substitute for maximizing the estimated Gaussian variance in PCA. The Dirichlet correlation among the *components* is defined as the estimated Dirichlet precision on projected data. The *components* are better de-correlated and separated with a smaller Dirichlet correlation. The notion of Dirichlet correlation extends the traditional "linear" interpretation of correlation connoted in the covariance structure of multivariate Gaussian and PCA. Because of our approach's affinity to the Dirichlet distribution, we call it *Dirichlet component analysis (DCA)*.

Although the Dirichlet distribution is a natural parametric family on the simplex, its role in modeling compositional data is not well studied. As pointed out in (Aitchison, 1982), the "ultimate independence" property of the Dirichlet family prevents us from directly applying it to model compositional data. Consequently, the use of Dirichlet family in compositional data analysis has been superseded by the *log-ratio* framework (eliminating the constraints by a transformation to $\mathbb{R}^N$) originated from (Aitchison, 1982). For example, the *centered log-ratio* is defined as dividing all *components* by their geometric mean and then applying the *log* function. Although this framework has been very successful, it has certain problems. The *log-ratio* well captures variability in the central area of the simplex, but encounters singularity in peripheral areas. For example, in sparse compositional data (e.g., term frequencies in documents with thousands of terms) the log-ratio is not well defined as most denominators would be zero.

In this paper, we make three main contributions. 1) We identify a rich family of dimensionality reduction transformations for compositional data, as an alternative to existing compositional operators such as *subcomposition*, *amalgamation*, and *partition* (Aitchison, 1982). 2) We exploit the Dirichlet family for compositional data analysis to capture data variability beyond traditional concepts of statistical correlation. 3) We show that the entire framework of DCA is effective and conceptually succinct, and validate its effectiveness on two synthetic datasets and two real-world datasets.

2. Dirichlet Component Analysis

2.1. The Projection Family

Compositional data are positive constant-sum vectors. Without loss of generality, we assume all *components* to sum to one:

$$\mathbf{x} = (x_1, x_2, \cdots, x_N)^T, \quad x_i \geq 0 \text{ for all } i, \quad \sum_{i=1}^{N} x_i = 1 \tag{1}$$

All points satisfying these constraints constitute the $(N-1)$-simplex, denoted as $\mathbb{S}^N$. As low dimensional examples, $\mathbb{S}^3$ is a triangle and $\mathbb{S}^4$ is a tetrahedron.

Given a target dimension K ($K \leq N$), our first aim in dimensionality reduction is to identify a family of projections from $\mathbb{S}^N$ to $\mathbb{S}^K$.

Proposition 1 *For linear projections*

$$\mathbf{y} = \mathbf{R}\,\mathbf{x} \quad \text{where} \qquad \mathbf{R} = (r_{ij})_{K\times N} \tag{2}$$

$\mathbf{y}$ *is in* $\mathbb{S}^K$ *for all* $\mathbf{x}$ *in* $\mathbb{S}^N$ ***if and only if***
1) $r_{ij} \geq 0$ *for all* i, j.
2) $\sum_{i=1}^{K} r_{ij} = 1$, *for* $j = 1, \cdots, N$.

The proof is quite straightforward and we omit it here for brevity.

Such projections could be viewed as *rearranging* mass from the N original *components* to the K new *components*, while the law of conservation of mass is satisfied. Hence we refer to such linear transforms from $\mathbb{S}^N$ to $\mathbb{S}^K$ as *rearrangements*.

Unfortunately, we could have degenerate *rearrangements* when some rows of $\mathbf{R}$ are close to zero and

[1] It is measured by the Pearson's correlation coefficient.

as a result, the corresponding new *component* is almost ignored in the *rearranging* process. Without *a priori* knowledge we should treat the K new *components* equally, which gives rise to the family of *balanced rearrangements*:

Definition 1 (Balanced Rearrangement) *A linear projection $\mathbf{R}\,\mathbf{x} = \mathbf{y}$ is a **balanced rearrangement**, if $\mathbf{R} = (r_{ij})_{K\times N}$ satisfies:*
1) $r_{ij} \geq 0$ for all i, j.
2) $\sum_{i=1}^{K} r_{ij} = 1$, for $j = 1, \cdots, N$.
3) $\sum_{j=1}^{N} r_{ij} = N/K$, for $i = 1, \cdots, K$.

The *balanced* is described by the following proposition, which gives rise to a univariate (symmetric) Dirichlet family, as we will discuss in Section 2.2.

Proposition 2 *If $\mathbf{R}_{K\times N}$ is a balanced rearrangement matrix, $\mathbf{x}$ is a random vector in $\mathbb{S}^N$ satisfying $\mathbf{E}(x_i) = \frac{1}{N}$ for all i, then $\mathbf{y} = \mathbf{R}\,\mathbf{x}$ is a random vector in $\mathbb{S}^K$ and $\mathbf{E}(y_i) = \frac{1}{K}$ for all i.*

The proof is straightforward given the linearity of the expectation operator.

The space of balanced rearrangement projections from $\mathbb{S}^N$ to $\mathbb{S}^K$ is a $NK - N - K + 1$ dimensional vector space, which is closed with respect to the operator of weighted average. This property is useful in developing the optimization algorithm in Section 3:

Proposition 3 *If $\mathbf{R_1}$ and $\mathbf{R_2}$ are balanced rearrangement matrices, α and β are positive real numbers, then $(\alpha\mathbf{R_1} + \beta\mathbf{R_2})/(\alpha+\beta)$ is a balanced rearrangement matrix.*

This is easy to validate from the definition of balanced rearrangement.

A noticeable property of balanced rearrangements is the "shrinking effects" stated as follows:

Proposition 4 *Let $\min(\mathbf{x})$ be the minimum component of $\mathbf{x}$. $\mathbf{R}_{K\times N}$ is a balanced rearrangement matrix with $K \leq N$, then $\min(\mathbf{Rx}) \geq \min(\mathbf{x})$ for all $\mathbf{x}$ in $\mathbb{S}^N$.*

The proof is obvious as long as we notice that each component of $\mathbf{Rx}$ is N/K times a weighted average of the components of $\mathbf{x}$, where equality holds only in some trivial cases. For example, $\mathbf{R}$ is the identify matrix or $\mathbf{x} = (1/N, 1/N, \cdots, 1/N)$.

Intuitively, Proposition 4 states that the balanced rearrangements always make data points "shrink" toward the central area of the simplex, which is undesirable because it diminishes variabilities of data[2]. To solve this problem, we induce the *regularization* operator for compositional data. As shown in Figure 1, we impose on the data points a parallel move along the direction $x_1 = x_2 = \cdots = x_N$, and then project the data points back to the simplex by radial projection:

Definition 2 (Regularization) *Given a compositional dataset $\mathcal{X} = \{\mathbf{x}^1, \mathbf{x}^2, \cdots, \mathbf{x}^M\}$, a **regularization** on the dataset is denoted as: $\widetilde{\mathcal{X}} = \{\widetilde{\mathbf{x}^1}, \widetilde{\mathbf{x}^2}, \cdots, \widetilde{\mathbf{x}^M}\}$, where $\widetilde{\mathbf{x}^i} = \frac{1}{\sum_{j=1}^{N}(x_j^i - \delta)}(x_1^i - \delta, x_2^i - \delta, \cdots, x_N^i - \delta,)$ for $i = 1, 2, \cdots, M$, and the **regularization factor** $\delta = \min(\min(\mathbf{x^1}), \min(\mathbf{x^2}), \cdots, \min(\mathbf{x^M}))$.*

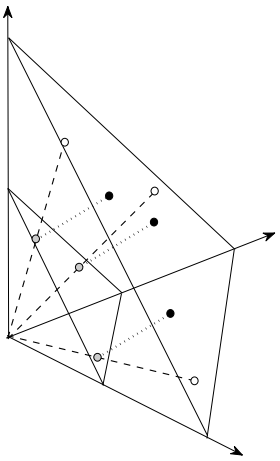

Figure 1. Regularization of compositional data points (black) is performed by parallel projection to the gray points, then radial projection to the white points.

The *regularization* operator can be viewed as a "scaling", which preserves Euclidean geometrical properties such as distance (allowing a constant scaling factor) and angle. Intuitively it "expands" the data points and compensates for the "shrinking effect" of balanced rearrangements. Its usefulness will be illustrated in a toy example in Section 2.3.1.

2.2. Dirichlet Correlation

The Dirichlet distribution (3) is conjugate prior of the multinomial, which is quite natural for compositional data arisen from independent *components*.

$$\mathrm{Dir}(\mathbf{x} \mid \alpha) = \frac{\Gamma(\sum_{i=1}^{N} \alpha_i)}{\prod_{i=1}^{N} \Gamma(\alpha_i)} \prod_{i=1}^{N} x_i^{\alpha_i - 1} \tag{3}$$

Parameters $\alpha = (\alpha_1, \alpha_2, \cdots, \alpha_N)$ could be summarized by the Dirichlet precision $\sum_{i=1}^{N} \alpha_i$ and the Dirichlet

[2] Actually, as we will show, it also increases the Dirichlet correlation among components, which is undesirable.

mean $(\alpha_1, \alpha_2, \cdots, \alpha_N)/\sum_{i=1}^{N} \alpha_i$. The Dirichlet mean actually encodes the expectation of each *component*:

$$\mathbf{E}_{\mathrm{Dir}}(x_i) = \alpha_i / \sum_{j=1}^{N} \alpha_j \tag{4}$$

Without domain knowledge, we assume the *components* in original data to be equally important. According to Proposition 2, the feature extraction process should not "prefer" any new *component*. We therefore adopt a uniform Dirichlet mean:

$$\mathrm{Dir}(\mathbf{x} \mid \alpha_0) = \frac{\Gamma(N\alpha_0)}{\Gamma(\alpha_0)^N} \prod_{i=1}^{N} x_i^{\alpha_0 - 1} \tag{5}$$

The traditional concept of "correlation" (Pearson product-moment correlation coefficient) encodes linear relationships between *components* (variables). With strong linear relationships, some *components* are redundant and the total amount of information declines. In information theory, the amount of information is measured by "uncertainty" of a distribution. The Gaussian distribution with larger variances is more "uncertain", thus is preferred in PCA. For the Dirichlet distribution (5), a smaller α_0 indicates higher "uncertainty" (amount of information) and less "correlation" among the *components* (see Figure 2), which coincides with the traditional statistical interpretation of "correlation". Hence we define correlation for compositional data in terms of α_0:

Definition 3 (Dirichlet Correlation) *Given i.i.d. compositional data set $\mathcal{X} = \{\mathbf{x^1}, \mathbf{x^2}, \cdots, \mathbf{x^M}\}$ arisen from (5), the **Dirichlet correlation** among the components with respect to $\mathcal{X}$ is defined as the maximum likelihood estimation of α_0.*

Note that α_0 is the overall (not pairwise) "correlation" among *all* components.

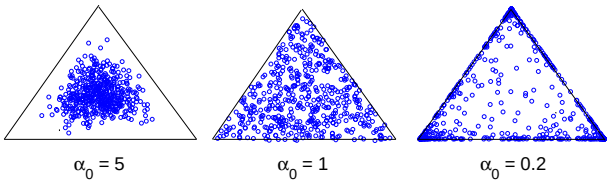

Figure 2. Points sampled from the univariate Dirichlet distribution (5) on $\mathbb{S}^3$ with different α_0.

The intuitive interpretation of the Dirichlet correlation is shown in Figure 2: 1) when $\alpha_0 > 1$, the distribution is bump-shaped, where the *components* are highly correlated and are likely to mix together in samples; 2) when $\alpha_0 = 1$, the distribution is uniform, and any proportion of mixture is equally preferred; 3) when $\alpha_0 < 1$, the distribution is valley-shaped with peaks at simplex vertices, and the *components* are better de-correlated such that the components present themselves as more purified elements in the data samples.

With the specially designed transform family and correlation measure for compositional data, we define Dirichlet component analysis (DCA) as follows:

Definition 4 (Dirichlet Component Analysis) *Given i.i.d. compositional data set $\mathcal{X} = \{\mathbf{x^1}, \mathbf{x^2}, \cdots, \mathbf{x^M}\}$ with N components, and the target dimension K, **Dirichlet component analysis** (DCA) applies a balanced rearrangement $\bar{\mathbf{R}}_{K\times N}$ and a regularization on $\mathcal{X}$ to minimize the Dirichlet correlation among the resulted K components:*

$$\bar{\mathbf{R}} = \operatorname*{argmin}_{\mathbf{R}} \operatorname*{argmax}_{\alpha_0} \mathrm{Dir}(\widetilde{\mathbf{R}(\mathcal{X})} \mid \alpha_0) \tag{6}$$

where $\widetilde{\mathbf{R}(\mathcal{X})}$ denotes that we first apply balanced rearrangement $\mathbf{R}$ to $\mathcal{X}$, and then apply a *regularization* according to Definition 2. The *i.i.d.* assumption is for factorization of the joint likelihood. The optimization problem will be discussed in Section 3.

2.3. Illustrative Examples

2.3.1. Example 1: Composition of Rocks in Geology

In this example, suppose that some rock samples are collected in a geological study in an attempt to analyze their composition. Original representation of each rock sample is a point in $\mathbb{S}^3$ (see Figure 3 left) indicating relative proportion of 3 minerals. The data points demonstrate three peaks that correspond to three substances that have fixed compositions in terms of the minerals. These peaks are formed because the formation of different substances depends on certain geological factors that vary from site to site. Hence a particular substance tends to dominate rock samples collected from some particular site. The substances had been decomposed by the chemical tests on the rocks, so that we only observe proportions of minerals.

Given the target dimension of three, DCA obtains a new representation of the rock samples (see Figure 3 right). The learned new components correspond to three underlying substances in the rock samples. Three peaks are found near the vertices of the simplex, which indicates that the new *components* are "decorrelated" in the sense that the samples tend to be

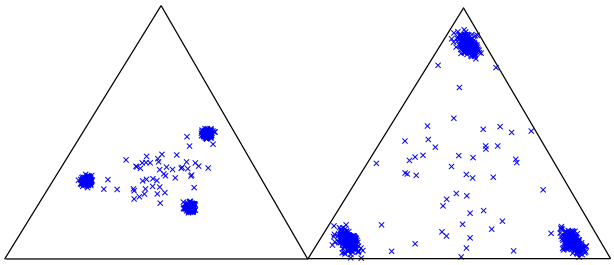

Figure 3. Left: synthetic data, composition of rock samples (small 'x') in terms of the old *components*. Right: representation in terms of new *components* (right) obtained by optimization algorithm discussed in Section 3.

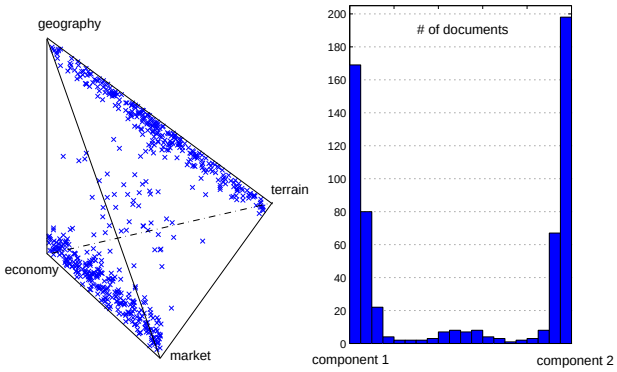

Figure 4. Left: Term frequencies of four words on $\mathbb{S}^4$, each small 'x' denotes a document. The data are synthetic. Right: new representation obtained by the optimization algorithm discussed in Section 3. The histogram illustrates the distribution of documents on $\mathbb{S}^2$.

explained by individual *components* instead of linear combinations of multiple *components*. This effect of de-correlation could be interpreted analogous to PCA. In PCA, we diagonalize the covariance matrix in order that variance in data is separately "explained" by individual variables rather than linear combinations of multiple variables. In our representation, we reveal more information about the rocks' substances because the individual components are easier to explain in further statistical analysis. In contrast, we note that PCA cannot be used to solve this rock analysis problem because by its nature this problem cannot be resolved through an orthogonal transformation.

2.3.2. Example 2: Term Frequencies in Document Retrieval

We consider a simplified bag-of-words model for document retrieval, where relative frequency values of four terms are counted in a set of documents. Each document is represented as a point in $\mathbb{S}^4$ (see Figure 4 left).

Predictably, many documents would mention both "economy" and "market" a lot, and many documents would mention both "terrain" and "geography" a lot, which gives rise to two ridge-shaped modes, corresponding to two underlying classes in these documents (one concerns economical issues, and the other discusses geological issues). Reducing the dimensionality is very likely to boost the prediction performance in classification tasks because it helps avoid overfitting (the curse of dimensionality), especially in more sophisticated high-dimensional document datasets.

Given the target dimension of two, DCA identifies two latent *components* (see Figure 4 right). The projection actually merges two pairs of semantically close *components*, and the resulting representation best preserves the information that distinguishes the two classes. Note that as an unsupervised approach, DCA cannot see any class label—all it does is minimizing the Dirichlet correlation. Although applying PCA to this toy case may have similar effects, our approach greatly outperforms PCA in higher dimensional cases, because it is specially designed for compositional data (as shown on a real-world dataset in Section 4.2).

3. Optimization

The optimization problem of DCA as defined in (6) lacks an explicit analytical loss function. Moreover, the *regularization* operator adds to the difficulty in identifying gradients or judging convexity in the parameter space.

Maximum likelihood estimation of Dirichlet precision can be carried out efficiently (Minka, 2003). The solution space is closed with respect to weighted average (Proposition 3), which motivates us to use the *genetic algorithm* (Goldberg, 1988), in which the weighted average serves as the *crossover* operator[3]. Although *genetic algorithm* is generally inefficient, it is still tractable with additional acceleration tricks. Nevertheless, genetic algorithm is just one of many choices in the optimization of DCA.

The algorithm is formalized in Algorithm 1, where "BR" is abbreviation for balanced rearrangement matrix; "DC" is abbreviation for Dirichlet correlation; "MAX" is the maximum number of iterations allowed; "SIZE" is the size of population. The *fitness* score is

[3]We do not use the *mutation* operator in our algorithm.

  Find minimum DC in P_{iter}
  if converged **then**
    break
  end if
  Put the BR with minimum DC into P_{iter+1}
  Compute *fitness* score for all BR
  Reduce SIZE
  for $j = 1$ **to** SIZE $- 1$ **do**
    Sample two BR from P_{iter}, probability proportional to their *fitness* scores
    Put their average, weighted by *fitness* scores, into P_{iter+1},
  end for
end for

computed as:

$$fitness = -\log(\min(\frac{DC}{\text{median } DC}, 1)), \qquad (7)$$

where "median DC" is the median Dirichlet correlation in current population. This is a key trick to accelerate the algorithm, because it prunes half of the population by assigning zero *fitness* scores. The pruning is based on the intuitive observation that: 1) the *regularization* factor is a continuous function of the BR matrix given the dataset $\mathcal{X}$; 2) the Dirichlet precision is a continuous function of the *regularization* factor and BR matrix. Hence the target function is approximately continuous and smooth in the solution space. Retaining 50% good candidate solutions in each generation is sufficient. Since the total diversity of the population diminishes, the population size could be reduced accordingly in each iteration.

4. Experimental Results

4.1. The Llobregat River Basin Hydrogeochemistry

We investigate the hydrogeochemistry dataset from the Llobregat River Basin (northeast Spain)[4] with DCA. This dataset had been studied in (Tolosana-Delgado, 2005) using factor analysis under the log-ratio framework, with which they obtained interpretable latent factors. Applying our approach on this dataset yields even more interesting results.

[4]This dataset "Hydrochem.txt" is available online at: http://rss.acs.unt.edu/Rdoc/library/compositions/data/

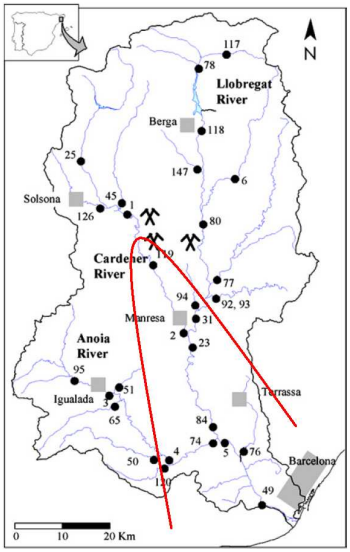

Figure 5. Sampling sites in the Llobregat River Basin, classified as "upstream" and "downstream" by the red line.

The dataset consists of 485 samples, each being a 14 dimensional compositional vector representing the concentrations of major ions (e.g. H^+, Na^+, NH_4^+, Cl^-, HCO_3^-, etc.) in the water samples. These samples are collected monthly over a certain period of time from 31 sites in the Llobregat River Basin. We classify the sites into two categories: *upstream* and *downstream*, separated by the red line (see figure 5). The 485 water samples are also classified into two categories according to the site from which they had been collected.

DCA is applied on this dataset with a target dimension of three to facilitate visualization. Visualization of high-dimensional data is crucial in disciplines such as geology, chemistry, etc., because it facilitates further analysis by domain experts.

Interestingly, although there is no location information in this dataset (locations are known from labels unseen for DCA), the two categories are well separated in the latent representation (see Figure 6). This underlying pattern is attributable to various geological and anthropogenic factors thoroughly described in (Tolosana-Delgado, 2005), which we omit here for brevity. These new patterns that are discovered by DCA was not reported in (Tolosana-Delgado, 2005), a fact highlighting the power of DCA in knowledge discovery.

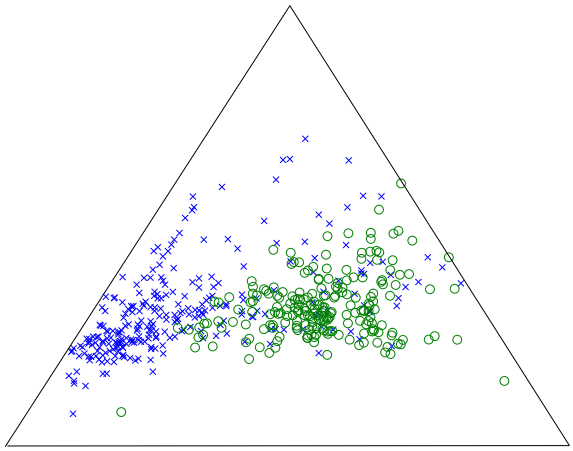

Figure 6. Latent representation of the hydrogeochemistry dataset on $\mathbb{S}^3$, learned by DCA. The two classes are well separated, see text for explanation.

4.2. Twenty newsgroups dataset

Using the 20 newsgroup data set [5], we consider a classification task of the "alt" class (798 documents) versus the "misc" class (965 documents). We show that our approach avoids overfitting and improves the prediction accuracy when we train the classifiers with a very small number of training examples, in which case the problem of overfitting could be the severest. In the preprocessing step, the "stop words" and scarce words with less than 10 total occurrences are removed. Thus the dataset we used consists of 1763 documents, where each document is represented by a 2711 dimensional sparse vector of relative word frequency values, which satisfy the constant-sum constraint.

The dimensionality is reduced to K with DCA, PCA, and LDA (latent Dirichlet allocation) (Blei, 2003), respectively. We then used a linear SVM to classify these low dimensional representations as well as the original high dimensional data for comparison. Performance results on the test test dataset are plotted with a varying number of training samples (see Figure 7) for target dimensions of $K = 10$, 20, and 50. Different choices of training data may affect the prediction performance, especially in our case where the size of training set is very small. So the performance results in our experiments are averaged over 500 different random choices of the training set. The advantage of DCA in improving prediction is clear when comparing to other techniques with the same target dimensionality, especially with very small training sets.

[5]The dataset is available at http://people.csail.mit.edu/ jrennie/20Newsgroups/

Although the highly specialized technique for bag-of-words data (LDA) beats our approach in some cases, these cases are extreme (the target dimension is 10 and the number of training samples exceeds 30). The results also justify the applicability of DCA on sparse compositional data, for which the traditional *log-ratio* framework (Aitchison, 1982) is not applicable.

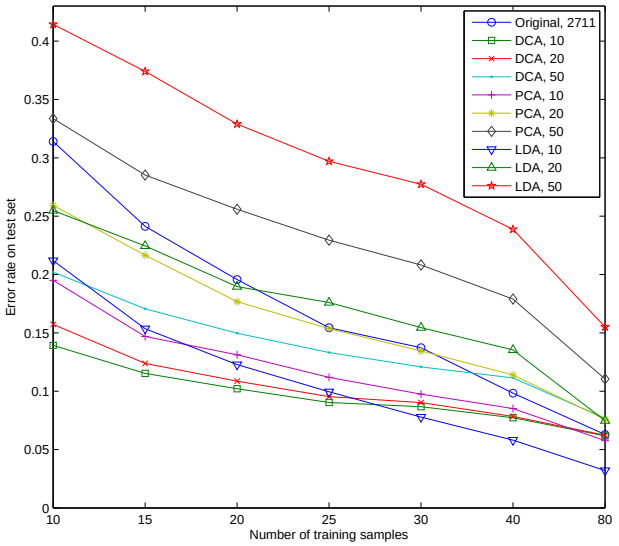

Figure 7. The "alt" versus "misc" classification performances using linear SVM. Representations with different dimensionality obtained by different methods are compared. E.g., "LDA, 10" indicates 10 dimensional representation obtained by latent Dirichlet allocation.

To make the optimization step tractable for high-dimensional data, we employed several variations in implementation. In order to reduce the solution space, we used a restricted family of transformations rather than general rearrangements. The restricted family is "amalgamations" (binary rearrangement matrices) introduced in (Aitchison, 1982), and the "balanced" requirement is not imposed. This is inspired from the toy example in Section 2.3, for which the optimal rearrangement matrix is actually an amalgamation.

5. Related Work

Feature extraction for de-correlating and reducing variables date back to K. Pearson's original idea (Pearson, 1901) on PCA. There have been a large body of research papers in the statistics and machine learning literature that address this issue, including ICA (Hyvärinen, 2001), kernel PCA (Schölkopf, 1998), etc. Directed and undirected graphical models (Blei, 2003; Welling, 2004) have also been exploited to handle this

problem, where they treat the target variables as latent nodes in the graph. Besides, the manifold assumption motivates a family of non-linear methods (Tenenbaum, 2000; Roweis, 2000), in which they use coordinates on the manifold to encode original high dimensional data.

Statistical analysis of compositional data has received a lot of concern since J. Aitchison's seminal work (Aitchison, 1982). The author proposed to transform from $\mathbb{S}^N$ to $\mathbb{R}^{N+1}$ by *log-ratio* functions, and transplanted PCA to $\mathbb{S}^N$ under the log-ratio framework (Aitchison, 1983). Our approach is an alternative PCA-like technique on $\mathbb{S}^N$, which focuses on different statistical properties (Dirichlet correlation) of data. Moreover, the *log-ratio* is not well-defined for sparse compositional data. In contrast, our approach do not have this problem. Algebraic-geometric structures (Pawlowsky-Glahn, 2001) on the simplex had been investigated, which facilitate analysis of relationship among compositional data points. Unsupervised metric learning for compositional data had been addressed in the machine learning literature (Lebanon, 2003; Wang, H.-Y., 2007).

6. Discussion

A major unresolved issue in the DCA framework is the theoretical implication of the *regularization* operator (see Figure 1), which is not compatible with the popular *log-ratio* framework, because it does not preserve the ratio between different *components*. Nevertheless, the *regularization* operator preserves Euclidean geometrical properties such as distance (allowing a constant scaling factor) and angle. Although these properties are not emphasized in the log-ratio framework, they are nonetheless meaningful as long as classification or regression tasks are concerned.

Abstract

In multiple instance learning (MIL), how the instances determine the bag-labels is an essential issue, both algorithmically and intrinsically. In this paper, we show that the *mechanism* of how the instances determine the bag-labels is different for different application domains, and does not necessarily obey the traditional assumptions of MIL. We therefore propose an *adaptive* framework for MIL that adapts to different application domains by learning the domain-specific *mechanisms* merely from labeled bags. Our approach is especially attractive when we are encountered with novel application domains, for which the *mechanisms* may be different and unknown. Specifically, we exploit mixture models to represent the composition of each bag and an adaptable kernel function to represent the relationship between the bags. We validate on synthetic MIL datasets that the kernel function automatically adapts to different *mechanisms* of how the instances determine the bag-labels. We also compare our approach with state-of-the-art MIL techniques on real-world benchmark datasets.

1. Introduction

Multiple instance learning (MIL) has become an active area of investigation in machine learning since it was first put forward for drug activity prediction(Dietterich, 1997). In MIL, we consider "instance-bags", which are unordered sets of instances. Each instance is represented as a feature vector. According to the original definition, a bag of instances is labeled as positive if at least one of its instances is positive, and it is labeled as negative if all of its instances are negative. In real-world applications of MIL, the focus is on assigning labels to bags rather than instances. Many methods have been proposed to solve the MIL problem, including Axis-Parallel Rectangles (Dietterich, 1997), Diverse Density (Maron, 1998), EM-DD (Zhang, 2001), Citation k-NN (Wang, J., 2000), and variations of SVM (Andrews, 2003; Gartner, 2002; Kwok, 2007; Bunescu, 2007).

A major difficulty of MIL arises from the ambiguity caused by not knowing which instances determined the bag labels. According to the original definition of MIL (Dietterich, 1997), a bag can be labeled as positive based on just one positive instance in it. However, since the instance-labels are unknown in the outset, we need to leverage the available information conveyed by all instances to determine the label of a bag. This motivates us to carefully examine the underlying *mechanism* of how the bag labels are determined by the instances within the bag.

Firstly, examining the algorithmic aspect of the *mechanism* we could conclude that, even if there is an unambiguous intrinsic *mechanism* (*e.g.*, a bag is positive *iff* at least one instance is positive), it can hardly benefit a MIL algorithm deterministically due to the unknown instance labels. Instead, possible instance labels are usually leveraged in a probabilistic manner. For example, (Zhang, 2001) computes posteriors of instance labels in an EM-like algorithm; (Kwok, 2007) marginalizes a kernel function over possible instance

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

labels. In other words, virtually *all* instances in a bag can contribute to a bag label.

Our second observation is that the intrinsic *mechanisms* of how the instances determine the bag-labels can vary in different application domains of MIL; these *mechanisms* do not necessarily obey the original definition of MIL. Instead, they must be relaxed to allow more flexibility. Recall that in the original definition of MIL, a bag is positive *iff* at least one instance is positive. This clearly defines MIL problems in some applications such as drug activity prediction, because the "positive" instances in these applications could serve as *strong* or even *definite* evidence for labeling a bag as positive. For example, if a molecule binds well to some target protein (positive instance), the molecule undoubtedly binds well and the associated bag is labeled positive. However, in other applications, this restriction is too limiting. In many real world applications, the bag-label determining *mechanism* can allow a bag label to be negative even when there exists a positive instance in it; such relationship between instances and bags should be probabilistic in nature. For example, in content-based image retrieval (Zhang, 2002), images are represented as "bags" of localized features (regions). The low-level instance representation, describing color, texture, and shape, may have no direct correspondence to high-level image-labels (*e.g.*, human faces, buildings, the sky *etc.*). Instead, they only serve as *weak* evidences that should be integrated together to determine the image-label. Intuitively, the localized image feature descriptors can be "a region appears like a human eye or a region appears like a human nose". The decision to label an image as a "human face" should leverage many such pieces of evidence, because a non-face images (negative bags) can also contain some other object that appears like a human nose (positive instance). In this example, a positive instance can be found in a negative bag, which violates the traditional definition of MIL. Therefore, our solution to the MIL problem should be flexible enough to allow for different bag-label determining *mechanisms*.

The *mechanisms* of how the instances determine the bag labels is an essential issue in MIL. However, to our best knowledge, none of existing MIL techniques has explicitly addressed the issue of the cross-domain differences of this *mechanism*. In this paper, we propose a new framework for MIL that includes the original definition of MIL as a special case, and yet allows for more flexible cases. Our solution is to automatically *adapt* the instance-to-bag-label *mechanism* to accommodate the differences in various formulations of the MIL problems. Our main contribution is to capture the *mechanism* by a simple model, embodied in a parameter p of a kernel function (Schölkopf, 2001) defined over the bags. This parameter is learned from labeled bags in the training data without *a priori* knowledge of that *mechanism*.

Our *adaptive* framework for MIL is supported by a number of motivations. First, explicitly describing the *mechanism* (as (Dietterich, 1997) did for drug activity prediction) for an application domain calls for strong domain knowledge. Second, a hand-crafted *mechanism* could be subjective and unreliable. Third, designing different MIL methods for different application domains is inefficient, given the large number of applications that has a potential to be formalized as MIL. Thus it is better to design an *adaptive* formalism for this task.

In our framework, a two-phase learning procedure is adopted to characterize a kernel function on the bags, which can be used as a distance function in classification via algorithms such as SVM, or as a similarity measure for information retrieval.

The first learning phase exploits the unlabeled instances with a mixture model to characterize the intrinsic structures of the feature space of instances. Each bag is represented by some *aggregate posteriors* on a mixture of components, which summarizes the bag as compositions of different "patterns".

While the first learning phase adapts to different characteristics of the instance space, the adaptive nature of our approach is shown mostly in the second learning phase. We define a kernel mapping by computing a power p of the aggregate posteriors. As we will show in the rest of the paper, the parameter p explicitly captures the domain-specific *mechanism* of how the instances determine the bag-labels, where the parameter p is learned by optimizing an objective function defined over the labeled bags. In this way, our framework can adapt MIL algorithms to different instance-to-bag-label *mechanisms* in many application domains, even if we have no *a priori* knowledge about them.

2. The p-Posterior Mixture Model Kernel

2.1. Aggregate posteriors

We use lowercase $\mathbf{x}$ to denote instances, and uppercase $\mathbf{X}$ to denote bags. In MIL, we are provided with a training set $\{(\mathbf{X}_i, y_i)\}_{i=1}^N$ consisting of labeled bags, where $y_i \in \{+1, -1\}$ are labels[1]. Let $\{\mathbf{x}_i\}_{i=1}^n$

[1] Although we address two-class classification in this paper, it is straightforward to generalize our approach to multi-class classification and continuous-output regression.

be all instances available for the learning algorithm, where each instance $\mathbf{x}_i$ resides in a feature space $\mathbb{R}^D$. The training set includes both the instances in labeled bags and possibly a large number of other unlabeled instances, because the unlabeled instances are often much easier to obtain than the labeled bags in many applications[2]. The distribution of instances in the sampling domain could demonstrate sophisticated patterns due to the underlying unknown *generative model* of instances. Previous approaches usually impose over simplified assumptions on the generative model; for example, APR (Dietterich, 1997) assumes that "positive" instances reside in an axis-parallel rectangle, and Diverse Density (Maron, 1998) assumes that the "positive" instances demonstrate a Gaussian-like pattern around some concept point. In our approach, a mixture model approximates the underlying generative model of instances, which is much more flexible and informative. We make no additional constraint on the instances used; the instances are chosen for training as long as they are from the same underlying generative model. Note that this is different from semi-supervised learning (Zhu, 2005), for which we usually require the unlabeled samples to come from the specific classes of labeled samples.

We approximate the underlying generative model of instances by several mixture models in $\mathbb{R}^D$. Fitting the mixture models to all unlabeled instances with a given number of mixture components K results in the optimal parameters and weights $\{(\mathbf{\Lambda}_i, w_i)\}_{i=1}^K$. For Gaussian mixture models (GMM) adopted in our experiments, we have $\{(\mu_i, \mathbf{\Sigma}_i, w_i)\}_{i=1}^K$.

Given the above, the likelihood of an instance $\mathbf{x}$ under the i-th mixture component is denoted as:

$$p_i(\mathbf{x}) := \Pr(x|\mathbf{\Lambda}_i) \tag{1}$$

For a bag of instances $\mathbf{X} = \{\mathbf{x}_i\}_{i=1}^M$ and a mixture model $\{(\mathbf{\Lambda}_i, w_i)\}_{i=1}^K$, we define the aggregation posteriors of a bag on the mixture components:

Definition 1 (Aggregate Posteriors) *The **aggregate posteriors** of a bag of instances $\mathbf{X} = \{\mathbf{x}_i\}_{i=1}^M$ with respect to the mixture model $\{(\mathbf{\Lambda}_i, w_i)\}_{i=1}^K$ is denoted as:*

$$\psi(\mathbf{X}) := \mathcal{C} \sum_{i=1}^{M} \left(\frac{w_1 p_1(\mathbf{x}_i)}{\sum_{j=1}^K w_j p_j(\mathbf{x}_i)}, \cdots, \frac{w_K p_K(\mathbf{x}_i)}{\sum_{j=1}^K w_j p_j(\mathbf{x}_i)} \right)$$

where $\mathcal{C}$ is a normalizing operator indicating dividing a vector by the sum of all its elements.

[2]For example, we can extract image regions (instances) in thousands of arbitrary unlabelled images collected from the Internet. This is much easier than manually labeling even a small number of these images which are bags.

It is straightforward to validate that $\frac{w_j p_j(\mathbf{x}_i)}{\sum_{j=1}^K w_j p_j(\mathbf{x}_i)}$ is the posterior probability that $\mathbf{x}_i$ is generated from the j-th mixture component. The normalizing operator $\mathcal{C}$ is induced such that the kernel function (defined later) would be unbiased towards sizes of bags; "large" bags and "small" bags are treated equally. The aggregate posteriors summarize frequencies of different "pattern" within the bag, which could be viewed as a "Bayesian" histogram because a frequentist would replace the K-component mixture model with K-means clustering, and replace the posteriors with a deterministic vote. Thus, the aggregate posteriors degenerate to a normalized histogram.

The first learning phase of our framework is itself endowed with much flexibility and can be customized for specific situations. For example, in some applications the number of available unlabeled instances may be small. We therefore have to reduce the degree of freedom in the mixture model accordingly. For example, we could add the restriction that the components of the Gaussian mixture model have diagonal covariance, or even isotropic covariance[3]. When the dimensionality of the instance space is too high to fit a Gaussian mixture model, we can also adopt the frequentist's point of view by representing the training bags as histograms obtained by K-means clustering of the instances.

2.2. The order-p kernel mapping

We have defined a mapping from bags of instances $\mathbf{X}$ to aggregate posteriors $\psi(\mathbf{X}) \in \mathbb{S}^K$, where $\mathbb{S}^K$ is the $(K-1)$-simplex that consists of all positive constant-sum real vectors. The aggregate posteriors summarize frequencies of different patterns[4] within the bag. For example, consider a toy case where $\mathbf{X}_1$, $\mathbf{X}_2$, and $\mathbf{X}_3$ are three bags in some MIL problem, and we have:

$$\begin{aligned}
\psi(\mathbf{X}_1) &= (0, \quad 0.3, \quad 0.5, \quad 0.2), \\
\psi(\mathbf{X}_2) &= (0, \quad 0.2, \quad 0.6, \quad 0.2), \\
\psi(\mathbf{X}_3) &= (0.2, \quad 0.1, \quad 0.6, \quad 0.1).
\end{aligned}$$

We will carefully examine this toy case for an intuitive understanding of our approach. Aggregate posteriors of these bags all demonstrate relatively high values on the third mixture component, and low values on others. According to the definition of aggregate posteriors, the bags all have "major patterns" represented by the third mixture component, with a lot

[3]An isotropic covariance matrix is in the form $\lambda\mathbf{I}$.

[4]The "patterns" are represented by the components of the mixture model.

of instances contributing to that pattern, and "minor patterns" represented by other components, with fewer instances contributing to them.

The kernel function for the bags serves as a similarity measure that affects the decisions in label prediction. Therefore how to define the kernel function depends on the intrinsical *mechanism* that the bag-labels are determined. Since the *mechanism* varies in different application domains, the kernel function should vary accordingly. On one hand, in some applications such as drug activity prediction, positive bags are determined by a few (at least one, actually) positive instances serving as *strong* evidences, and there can be many negative instances in positive bags. Hence the "minor patterns" in the aggregate posteriors are endowed with considerable significance, given that the "major patterns" could be dominated by overwhelming negative instances. On the other hand, in other applications such as image classification, the positive bags are determined by integrating a lot of low-level *weak* evidences from instances. Hence we should focus on the "major patterns" in accordance with the voting-like *mechanism*. The "minor patterns", however, should be underrated because they are attributable to random noise and outliers. For example, in an image classification task, the "minor patterns" could be generated by the image background clutter.

For the toy case, the similarity in minor patterns between $\mathbf{X}_1$ and $\mathbf{X}_2$ is greater than that between $\mathbf{X}_2$ and $\mathbf{X}_3$, but the similarity in major patterns between $\mathbf{X}_2$ and $\mathbf{X}_3$ is greater than that between $\mathbf{X}_1$ and $\mathbf{X}_2$. According to our previous analysis, whether $\mathbf{X}_2$ should be considered more similar to $\mathbf{X}_1$ or $\mathbf{X}_3$ depends on whether we should place more emphasis on major or minor patterns; the latter in turn depends on the domain-specific instance-to-bag-label *mechanism*. To endow the kernel function with such flexibility, we define the p-posterior-mixture-model (*ppmm*) kernel:

Definition 2 (p-Posterior-Mixture-Model Kernel) *The p-posterior-mixture-model (ppmm) kernel function on a pair of bags $\mathbf{X}_1$ and $\mathbf{X}_2$ is defined as*

$$\kappa_p(\mathbf{X}_1, \mathbf{X}_2) := < \psi(\mathbf{X}_1)^p, \psi(\mathbf{X}_2)^p >$$

where $p \in (0, \infty)$, and $< \bullet, \bullet >$ denotes the standard inner-product in $\mathbb{R}^K$.

For the toy case, it is easy to validate that:

$$\begin{aligned} \kappa_p(\mathbf{X}_1, \mathbf{X}_2) &> \kappa_p(\mathbf{X}_2, \mathbf{X}_3), \quad \text{if} \quad p < 1; \\ \kappa_p(\mathbf{X}_1, \mathbf{X}_2) &= \kappa_p(\mathbf{X}_2, \mathbf{X}_3), \quad \text{if} \quad p = 1; \\ \kappa_p(\mathbf{X}_1, \mathbf{X}_2) &< \kappa_p(\mathbf{X}_2, \mathbf{X}_3), \quad \text{if} \quad p > 1. \end{aligned}$$

The parameter p tunes the kernel in a way that a larger p makes it put more emphasis on major patterns, and a smaller p draws more attention to the minor patterns. According to our previous analysis, we can predict that a larger p is preferred in applications such as image classification, and a smaller p is preferred in applications such as drug activity prediction. However these judgements are based on the fact that we already have sufficient *a priori* knowledge about these two application domains. If we encounter a novel application domain of MIL, for which we have no *a priori* knowledge, the p-posterior-mixture-model kernel can be adapted to that novel domain by learning the domain-specific instance-to-bag-label *mechanism*. Learning the *mechanism* is implemented by optimizing an objective function of p defined on labeled bags.

Given labeled bags $\{(\mathbf{X}_i, y_i)\}_{i=1}^N$, $y_i \in \{+1, -1\}$, we learn the parameter p via maximizing the *alignment* (Cristianini, 2002) between the p-posterior-mixture-model kernel and the ideal kernel, which measures the kernel's degree of agreement with the bag-labels:

$$\arg\max_p \frac{< \mathbf{K}_p \, , \, \mathbf{y}\mathbf{y}^T >_F}{\sqrt{< \mathbf{K}_p \, , \, \mathbf{K}_p >_F < \mathbf{y}\mathbf{y}^T \, , \, \mathbf{y}\mathbf{y}^T >_F}} \qquad (2)$$

where $< \bullet, \bullet >_F$ denotes the Frobenius inner-product between matrices. $\mathbf{K}_p$ is the p-posterior-mixture-model kernel matrix.

The optimization problem in (2) is easily resolved by exhaustive search within a certain interval of p (*e.g.* $p \in (0, 3]$ in our later experiments). Because the target function is extremely easy to evaluate and empirically quite smooth, and the search space is only one dimensional, even the exhaustive search is fast and scales linearly with respect to the interval considered.

3. Experiments

3.1. Synthetic data

To empirically validate our analysis in previous sections, we simulate three different multiple instance learning datasets endowed with different instance-to-bag-label *mechanisms*.

MIL dataset 1 is synthesized as follows: 1) randomly generate isotropic-covariance Gaussian mixture models in $\mathbb{R}^D$ with K equally weighted components, from which $N \times S$ instances are sampled; 2) one mixture component is randomly chosen, and the instances generated by that component are labeled as positive; 3) all $N \times S$ instances are randomly put into N bags, with S instances in each; 4) each bag is labeled as positive

iff there is at least one positive instance in it.

MIL dataset 2 and 3 are synthesized similarly. But the instances generated by $\frac{K}{5}$ mixture components are labeled as positive in MIL dataset 2, and each bag is labeled as positive *iff* positive instances in the bag exceed 20%. The instances generated by $\frac{K}{2}$ mixture components are labeled as positive in MIL dataset 3, and each bag is labeled as positive *iff* positive instances in the bag exceed 50%.

Although the synthetic datasets are endowed with different instance-to-bag-label *mechanisms*, all other aspects of these datasets are the same, which can *not* be exploited by the algorithm to distinguish these datasets. They all have approximately the same ratio of positive and negative bags if K and S are properly chosen. Although these tasks have different ratios of positive and negative instances, the instance labels are kept from the learning algorithm, which only observe 50%-50% bag-labels. Our approach is expected to discover the *mechanism* difference among these datasets in such a challenging setting. Moreover, in the first learning phase, the number of mixture components is deliberately set to be different from K, in order to simulate the fact that the characteristics of the underlying true generative model are usually unknown.

We repeated this experiment for many different choices of the bag size S, mixture model size K, instance space dimensionality D, and we observed that the optimal p value is almost always the smallest for MIL dataset 1, intermediate for MIL dataset 2, and the largest for MIL dataset 3. In Figure 1 we plotted the kernel alignment as a function of p in a typical run of the experiment with $K = 20$, $D = 5$, $S = 13$, and total number of bags $N = 200$. Note that this specific setting results in approximately the same number of positive bags and negative bags in all datasets.

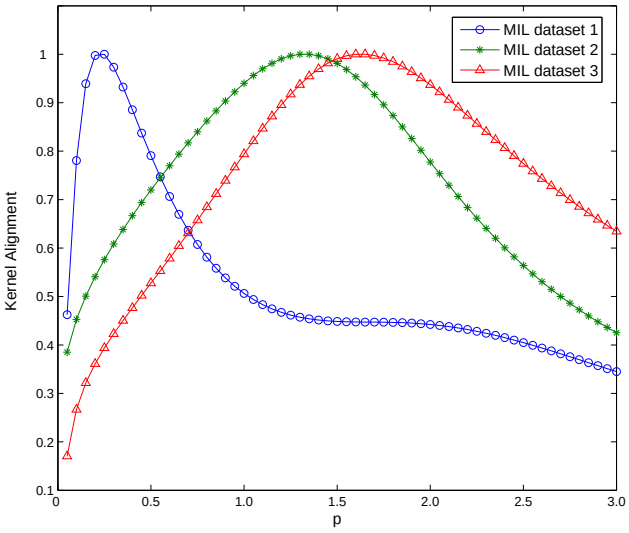

Figure 1. p versus kernel alignment in synthetic MIL dataset 1, 2, and 3. Kernel alignment values are normalized by its maximum value in either dataset. The optimal p values in these datasets justified our previous analysis.

3.2. MIL benchmark datasets

We tested our method on standard MIL benchmark datasets[5] (Andrews, 2003), which consist of MIL tasks in various application domains including drug activity prediction, image classification, and text classification.

3.2.1. Drug activity prediction

The concept of multiple instance learning had been originated from the application of drug activity prediction. In this application, the molecules are regarded as bags, and various shapes a molecule can adopt constitute instances within the bag. A molecule is considered a "positive" bag if it binds well to some target protein, which is true if at least one of its shapes (instances) binds well. The instances are represented as vectors describing that shape. In bio-chemical experiments, we can only observe whether a molecule binds well or not, but if the molecule binds well, we cannot further identify which shape(s) binds well and contributes to the positive bag-label.

Datasets of drug activity prediction for MIL are MUSK1 and MUSK2. The MUSK1 dataset consists of 47 positive bags, 45 negative bags, and totally 476 instances, each represented as a 166 dimensional vector. The MUSK2 dataset consists of 39 positive bags, 63 negative bags, and totally 6598 instances.

3.2.2. Image classification

Content-based image classification/retrieval is another application domain of multi-instance learning. Its major difficulty arises from the fact that an image consists of not only the object-of-interest, which determines its category label, but also background clutter, which may take up even a larger portion of the image. To segment the object-of-interest from background clutter is yet a challenging open problem in computer vision. A common strategy to perform classification without identifying the object-of-interest beforehand is to represent an image by many localized feature vectors instead of a single global feature description. Each localized feature is computed based on a small region of the image,

[5]The datasets used in this section are available online at http://www.cs.columbia.edu/ andrews/mil/datasets.html

so we could expect that the object-of-interest is captured by a number of local features, even if there are also other irrelevant local features arisen from background clutter. It is therefore quite natural to formalized content-based image classification/retrieval as a multi-instance learning problem, where images are the bags and local features are the instances.

The MIL benchmark dataset includes three image classification tasks—to discriminate images that contain *elephant*, *tiger*, and *fox* from irrelevant images, respectively. Each image (bag) is segmented into a set of regions (instances), and each region is represented as a 230 dimensional vector describing its color, texture, and shape characteristics. Each classification tasks has 100 positive bags and 100 negative bags.

3.2.3. Text classification

Another application domain of multiple instance learning is text classification/retrieval. A document can be divided into a number of segments, which could have different topic focuses. And the category label of the whole document (bag) should be decided by taking into account all these segments (instance), which constitutes a multiple instance learning problem.

The MIL benchmark dataset contains text data chosen from the OHSUMED (Hersh, 1994) dataset on medical issues. We perform two text classification tasks: TREC1 and TREC2. Each consists of 200 positive documents (bags) and 200 negative documents. Each document is segmented into overlapping 50-word-passages, which results in over 3000 passages (instances) in either of the tasks. Each passage is indexed by a sparse high-dimensional (over 60,000 index terms) feature vector.

3.2.4. Results

In order to make our results comparable to previous published results on these datasets, our experiments are conducted in the same way as in most previous works. For each classification task, we use 10-fold cross-validation. Classification accuracies are measured on the 10% hold-out data. Our method is compared with a number of existing multiple instance learning techniques. We replicated the results reported in their original papers for comparison if their results are measured similarly (using 10-fold cross-validation). Some results not available in their papers are marked as N/A (see Table 1).

For our approach (The PPMM Kernel), the only parameter that has to be manually set is the dimensionality K of aggregate posteriors (*i.e.* number of mixture components). We set $K = 30$ for drug activity prediction data and image data, and $K = 40$ for text data, since the instances in the text data have higher dimensionality and there are more labeled bags for training. Note that K is chosen subjectively but not carefully tuned for each task—tuning the parameter for each task could results in higher classification performance but may be impractical in real-world scenarios. Other implementation details of our approach in these experiments are the same as in Section 3.1, except that we adopt K-means clustering and histogram representations for these tasks, because they generally have high dimensional instance representation, and relatively small number of instances. Due to the local-optimal nature of K-means clustering, we tried multiple randomly seeded runs of algorithm, and chose the best one based on their performances on the training set.

One major advantage of our approach is the capacity to utilize a large number of unlabeled instances, but no extra unlabeled instance is available for the benchmark datasets, which implicates that the potential performance of our approach could possibly be underestimated in these experiments. Nevertheless, our approach performs generally better than or comparable with other MIL techniques (see Table 1). Since the benchmark datasets for MIL are rather small (number of bags ranges from tens to hundreds), slight differences in classification accuracy should not be overly emphasized. Instead, the most encouraging result we obtained is the optimal p values learned in these datasets. Note that the p values for drug activity prediction tasks (MUSK1 and MUSK2) are generally smaller than that for image classification tasks (ELEPHANT, TIGER, and FOX). Although the p value learned in the FOX dataset is smaller than other image datasets, we can further observe that all methods perform unsatisfactorily on the FOX dataset, which may indicate that this classification task itself could be impractical, hence the learned p value may be unreliable. Interestingly, comparing Table 1 and Figure 1 we could observe that the p values learned in real-world drug activity prediction tasks are close to that learned in synthetic task 1, and the p values learned in real-world image classification tasks are close to that learned in task 2 and task 3. We can also observe that the p values for text classification tasks (TREC1 and TREC2) are also small; possibly this is because the instance representation in the text domain are also high-level, and serving as *strong* evidences for bag-labels. In contrast, instance representation in the image domain are generally low-level (*e.g.* color, texture, shape), and they can only be considered as *weak* evidences for the

Table 1. Empirical results of multiple instance learning methods, the last row shows the optimal p value learned in each task. MUSK1 and MUSK2 are drug activity prediction datasets. ELEPHANT, TIGER, FOX are image classification datasets. TREC1 and TREC2 are text classification datasets. Best performance in each task is in bold. The average performance over all tasks is shown in the last column.

high-level bag-labels (*i.e.* elephant, tiger, fox).

4. Related Work

The concept of multiple instance learning was originally proposed in (Dietterich, 1997) for the application of drug activity prediction. The author assumes that positive instances all reside in an axis-parallel rectangle (APR), which implicates specific constraints that the shape should satisfy in order to bind well to some target protein. Although this assumption can be appropriate for this specific application, it is not clear how to adapt it to other applications, which may have more complex intrinsic structures in the instance space, and different instance-to-bag-label *mechanisms*.

Diverse Density (DD) (Maron, 1998) is another general framework for MIL. The author assumes that positive instances form a Gaussian-like pattern around some "concept point" in the instance space, which is expected to be close to at least one point in each positive bag and far away from all instances in negative bags. This assumption on the structure of instance space could also be over-simplified for some applications. And the algorithm, by definition, relies on the instance-to-bag-label *mechanism* in the original definition of multiple instance learning.

Citation k-NN adapts the memory based classification method k-NN to MIL, which considers not only the *references*, but also the *citers* as neighbors of a bag in determine its label, in order to be less affected by the negative instances in positive bags. It had been empirically proved to be more robust than standard k-NN. Nevertheless, the role of instance-to-bag-label *mechanism* is not clear in this framework.

Support vector machines (SVM) and the kernel trick (Schölkopf, 2001) have been very successful in traditional supervised learning. There also have been many attempts to apply them to MIL. These works falls into two major categories as summarized in (Kwok, 2007). The first family of methods try to modify the optimization problem of SVM, such as MI-SVM and mi-SVM (Andrews, 2003), which may result in non-convex optimization problems and suffer from local minima. The second family of methods design kernel functions on the bags, including (Gartner, 2002) and (Kwok, 2007). Our approach also falls into the second category, but it possesses a unique characteristic as *adapts* to various application domains with different instance-to-bag-label *mechanisms*.

The aggregate posteriors are essentially positive constant-sum real vectors, which reside in a simplex. Data in a simplex had been addressed from the metric learning perspective (Lebanon, 2003; Wang, H.-Y., 2007), which are related to our approach because the kernel defined for aggregate posteriors also gives rise to a distance metric on the simplex.

The idea of defining a kernel function based on posterior probabilities on mixture models had also been exploited in (Hertz, 2006). The author proposed the *KernelBoost* algorithm for learning with a large number of unlabeled data and few labeled data, in which the weak kernel mappings are defined as posterior probabilities on mixture models.

The two-phase learning scheme in our approach makes use of both unlabeled instances and labeled bags. It

is therefore conceptually related to semi-supervised learning (Zhu, 2005) and self-taught learning (Raina, 2007).

5. Conclusion

In this paper, we proposed a novel framework for *adapting* multiple instance learning to different *mechanisms* of how the instances determine the bag-labels. We showed that this *mechanism* is different in different application domains of multiple instance learning, and our approach well captures this domain-specific *mechanism* through learning with unlabeled instances and labeled bags.

To the best of our knowledge, this paper is the first work that addresses the problem of *adapting* multiple instance learning to different application domains with different instance-to-bag-label *mechanisms*. The major advantage of such a self-adaptive framework lies in that, if we are encountered with some novel application domain, which could be well formalized as multiple instance learning, but we have no *a priori* knowledge about the instance-to-bag-label *mechanisms* in that domain, we can learn the *mechanisms* from labeled bags, and design a kernel function *adapted* to this *mechanism*.

Abstract

Graph transduction methods label input data by learning a classification function that is regularized to exhibit smoothness along a graph over labeled and unlabeled samples. In practice, these algorithms are sensitive to the initial set of labels provided by the user. For instance, classification accuracy drops if the training set contains weak labels, if imbalances exist across label classes or if the labeled portion of the data is not chosen at random. This paper introduces a propagation algorithm that more reliably minimizes a cost function over both a function on the graph and a binary label matrix. The cost function generalizes prior work in graph transduction and also introduces node normalization terms for resilience to label imbalances. We demonstrate that global minimization of the function is intractable but instead provide an alternating minimization scheme that incrementally adjusts the function and the labels towards a reliable local minimum. Unlike prior methods, the resulting propagation of labels does not prematurely commit to an erroneous labeling and obtains more consistent labels. Experiments are shown for synthetic and real classification tasks including digit and text recognition. A substantial improvement in accuracy compared to state of the art semi-supervised methods is achieved. The advantage are even more dramatic when labeled instances are limited.

1. Introduction

Graph transduction refers to a family of algorithms that achieve state of the art performance in semi-supervised learning and classification. These methods incur a tradeoff between a classification function's accuracy on labeled examples and a regularizer term that encourages the function to remain smooth over a weighted graph connecting the data samples. The weighted graph and the minimized function ultimately propagate label information from labeled data to unlabeled data to provide the desired transductive predictions. Popular algorithms for graph transduction include the Gaussian fields and harmonic functions based method (*GFHF*) (Zhu et al., 2003) as well as the local and global consistency method (*LGC*) (Zhou et al., 2004). Other closely related methods include the manifold regularization framework proposed in (Sindhwani et al., 2005; Belkin et al., 2006) where graph Laplacian regularization terms are combined with regularized least squares (*RLS*) or support vector machine (*SVM*) function estimation criteria. These methods lead to graph-regularized variants denoted as Laplacian *RLS* (*LapRLS*) and Laplacian *SVM* (*LapSVM*) respectively. For certain synthetic and real data problems, graph transduction approaches do achieve promising performance. However, this article identifies several realistic settings and labeling situations where this performance can be compromised. An alternative algorithm which generalizes the previous techniques is proposed by defining a joint iterative optimization over the classification function *and* a balanced label matrix.

Even if one assumes the graph structures used in the above methods faithfully describe the data manifold, graph transduction algorithms may still be misled by problems in the label information. Figure 1 depicts several cases where the label information leads to invalid graph transduction solutions for all the aforemen-

tioned algorithms. The top row of Figure 1 shows a separable pair of manifolds where unbalanced label information affects the propagation results. Although a clear separation region is visible between the two manifolds, the imbalance in the labels misleads the previous algorithms which prefer assigning points to the class with the majority of labels. In the bottom row of Figure 1, a non-separable problem is shown where two otherwise separable manifolds are peppered with noisy outlier samples. Here, the outliers do not belong to either class but once again interfere with the propagation of label information. In both situations, conventional transductive learning approaches such as *GFHF*, *LGC*, *LapRLS*, and *LapSVM* fail to give acceptable labeling results.

In order to handle such situations, we extend the graph transduction optimization problem by casting it as a *joint* optimization over the classification function *and* the labels. The optimization is solved iteratively and remedies the instability previous methods seem to have vis-a-vis the initial labeling. In our novel framework, initial labels simply act as the starting value of the label matrix variable which is incrementally refined until convergence. The overall minimization over the continuous classification function and the binary label matrix proceeds by an alternating minimization over each term separately and converges to a local minimum. Moreover, to handle the imbalanced labels issue, a node regularizer term is introduced to balance the label matrix among different classes. These two fundamental changes to the graph transduction problem produce significantly better performance on both artificial and real datasets.

The remainder of this paper is organized as the follows. In Section 2, we revisit the graph regularization framework of (Zhou et al., 2004) and extend it into a bivariate graph optimization problem. A corresponding algorithm is provided that solves the new optimization problem by iterative alternating minimization. Section 3 provides experimental validation for the algorithm on both toy and real classification datasets, including text classification and digital recognition. Comparisons with leading semi-supervised methods are made. Concluding remarks and a discussion are then provided in Section 4.

2. Graph Transduction

Consider the dataset $\mathcal{X} = (\mathcal{X}_l, \mathcal{X}_u)$ of labeled inputs $\mathcal{X}_l = \{\mathbf{x}_1, \cdots, \mathbf{x}_l\}$ and unlabeled inputs $\mathcal{X}_u = \{\mathbf{x}_{l+1}, \cdots, \mathbf{x}_n\}$ along with a small portion of corresponding labels $\{y_1, \cdots, y_l\}$, where $y_i \in \mathcal{L} = \{1, \cdots, c\}$. For transductive learning, the objective is to infer the labels $\{y_{l+1}, \cdots, y_n\}$ of the unlabeled data $\{\mathbf{x}_{l+1}, \cdots, \mathbf{x}_n\}$, where typically $l << n$. The graph transduction methods define an undirected graph represented by $\mathcal{G} = \{\mathcal{X}, \mathcal{E}\}$, where the set of node or vertices is $\mathcal{X} = \{\mathbf{x}_i\}$ and the set of edges is $\mathcal{E} = \{e_{ij}\}$. Each sample $\mathbf{x}_i$ is treated as the node on the graph and the weight of edge e_{ij} is w_{ij}. Typically, one uses a kernel function $k(\cdot)$ over pairs of points to recover weights, in other words $w_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$ with the RBF kernel being a popular choice. The weights for edges are used to build a weight matrix which is denoted by $\mathbf{W} = \{w_{ij}\}$. Similarly, the node degree matrix $\mathbf{D} = diag([d_1, \cdots, d_n])$ is defined as $d_i = \sum_{j=1}^{n} w_{ij}$. The binary label matrix $\mathbf{Y}$ is described as $Y \in \mathcal{B}^{n \times c}$ with $\mathbf{Y}_{ij} = 1$ if $\mathbf{x}_i$ has label $y_i = j$ and $\mathbf{Y}_{ij} = 0$ otherwise. This article will often refer to row and column vectors of such matrices, for instance, the ith row and jth column vectors of $\mathbf{Y}$ are denoted as $Y_{i\cdot}$ and $Y_{\cdot j}$, respectively. The graph Laplacian is defined as $\mathbf{\Delta} = \mathbf{D} - \mathbf{W}$ and the normalized graph Laplacian is $\mathbf{L} = \mathbf{D}^{-1/2}\mathbf{\Delta}\mathbf{D}^{-1/2} = \mathbf{I} - \mathbf{D}^{-1/2}\mathbf{W}\mathbf{D}^{-1/2}$.

2.1. Consistent Label Propagation

Graph based semi-supervised learning methods propagate label information from labeled nodes to unlabeled nodes by treating all samples as nodes in a graph and using edge-based affinity functions between all pairs of nodes to estimate the weight of each edge. Most methods then define a continuous classification function $F \in \mathcal{R}^{n \times c}$ that is estimated on the graph to minimize a cost function. The cost function typically enforces a tradeoff between the smoothness of the function on the graph of both labeled and unlabeled data and the accuracy of the function at fitting the label information for the labeled nodes. Such is the case for a large variety of graph based semi-supervised learning techniques ranging from the the mincuts method (Blum & Chawla, 2001), the Gaussian fields and harmonic functions (*GFHF*) method, and the local and global consistency (*LGC*) method. A detailed survey of these methods is available in (Zhu, 2005).

In trading off smoothness for accuracy, both *GFHF* and *LGC* approaches attempt to preserve consistency on the data manifold during the optimization of the classification function. The loss function for both methods involves the additive contribution of two penalty terms the global smoothness Q_{smooth} and local fitness Q_{fit} as shown below:

$$\mathbf{F}^* = \arg\min_{\mathbf{F}} \mathcal{Q}(\mathbf{F}) = \arg\min_{\mathbf{F}} \{Q_{smooth}(\mathbf{F}) + Q_{fit}(\mathbf{F})\} \quad (1)$$

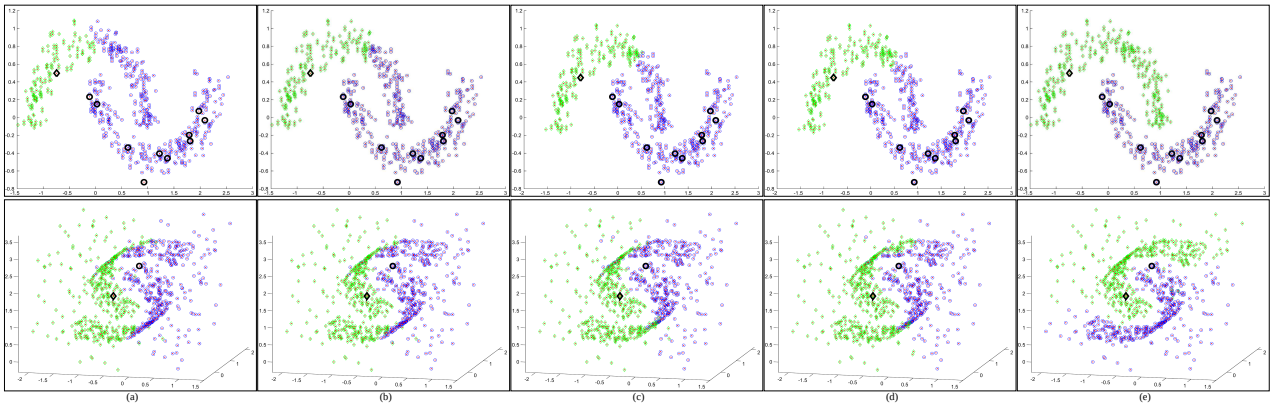

Figure 1. A demonstration with artificial data of the sensitivity graph transduction exhibits for certain initial label settings. The top row shows how imbalanced labels adversely affect even a well-separated 2D two-moon dataset. The bottom row shows a 3D two-moon data where graph transduction is again easily misled by the introduction of a cloud of outliers. Large markers indicate known labels and the two-color small markers represent the predicted classification results. Columns depict the results from (a) the *GFHF* method (Zhu et al., 2003); (b) the *LGC* method (Zhou et al., 2004); (c) the *LapRLS* method (Belkin et al., 2006); (d) the *LapSVM* method (Belkin et al., 2006); and (e) Our method (*GTAM*).

In particular, recall that *LGC* uses an elastic regularizer framework with the following cost function (Zhou et al., 2004).

$$\mathcal{Q}(\mathbf{F}) = \frac{1}{2}\left(\sum_{i,j=1}^{n} w_{ij}\left\|\frac{\mathbf{F}_{i\cdot}}{\sqrt{\mathbf{D}_{ii}}} - \frac{\mathbf{F}_{j\cdot}}{\sqrt{\mathbf{D}_{jj}}}\right\|^2 + \mu\sum_{i=1}^{n}\|\mathbf{F}_{i\cdot} - \mathbf{Y}_{i\cdot}\|^2\right) \tag{2}$$

where the coefficient μ balances global smoothness and local fitting penalty terms. If we set $\mu = \infty$ and use a standard graph Laplacian for the smoothness term, the above framework reduces to the harmonic function formulation as shown in (Zhu et al., 2003).

While *LGC* and *GFHF* formulations remain popular and have been empirically validated in the past, it is possible to discern some key limitations. First, the optimization can be broken up into a separate parallel problems since the cost function decomposes into terms that only depend on individual columns of the matrix $\mathbf{F}$. Because each column of $\mathbf{F}$ indexes the labeling of a single class, such a decomposition reveals that biases may arise if the input labels are disproportionately imbalanced. In practice, both propagation algorithms tend to prefer predicting the class with the majority of labels. Second, both learning algorithms are extremely dependent on the initial labels provided in $\mathbf{Y}$. This is seen in practice but can also be explained mathematically by fact that $\mathbf{Y}$ is starts off extremely sparse and has many unknown terms. Third, when the graph contains background noise and makes class manifolds nonseparable, these graph transduction approaches fail to output reasonable classification results. These difficulties were illustrated in Figure 1 and seem to plague many graph transduction approaches. However, the proposed method, graph transduction via alternating minimization (*GTAM*) appears resilient.

To address these problems, we will make modifications to the cost function in Eq. 1. The first one is to explicitly show the optimization over both the classification function $\mathbf{F}$ and the binary label matrix $\mathbf{Y}$:

$$(\mathbf{F}^*, \mathbf{Y}^*) = \arg\min_{\mathbf{F}\in\mathcal{R}^{n\times c}, \mathbf{Y}\in\mathcal{B}^{n\times c}} \mathcal{Q}(\mathbf{F}, \mathbf{Y}). \tag{3}$$

Where $\mathcal{B}^{n\times c}$ is the set of all binary matrices $\mathbf{Y}$ of size $n \times c$ that satisfy $\sum_j \mathbf{Y}_{ij} = 1$ and, for the labeled data $\mathbf{x}_i \in \mathcal{X}_l$, $\mathbf{Y}_{ij} = 1$ if $y_i = j$. More specifically, our loss function is:

$$\mathcal{Q}(\mathbf{F}, \mathbf{Y}) = \frac{1}{2}\mathrm{tr}\left\{\mathbf{F}^T\mathbf{L}\mathbf{F} + \mu(\mathbf{F} - \mathbf{V}\mathbf{Y})^T(\mathbf{F} - \mathbf{V}\mathbf{Y})\right\} \tag{4}$$

where we have introduced the matrix $\mathbf{V}$ which is a node regularizer to balance the influence of labels from different classes. The matrix $\mathbf{V} = diag(\mathbf{v})$ is a function of the current label matrix $\mathbf{Y}$:

$$\mathbf{v} = \sum_{j=1}^{c} \frac{\mathbf{Y}_{\cdot j} \odot \mathbf{D}\vec{\mathbf{1}}}{\mathbf{Y}_{\cdot j}^T\mathbf{D}\vec{\mathbf{1}}} \tag{5}$$

where the symbol $\odot$ denotes the Hadamard product and column vector $\vec{\mathbf{1}}$ represents $\vec{\mathbf{1}} = [1\cdots 1]^T$. This node regularizer permits us to work with a normalized version of the label matrix $\mathbf{Z}$ defined as: $\mathbf{Z} = \mathbf{V}\mathbf{Y}$.

By definition, we see that the normalized label matrix satisfies $\sum_i \mathbf{Z}_{ij} = 1$. Using the normalized label matrix $\mathbf{Z}$ in a graph regularization allows labeled nodes with high degree to contribute more during the graph diffusion and label propagation process. However, the

total diffusion of each class is kept equal and normalized to be one. Therefore, the influence of different classes is balanced even if the given class labels are imbalanced. If class proportion information is known a priori, it can be integrated by scaling the diffusion with the prior class proportion. However, because of the nature of graph transduction and unknown class prior knowledge, equal class balancing leads to generally more reliable solutions than label proportional weighting. This intuition is in line with prior work that uses class proportion information in transductive inference such as (Chapelle et al., 2007) where class proportion is enforced as a hard constraint on the labels or in (Mann & McCallum, 2007) where such information is used as a regularizer. We next discuss the alternating minimization procedure which is the key modification to the overall framework.

2.2. Alternating Minimization Procedure

In our proposed graph regularization framework, the cost function involves two variables to be optimized. While simultaneously recovering both solutions is intractable due to the mixed integer programming problem over binary $\mathbf{Y}$ and continuous $\mathbf{F}$, we will propose a greedy alternating minimization approach. The first update of the continuous classification function $\mathbf{F}$ is straightforward since the resulting cost function is convex and unconstrained allowing us to recover the optimal $\mathbf{F}$ by setting the partial derivative $\frac{\partial \mathcal{Q}}{\partial \mathbf{F}}$ to be zero. However, since $\mathbf{Y} \in \mathcal{B}$ is a binary matrix and subject to linear constraints of the form $\sum_j \mathbf{Y}_{ij} = 1$, the other step in our alternating minimization requires solving a linearly constrained max cut problem which is NP (Karp, 1972). Due to the alternating minimization outer loop, investigating guaranteed approximation schemes (Goemans & Williamson, 1995) to solve a constrained max cut problem for $\mathbf{Y}$ is unjustified due to the solution's dependence on the dynamically varying classification function $\mathbf{F}$ during the alternating minimization procedure. Instead, we use a greedy gradient based approach to incrementally update $\mathbf{Y}$, while keeping the classification function $\mathbf{F}$ at the corresponding optimal setting. Moreover, because the node regularizer term $\mathbf{V}$ normalizes the labeled data, we also interleave updates of $\mathbf{V}$ based on the revised $\mathbf{Y}$.

Minimization for F :
The classification function $\mathbf{F} \in \mathcal{R}^{n \times c}$ is continuous and its loss terms are convex allowing the minimum to be recovered by zeroing the partial derivative:

$$\frac{\partial \mathcal{Q}}{\partial \mathbf{F}^*} = 0 \implies \mathbf{L}\mathbf{F}^* + \mu(\mathbf{F}^* - \mathbf{V}\mathbf{Y}) = 0$$
$$\implies \mathbf{F}^* = (\mathbf{L}/\mu + \mathbf{I})^{-1}\mathbf{V}\mathbf{Y} = \mathbf{P}\mathbf{V}\mathbf{Y} \quad (6)$$

where we denote $\mathbf{P} = (\mathbf{L}/\mu + \mathbf{I})^{-1}$ as the propagation matrix and assume the graph is symmetrically built (i.e. $\mathbf{L} = \mathbf{L}^T$).

Greedy minimization of Y:
To update $\mathbf{Y}$, first replace $\mathbf{F}$ in Eq. 4 by its optimal vlue $\mathbf{F}^*$ from the solution of Eq. 6.

$$\begin{aligned}\mathcal{Q}(\mathbf{Y}) =& \frac{1}{2}\mathrm{tr}(\mathbf{Y}^T\mathbf{V}^T\mathbf{P}^T\mathbf{L}\mathbf{P}\mathbf{V}\mathbf{Y} \\ &+\mu(\mathbf{P}\mathbf{V}\mathbf{Y} - \mathbf{V}\mathbf{Y})^T(\mathbf{P}\mathbf{V}\mathbf{Y} - \mathbf{V}\mathbf{Y})) \\ =& \frac{1}{2}\mathrm{tr}\left(\mathbf{Y}^T\mathbf{V}^T\left[\mathbf{P}^T\mathbf{L}\mathbf{P} + \mu(\mathbf{P}^T - \mathbf{I})(\mathbf{P} - \mathbf{I})\right]\mathbf{V}\mathbf{Y}\right)\end{aligned} \quad (7)$$

The optimization still involves the node regularizer $\mathbf{V}$ in Eq. 5, which depends on $\mathbf{Y}$ and normalizes the label matrix over columns. Due to the dependence on the current estimate of $\mathbf{F}$ and $\mathbf{V}$, only an incremental step will be taken greedily to reduce $\mathcal{Q}(\mathbf{Y})$. In each iteration, we find position (i^*, j^*) in the matrix $\mathbf{Y}$ and change the binary value of $\mathbf{Y}_{i^*j*}$ from 0 to 1. The direction with largest negative gradient guides our choice of binary step on $\mathbf{Y}$. Therefore, we need to evaluate $\| \bigtriangledown \mathcal{Q}_{\mathbf{Y}} \|$ and find the largest negative value to determine (i^*, j^*).

Note that setting $\mathbf{Y}_{i^*,j^*} = 1$ is equivalent to a similar operation on the normalized label matrix $\mathbf{Z}$ by setting $\mathbf{Z}_{i^*,j^*} = \epsilon, 0 < \epsilon < 1$, and $\mathbf{Y}, \mathbf{Z}$ have one to one correspondence. Thus, the greedy optimization of $\mathcal{Q}$ with respect to $\mathbf{Y}$ is equivalent to greedy minimization of $\mathcal{Q}$ with respect to $\mathbf{Z}$. More formally: $\frac{\partial \mathcal{Q}}{\partial \mathbf{Y}} = \frac{\partial \mathcal{Q}}{\partial \mathbf{Z}}\frac{\partial \mathbf{Z}}{\partial \mathbf{Y}}$ and with straightforward algebra we see that:

$$(i^*, j^*) = \arg\min_{i,j} \frac{\partial \mathcal{Q}}{\partial \mathbf{Y}} = \arg\min_{i,j} \frac{\partial \mathcal{Q}}{\partial \mathbf{Z}} \quad (8)$$

Then we can rewrite the loss function using the variable $\mathbf{Z}$ as:

$$\begin{aligned}\mathcal{Q}(\mathbf{Z}) &= \frac{1}{2}\mathrm{tr}\left(\mathbf{Z}^T\left[\mathbf{P}^T\mathbf{L}\mathbf{P} + (\mathbf{P}^T - \mathbf{I})(\mathbf{P} - \mathbf{I})\right]\mathbf{Z}\right) \\ &= \frac{1}{2}\mathrm{tr}\left(\mathbf{Z}^T\mathbf{A}\mathbf{Z}\right)\end{aligned} \quad (9)$$

where $\mathbf{A}$ represents $\mathbf{A} = \mathbf{P}^T\mathbf{L}\mathbf{P} + (\mathbf{P}^T - \mathbf{I})(\mathbf{P} - \mathbf{I})$. Notice that $\mathbf{A}$ is symmetric if the graph is symmetrically built. We derive the gradient of the above loss function and recover it with respect to $\mathbf{Y}$ as:

$$\frac{\partial \mathcal{Q}}{\partial \mathbf{Z}} = \mathbf{A}\mathbf{Z} = \mathbf{A}\mathbf{V}\mathbf{Y} \quad (10)$$

As described earlier, we search the gradient matrix $\nabla_{\mathbf{Z}}\mathcal{Q}$ to find the minimal element for updating

$$(i^*, j^*) = \arg\min_{\mathbf{x}_i \in \mathcal{X}_u, 1 \le j \le c} \nabla_{\mathbf{Z}_{ij}}\mathcal{Q} \quad (11)$$

Then update the label matrix by setting $\mathbf{Y}_{i^*j^*} = 1$. Because of the binary nature of $\mathbf{Y}$, we simply set $\mathbf{Y}_{i^*j^*} = 1$ instead of using a continuous gradient approach. In the $t+1$th iteration, the node regularizer $\mathbf{v}^{t+1}$ can be recalculated with the updated $\mathbf{Y}^{t+1}$.

The update $\mathbf{Y}$ is indeed greedy. Therefore, it could oscillate and backtrack from predicted labelings in previous iterations without convergence guarantees. We propose a straightforward way to guarantee convergence and avoid backtracking, inconsistency or unstable oscillation in the greedy propagation of labels. Once an unlabeled point has been labeled, its labeling can no longer be changed. Thus, we remove the most recently labeled point (i^*, j^*) from future consideration and only permit the algorithm to search for the minimal gradient entries corresponding to the remaining unlabeled examples. Thus, to avoid changing the labeling of previous predictions, the new labeled node $\mathbf{x}_{i^*}$ will be removed from $\mathcal{X}_u$ and added to $\mathcal{X}_l$.

In the following, we summarize the updating rules from step t to $t+1$ in the alternative minimization scheme. Although the optimal $\mathbf{F}^*$ is being computed in each iteration as shown in Eq. 6, we do not explicitly need to update it. Instead, it is implicitly used in Eq. 8 to directly update $\mathbf{Y}$.

$$\begin{aligned}
\nabla_{\mathbf{Z}}\mathcal{Q}^t &= \mathbf{A}diag(\mathbf{v}^t)\mathbf{Y}^t \qquad (12)\\
(i^*, j^*) &= \arg\min_{\mathbf{x}_i \in \mathcal{X}_u, 1 \le j \le c} \nabla_{\mathbf{Z}_{ij}}\mathcal{Q}^t \\
\mathbf{Y}^{t+1}_{i^*j^*} &= 1 \\
\mathbf{v}^{t+1} &= \sum_{j=1}^{c} \frac{\mathbf{Y}^{t+1}_{\cdot j} \odot \mathbf{D}\vec{\mathbf{1}}}{{\mathbf{Y}^{t+1}_{\cdot j}}^T \mathbf{D}\vec{\mathbf{1}}} \\
\mathcal{X}_l^{t+1} &\longleftarrow \mathcal{X}_l^t + \mathbf{x}_{i^*} \;\; ; \;\; \mathcal{X}_u^{t+1} \longleftarrow \mathcal{X}_u^t - \mathbf{x}_{i^*}
\end{aligned}$$

The procedure above repeats until all points have been labeled.

2.3. Algorithm Summary and Convergence

From the above discussion, our method is unique in that it optimizes the loss function over both continuous-valued $\mathbf{F}$ space and binary-valued $\mathbf{Y}$ space. Starting from a few given labels, the method iteratively and greedily updates the label matrix $\mathbf{Y}$, node regularizer $\mathbf{v}$, and gradient matrix $\nabla_{\mathbf{Z}}\mathcal{Q}$. In each individual iteration, new labeled samples are obtained to drive a better graph propagation in the next iteration. In our approach, we directly acquire new labels instead of calculating $\mathbf{F}^*$ and then conducting a mapping to $\mathbf{Y}$, which is the regular procedure in other graph transduction methods like *LGC* and *GFHF*. This unique feature makes the proposed algorithm very efficient since we only update the gradient matrix $\nabla_{\mathbf{Z}}\mathcal{Q}$ in each iteration. Furthermore, similar to the graph superposition approach introduced in (Wang et al., 2008), the calculation of the node regularizer $\mathbf{v}$ and gradient matrix $\nabla_{\mathbf{Z}}\mathcal{Q}$ can be more efficient by incremental updating as a result of the newly gained labels.

Due to greedy assignment, the algorithm can only loop the alternative minimization (or the gradient computation equivalently) at most $n-l$ times. The update of the graph gradient, finding the largest element in the gradient and the matrix algebra involved can be done efficiently by modifying only a single entry in $\mathbf{Y}$ per loop. Each minimization step over $\mathbf{F}$ and $\mathbf{Y}$ thus requires $\mathcal{O}(n^2)$ time and the total runtime of the greedy *GTAM* algorithm is $\mathcal{O}(n^3)$. Empirically, the value of the loss function $\mathcal{Q}$ decreases rapidly in the the first dozen iterations and achieves steady convergence afterward. This phenomenon indicates that the label propagation loop could be early stopped by solving for the labels from the optimized $\mathbf{F}^*$ (Eq. 6) after only a few iterations. The above algorithm chart summarizes the proposed *GTAM* method.

3. Experiments

In this section, we demonstrate the superiority of the proposed *GTAM* method in comparison to state of the art semi-supervised learning methods over both synthetic and real data. For instance, on the WebKB data, previous work shows that *LapSVM* and *LapRLS* are better than other semi-supervised approaches, such as Transductive SVMs *TSVM* (Joachims, 1999) and ∇*TSVM*. Therefore, we only compare our method with *LapRLS*, *LapSVM* and two related methods, $LapRLS_{joint}$ and $LapSVM_{joint}$ (Sindhwani et al., 2005). In all experiments, we used the same parameter settings reported in the literature. The *GTAM* approach only requires a single μ parameter which controls the tradeoff between the global smoothness and local fitting terms in the cost function. Although our experiments show that *GTAM* is fairly robust to the setting of μ, we set $\mu = 99$ throughout all experiments.

For all real implementations of graph-based methods, one needs a construction method that builds a graph from the training data $\mathcal{X}$, which involves a procedure for computing the weight of links via a kernel or similarity function. Typically, practitioners use RBF kernels for image recognition and cosine distances for text classification (Zhou et al., 2004; Ng et al., 2001; Chapelle et al., 2003; Hein & Maier, 2006). However, finding adequate parameters for the kernel or similarity function, such as the RBF kernel size δ, is not always straightforward particularly if labeled data is scarce. Empirical evidence has shown that the prop-

Algorithm 1 Graph Transduction via Alternating Minimization (*GTAM*)

Input: data set $\mathcal{X} = \{\mathbf{x}_1, \cdots, \mathbf{x}_l, \mathbf{x}_{l+1}, \cdots, \mathbf{x}_n\}$, labeled subset $\mathcal{X}_l = \{\mathbf{x}_1, \cdots, \mathbf{x}_l\}$, unlabeled subset $\mathcal{X}_u = \{\mathbf{x}_{l+1}, \cdots, \mathbf{x}_n\}$, labels $\{y_1, \cdots, y_j, \cdots, y_l\}$, where $y_j \in \mathcal{L} = \{1, \cdots, l\}$. Affinity matrix $\mathbf{W} = \{w_{ij}\}$, node degree matrix $\mathbf{D}$, initial label matrix $\mathbf{Y}^0$;

Initialization:

iteration counter $t = 0$;

normalized graph Laplacian $\mathbf{L} = \mathbf{D}^{-1/2}\mathbf{\Delta}\mathbf{D}^{-1/2}$;

propagation matrix $\mathbf{P} = (\mathbf{L}/\mu + \mathbf{I})^{-1}$;

matrix $\mathbf{A} = \mathbf{P}^T\mathbf{L}\mathbf{P} + (\mathbf{P}^T - \mathbf{I})(\mathbf{P} - \mathbf{I})$;

node regularizer $\mathbf{v}^0 = \sum_{j=1}^{c} \frac{\mathbf{Y}^0_{\cdot j} \odot \mathbf{D}\vec{\mathbf{1}}}{\mathbf{Y}^{0\,T}_{\cdot j}\mathbf{D}\vec{\mathbf{1}}}$.

repeat

Compute graph gradient:

$\mathbf{Z}^t = diag(\mathbf{v}^t)\mathbf{Y}^t$, $\nabla_{\mathbf{Z}^t}\mathcal{Q}^t = \mathbf{A}\mathbf{Z}^t$;

Find the optimal element in $\nabla_{\mathbf{Z}^t}\mathcal{Q}^t$:

$(i^*, j^*) = \arg\min_{\mathbf{x}_i \in \mathcal{X}_u, 1 \le j \le c} \nabla_{\mathbf{Z}_{ij}}\mathcal{Q}^t$;

Update label matrix to obtain $\mathbf{Y}^{t+1}$ by setting:

$\mathbf{Y}^{t+1}_{i^* j^*} = 1$; also $\mathbf{y}_{i^*} = j^*$;

Update node regularizer by:

$\mathbf{v}^{t+1} = \sum_{j=1}^{c} \frac{\mathbf{Y}^{t+1}_{\cdot j} \odot \mathbf{D}\vec{\mathbf{1}}}{\mathbf{Y}^{t+1\,T}_{\cdot j}\mathbf{D}\vec{\mathbf{1}}}$;

Remove $\mathbf{x}_{i^*}$ from $\mathcal{X}_u$: $\mathcal{X}_u^{t+1} \longleftarrow \mathcal{X}_u^t - \mathbf{x}_{i^*}$;

Add $\mathbf{x}_{i^*}$ to $\mathcal{X}_l$: $\mathcal{X}_l^{t+1} \longleftarrow \mathcal{X}_l^t + \mathbf{x}_{i^*}$;

Update iteration counter: $t = t + 1$;

until $\mathcal{X}_u^t = \emptyset$

Output:

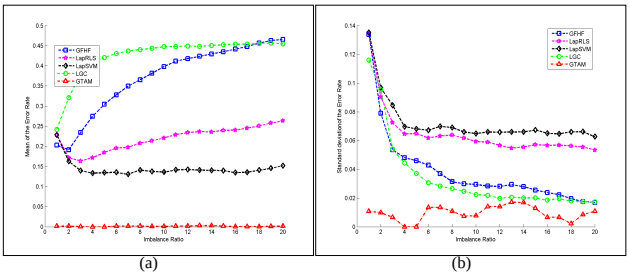
The labels of unlabeled samples $\{y_{l+1}, \cdots, y_n\}$.

agation results highly depend on the kernel parameter selection. Motivated by the approach reported in (Hein & Maier, 2006), we use an adaptive kernel size based on the mean distance of k-nearest neighborhoods ($k = 6$) for the experiments on real USPS handwritten digit data. On the WebKB data, we use the same graph construction suggested by (Sindhwani et al., 2005). For each dataset, the same graph is used for all the compared transductive learning approaches.

3.1. Two Moon Synthetic Data

Figure 1 illustrated synthetic experiments on $2D$ and 3D two-moon data. Despite the near-perfect classification results reported on such datasets in the literature (Zhou et al., 2004), we showed how small perturbations to the problem can have adverse effects on prior algorithms. The prior methods are overly sensitive to locations of the initial labels, ratios of the two-class labels, and the level of ambient noise or outliers.

A more thorough experimental study is also possible



(a) (b)

Figure 2. Performance comparison of *LGC*, *GFHF*, *LapRLS*, *LapSVM*, and *GTAM* on noisy 3D two moon data. Only one label is given for one class, while the other class has a varying number of labels, shown as imbalance ratio on the horizontal axis: (a) The mean of the test error; (b) The standard deviation of the test error.

for the two-moon data by exploring the effect of class imbalance. We start by fixing one class to have one observed label and select r labels from the other class. Here, r is also the imbalance ratio and the range we explore is $1 \le r \le 20$. These experiments use the 3D noisy two-moon data which contain 300 positive and 300 negative sample points as well as 200 additional background noise samples. Multiple round tests (100 trails) are evaluated for each imbalance condition by calculating the average prediction accuracy on the relevant 600 samples. For a fair comparison, we use the same graph Laplacian, which is constructed using k-NN ($k = 6$) neighbors with RBF weights. Moreover, the parameter for *LGC* is set as $\alpha = 0.99$. The parameters for *LapRLS* and *LapSVM* are $\gamma_A = 1, \gamma_I = 1$.

Figure 2 demonstrates the performance advantage of the proposed *GTAM* approach versus the *LGC*, *GFHF*, *LapRLS*, and *LapSVM* methods. From the figure, we can conclude that all the four strawman approaches are extremely sensitive to the initial labels and label class imbalance since none of them can produce perfect accuracy and the error rates of *LGC* and *GFHF* are dramatically increased when the label class becomes more imbalanced *even though more information is being provided to the algorithm.* However, *GTAM* is clearly superior, achieving the best accuracy regardless of the imbalance ratio and despite contamination with noisy samples. In fact only 1 or 2 of the 100 trails for each individual setting of r were imperfect using the *GTAM* method.

3.2. WebKB Dataset

For validation on real data, we first evaluated our method using the WebKB dataset, which has been widely used in semi-supervised learning experiments (Joachims, 2003; Sindhwani et al., 2005). The WebKB dataset contains two document categories, *course* and

non-course. Each document has two types of information, the webpage text content called *page* representation and *link* or pointer representation. For fair comparison, we applied the same feature extraction procedure as discussed in (Sindhwani et al., 2005), obtained 1051 samples with 1840-dimensional *page* attributes and 3000 *link* attributes. The graph was built based on cosine-distance neighbors with Gaussian weights (number of nearest neighbors is 200 as in (Sindhwani et al., 2005)). We compared our method with four of the best known approaches, *LapRLS*, *LapSVM*, and the two problem specific methods, $LapRLS_{joint}$, $LapSVM_{joint}$ reported in (Sindhwani et al., 2005). All the compared approaches used the same graph construction procedure and all parameter settings were set according to (Sindhwani et al., 2005), in other words $\gamma_A = 10^{-6}, \gamma_I = 0.01$. We varied the number of labeled data to measure the performance gain with increasing supervision. For each fixed number of labeled samples, 100 random trails were tested. The means of the test errors are shown in Figure 3.

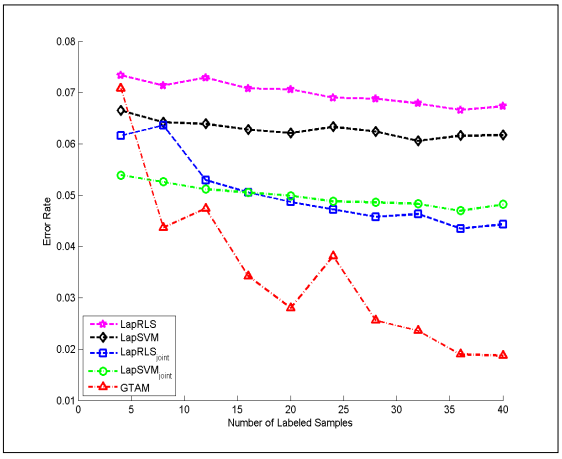


Figure 3. Performance comparison on text classification (WebKB dataset). The horizontal axis represents the number of randomly observed labels (guaranteeing there is at least one label for each class). The vertical axis shows the average error rate over 100 random trials.

As the Figure reveals, the proposed *GTAM* method achieved significantly better accuracy than all the other methods, except for the extreme case when only four labeled samples were available. The performance gain grows rapidly when the number of labeled samples increases, although in some cases the error rate does not drop monotonically.

3.3. USPS digit data

We also evaluated the proposed method in an image recognition task. Specifically, we used the data in (Zhou et al., 2004) for handwritten digit classification experiments. To evaluate the algorithms, we reveal a subset of the labels (randomly chosen and guaranteeing at least one labeled example is available for each digit). We compared our method with *LGC* and *GFHF*, *LapRLS*, and *LapSVM*. The error rates are calculated based on the average over 20 trials.

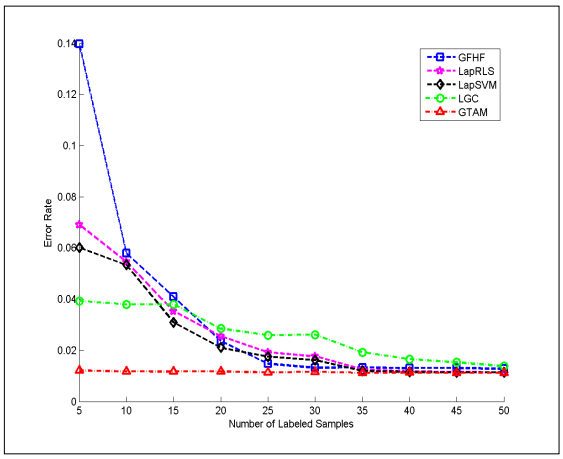

Figure 4. Performance comparison on handwritten digit classification (USPS database). The horizontal axis shows the total number of randomly observed labels (guaranteeing there is at least one label for each class). The vertical axis shows the average error rate over 20 random trials.

From Figure 4, we can conclude that *GTAM* significantly improved the classification accuracy, compared to the other approaches, especially when very few labeled samples are available. The mean accuracies of *GTAM* are consistently low for different numbers of labels and the standard deviation values are also very small (10^{-4} level). This demonstrates that the *GTAM* method is insensitive to the numbers and specified locations of the initially given labels. Only 1% of the test digit images were mislabeled. These failure cases are presented in Figure 5 and are often ambiguous or extremely poorly drawn digits. Compared to the performance on WebKB dataset shown in Figure 3, the USPS digit database experiments exhibit even more promising results. One possible reason is that the USPS digit dataset has relatively more samples (3874) and a lower feature dimensionality (256), compared to the WebKB dataset (which has 1840 samples in 4800 dimensions). Therefore the graph construction procedure is more reliable and the estimation of graph gradients in our algorithm is more robust.

Figure 5. USPS handwritten digit samples which are incorrectly classified.

4. Conclusion and Discussion

Existing graph-based transductive learning methods hinge on good labeling information and can easily be misled if the labels are not distributed evenly across classes, if the choice of initial label locations is varied or if excessive noise or outliers corrupt the underlying manifold structure. These degenerate settings seem to plague real world problems as well, compromising the performance of state-of-the-art graph transduction methods. Our experiments over synthetic data sets (two moon data sets) and real data sets (USPS digits and WebKB) confirm the shortcomings of existing tools.

This article addresses these shortcomings and proposes a novel graph based semi-supervised learning method, graph transduction via alternating minimization (*GTAM*). Therein, both the classification function and the label matrix are treated as variables in a cost function that is iteratively minimized. While the optimal classification function can be estimated exactly, greedy optimization is applied to update the label matrix. The algorithm iterates an alternating minimization between both variables and is guaranteed to converge via a greedy scheme. In each individual iteration, through the graph gradient, the unlabeled node with the largest cost reduction is labeled. We gradually update the label matrix by adding more labeled samples while keeping the classification function at its optimal setting. Furthermore, we enforce normalization of the label matrix to avoid degeneracies. This results in an algorithm that can cope with all the aforementioned degeneracies and in practice achieves significant gains in accuracy while remaining efficient and cubic in the number of samples. Future work will include out of sample extensions of this method such that new data points can be added to the training and test set without requiring a full retraining procedure.

On Multi-View Active Learning and the Combination with Semi-Supervised Learning

Wei Wang WANGW@LAMDA.NJU.EDU.CN
Zhi-Hua Zhou ZHOUZH@LAMDA.NJU.EDU.CN
National Key Laboratory for Novel Software Technology, Nanjing University, China

Abstract

Multi-view learning has become a hot topic during the past few years. In this paper, we first characterize the sample complexity of multi-view *active learning*. Under the α-*expansion* assumption, we get an exponential improvement in the sample complexity from usual $\widetilde{O}(\frac{1}{\epsilon})$ to $\widetilde{O}(\log \frac{1}{\epsilon})$, requiring neither strong assumption on data distribution such as the data is distributed uniformly over the unit sphere in $\mathbb{R}^d$ nor strong assumption on hypothesis class such as linear separators through the origin. We also give an upper bound of the error rate when the α-*expansion* assumption does not hold. Then, we analyze the combination of multi-view active learning and semi-supervised learning and get a further improvement in the sample complexity. Finally, we study the empirical behavior of the two paradigms, which verifies that the combination of multi-view active learning and semi-supervised learning is efficient.

1. Introduction

Learning from labeled data is well-established in machine learning, but labeling the training data is time consuming, sometimes may be very expensive since it may need human efforts. In many machine learning applications, unlabeled data can often be obtained abundantly and cheaply, so there has recently been substantive interest in using large amount of unlabeled data together with labeled data to achieve better learning performance.

There are two popular paradigms for using unlabeled data to complement labeled data. One is *semi-supervised learning*. Some approaches use a generative model for the classifier and employ EM to model the label estimation or parameter estimation process (Dempster et al., 1977; Miller & Uyar, 1997; Nigam et al., 2000); some approaches use the unlabeled data to regularize the learning process in various ways, e.g., defining a graph on the data set and then enforcing the label smoothness over the graph as a regularization term (Belkin et al., 2001; Zhu et al., 2003; Zhou et al., 2005); some approaches use the *multi-view* setting to train learners and then let the learners to label unlabeled examples (Blum & Mitchell, 1998; Goldman & Zhou, 2000; Zhou & Li, 2005). The multi-view setting is first formalized by Blum and Mitchell (1998), where there are several disjoint subsets of features (each subset is called as a *view*), each of which is sufficient for learning the target concept. For example, the web page classification task has two views, i.e., the text appearing on the page itself and the anchor text attached to hyper-links pointing to this page (Blum & Mitchell, 1998); the speech recognition task also has two views, i.e., sound and lip motion (de Sa & Ballard, 1998).

Another important paradigm for using unlabeled data to complement labeled data, which is the focus of this paper, is *active learning* (Cohn et al., 1994; Freund et al., 1997; Tong & Koller, 2001; Melville & Mooney, 2004). In active learning, the learners actively ask the user to label the *most informative* examples and hope to learn a good classifier with as few labeled examples as possible.

There have been many theoretical analyses on the sample complexity of *single-view* active learning. For some simple learning tasks the sample complexity of active learning can be $O(\log \frac{1}{\epsilon})$ which is exponentially improved in contrast to $O(\frac{1}{\epsilon})$ of *passive learning* taking into account the desired accuracy bound ϵ. Unfortunately, such an exponential improvement is not always achievable in active learning. Dasgupta (2006) illustrated that if the hypothesis class $\mathcal{H}$ is linear separators in $\mathbb{R}^2$ and if the data distribution is some density

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

supported on the perimeter of the unit circle, there are some target hypotheses in $\mathcal{H}$ for which $\Omega(\frac{1}{\epsilon})$ labels are needed to find a classifier with error rate less than ϵ, no matter what active learning approach is used. Under the strong assumptions that the hypothesis class is linear separators through the origin, that the data is distributed uniformly over the unit sphere in $\mathbb{R}^d$, and that the learning task is a *realizable* case (i.e., there exists a hypothesis perfectly separating the data), the sample complexity of active learning is $\widetilde{O}(d \log \frac{1}{\epsilon})$ taking into account the desired accuracy bound ϵ (Freund et al., 1997; Dasgupta et al., 2005) [1]. For some known data distribution $\mathbb{D}$ and specific hypothesis class, Dasgupta (2006) gave the coarse sample complexity bounds for realizable active learning. The study of sample complexity of active learning for realizable case without strong assumptions on the data distribution and the hypothesis class remains an open problem.

All the above results were obtained under the *single-view* setting. The first algorithm for active learning in multi-view setting is *co-testing* (Muslea et al., 2000; Muslea et al., 2006). It focuses on the set of *contention points* (i.e., unlabeled examples on which different views predict different labels) and asks the user to label some of them. This is somewhat related to Query-by-Committee (Freund et al., 1997) since *co-testing* also uses more than one learners to identify the most informative unlabeled examples to query, but the typical Query-by-Committee works under a single-view setting while *co-testing* exploits the multi-views explicitly. It was reported that *co-testing* outperforms existing active learners on a variety of real-world domains such as wrapper induction, Web page classification, advertisement removal and discourse tree parsing. To the best of our knowledge, however, there is no theoretical result on the sample complexity of multi-view active learning.

In this paper, we first theoretically analyze the sample complexity of multi-view active learning under the α-*expansion* assumption which is first mentioned by Balcan et al. (2005) and prove that the sample complexity of multi-view active learning can be exponentially improved to $\widetilde{O}(\log \frac{1}{\epsilon})$. A clear advantage is that we do not use strong assumptions which were employed in most previous studies, such as the hypothesis class is linear separators through the origin and the data is distributed uniformly over the unit sphere in $\mathbb{R}^d$. In case the α-*expansion* assumption does not hold, we give an upper bound of the error rate. Second, we analyze the combination of multi-view active learning and semi-supervised learning and get an further improvement in the sample complexity. Finally, we study the empirical behavior of the two paradigms, which verifies that the combination of multi-view active learning and semi-supervised learning is more efficient than pure multi-view active learning.

The rest of this paper is organized as follows. After introducing some preliminaries in Section 2, we analyze the sample complexity of multi-view active learning in Section 3. Then we analyze the sample complexity of the combination of multi-view active learning and semi-supervised learning in Section 4 and study the empirical behavior in Section 5. Finally we conclude the paper in Section 6.

2. Preliminaries

In the multi-view setting, an example x is described with several different disjoint sets of features. Without loss of generality, in this paper we only consider the *two-view* setting for the sake of simplicity. Suppose that the example space $X = X_1 \times X_2$ is with some unknown distribution $\mathbb{D}$, X_1 and X_2 are the two views, and $Y = \{-1, 1\}$ is the label space. Let $c = (c_1, c_2)$ be the underlying target concept, where c_1 and c_2 are the underlying target concepts in the two views, respectively. Suppose that the example space is consistent, that is, there is no such example $x = (x_1, x_2)$ that $c_1(x_1) \neq c_2(x_2)$ in X. Let $\mathcal{H}_1$ and $\mathcal{H}_2$ be the hypothesis class in each view, respectively. For any $h_j \in \mathcal{H}_j$ and $x = (x_1, x_2)$ we say $x_j \in h_j$ if and only if $h_j(x_j) = c_j(x_j)$ $(j = 1, 2)$. In this way any hypothesis in $\mathcal{H}_j$ can be thought of as a subset of X_j.

In each round of iterative multi-view active learning, the learners ask the user to label some unlabeled examples and add them into the labeled training data. These newly labeled examples provide more information about the data distribution. In this paper, we consider the *co-testing*-like Paradigm 1 described in Table 1. In Paradigm 1, the learners ask the user to label some contention points to refine the classifiers. If the confident set of each view is expanding by considering the other view together, Paradigm 1 may succeed. Intuitively, we can use the α-*expansion* assumption to analyze the process.

Suppose $S_1 \subseteq X_1$ and $S_2 \subseteq X_2$ denote the examples that are correctly classified in each view, respectively. Let $Pr(\mathbf{S}_1 \wedge \mathbf{S}_2)$ denote the probability mass on examples that are correctly classified in both views, while $Pr(\mathbf{S}_1 \oplus \mathbf{S}_2)$ denotes the probability mass on examples that are correctly classified only in one view (i.e., examples disagreed by the two classifiers). Now we give

[1] The $\widetilde{O}$ notation is used to hide factors $\log\log(\frac{1}{\epsilon})$, $\log(d)$ and $\log(\frac{1}{\delta})$

Input:
Unlabeled data set $\mathcal{U} = \{x^1, x^2, \cdots, \}$, where each example x^t is given as a pair (x_1^t, x_2^t)
Process:
Ask the user to label m_0 unlabeled examples drawn randomly from $\mathbb{D}$ to compose the labeled data set $\mathcal{L}$
Iterate $i = 0, 1, \cdots, s$
Train two classifiers h_1^i and h_2^i consistent with $\mathcal{L}$ in each view, respectively;
Apply h_1^i and h_2^i to the unlabeled data set $\mathcal{U}$ and find out the contention points set $\mathcal{Q}_i$;
Ask the user to label m_{i+1} unlabeled examples drawn randomly from $\mathcal{Q}_i$, then add them into $\mathcal{L}$ and delete them from $\mathcal{U}$.
Output:
$h_{final} = \text{combine}(h_1^s, h_2^s)$

Table 1. Paradigm 1: Multi-view active learning

our definition on α-*expansion*.

Definition 1 *$\mathbb{D}$ is α-expansion if for any $S_1 \subseteq X_1$, $S_2 \subseteq X_2$, we have*

$$Pr(\boldsymbol{S}_1 \oplus \boldsymbol{S}_2) \geq \alpha \min[Pr(\boldsymbol{S}_1 \wedge \boldsymbol{S}_2), Pr(\overline{\boldsymbol{S}_1} \wedge \overline{\boldsymbol{S}_2})].$$

We say that $\mathbb{D}$ is α-expanding with respect to hypothesis class $\mathcal{H}_1 \times \mathcal{H}_2$ if the above holds for all $S_1 \in \mathcal{H}_1 \cap X_1$, $S_2 \in \mathcal{H}_2 \cap X_2$ (here we denote by $\mathcal{H}_j \cap X_j$ the set $\{h \cap X_j : h \in \mathcal{H}_j\}$ for $j = 1, 2$).

Note that Definition 1 on α-*expansion* is almost the same as that in Balcan et al. (2005). To guarantee the success of iterative *co-training*, they made several assumptions such as that the learning algorithm used in each view is confident about being positive and is able to learn from positive examples only, and that the distribution $\mathbb{D}^+$ over positive examples is expanding. There are many concept classes, however, are not learnable from positive examples only. Apparently, all problems which satisfy the definition of Balcan et al. (2005) also satisfy our definition.

We will make use of the following lemma when deriving our sample complexity bound (Anthony & Bartlett, 1999).

Lemma 1 *Let $\mathcal{H}$ be a set of functions from X to $\{-1, 1\}$ with finite VC-dimension $V \geq 1$. Let $\mathbb{P}$ be an arbitrary, but fixed probability distribution over $X \times \{-1, 1\}$. For any ϵ, $\delta > 0$, if we draw a sample from $\mathbb{P}$ of size $N(\epsilon, \delta) = \frac{1}{\epsilon}(4V \log(\frac{1}{\epsilon}) + 2\log(\frac{2}{\delta}))$, then with probability $1 - \delta$, all hypotheses with error $\geq \epsilon$ are inconsistent with the data.*

3. Sample Complexity of Multi-View Active Learning

There are many strategies to combine the classifiers in Paradigm 1, for example, *weighted voting*, *majority voting* or *winner-take-all* (Muslea et al., 2006). In this paper, we use the following simple combination scheme for binary classification:

$$h_{com}^i(x) = \begin{cases} h_1^i(x_1) & \text{if } h_1^i(x_1) = h_2^i(x_2) \\ \textit{random guess} & \text{if } h_1^i(x_1) \neq h_2^i(x_2) \end{cases} \quad (1)$$

Assuming that the data distribution $\mathbb{D}$ is α-expanding with respect to hypothesis class $\mathcal{H}_1 \times \mathcal{H}_2$, we will analyze how many labels the user should label to achieve classifiers with error rate no larger than ϵ. We consider the iterative process and let $S_1^i \subseteq X_1$ and $S_2^i \subseteq X_2$ where S_1^i and S_2^i corresponds to the classifiers $h_1^i \in \mathcal{H}_1$ and $h_2^i \in \mathcal{H}_2$ in the i-th round, respectively. The initial m_0 unlabeled examples are randomly picked from $\mathbb{D}$ and labeled by the user according to the target concept c. Suppose m_0 is sufficient for learning two classifiers h_1^0 and h_2^0 whose error rates are at most $1/4$ (i.e., $Pr(\mathbf{S}_1^0) \geq 1 - 1/4$ and $Pr(\mathbf{S}_2^0) \geq 1 - 1/4$), and thus $Pr(\mathbf{S}_1^0 \wedge \mathbf{S}_2^0) \geq 1/2$. The α-*expansion* condition suggests

$$Pr(\mathbf{S}_1^0 \oplus \mathbf{S}_2^0) \geq \alpha Pr(\overline{\mathbf{S}_1^0} \wedge \overline{\mathbf{S}_2^0}).$$

In each round of Paradigm 1, the learners ask the user to label some unlabeled examples according to the target concept c and add them into the labeled data set. Then the two classifiers are refined. Some example x in X might be predicted with different labels between the i-th and $(i+1)$-th round. Intuitively, in order to get the classifiers improved in Paradigm 1, the reduced size of confident set should be no more than the size of contention set. Moreover, considering that there is no noise in the labeled data since all the labels are given by the user according to the target concept, and that the amount of labeled training examples are monotonically increasing, the asymptotic performance of PAC learners increase, we can assume that

$$Pr(\overline{\mathbf{S}_j^{i+1}} \mid \mathbf{S}_1^i \wedge \mathbf{S}_2^i) \leq \frac{\alpha Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i)}{16 Pr(\mathbf{S}_1^i \wedge \mathbf{S}_2^i)} \quad (j \in \{1, 2\}) \quad (2)$$

Intuitively, by multiplying the denominator at the right-hand to the left-hand (16 is used for a faster convergence; it can be 2 for an easier understanding), Eq. 2 implies that the total reduced size of confident sets on both views after using the newly labeled contention points is no more than the size of contention set. Apparently, all problems that satisfy the assumption of Balcan et al. (2005) also satisfy Eq. 2. Now we give our main theorem.

Theorem 1 *For data distribution $\mathbb{D}$ α-expanding with respect to hypothesis class $\mathcal{H}_1 \times \mathcal{H}_2$, let ϵ and δ denote the final desired accuracy and confidence parameters. If $s = \lceil \frac{\log \frac{\alpha}{8\epsilon}}{\log \frac{1}{C}} \rceil$ and $m_i = \frac{16}{\alpha}(4V \log(\frac{16}{\alpha}) + 2\log(\frac{8(s+1)}{\delta}))$ $(i = 0, 1, \cdots, s)$, Paradigm 1 will generate a classifier with error rate no more than ϵ with probability $1 - \delta$.*

Here, $V = \max[VC(\mathcal{H}_1), VC(\mathcal{H}_2)]$ where $VC(\mathcal{H})$ denotes the VC-dimension of the hypothesis class $\mathcal{H}$ and constant $C = \frac{\alpha/4+1/\alpha}{1+1/\alpha}$.

Proof. In Paradigm 1, we use Eq. 1 to combine the two classifiers, thus the error rate of the combined classifier h^i_{com} is

$$\begin{aligned} error_{h^i_{com}} &= Pr(\overline{\mathbf{S}_1^i} \wedge \overline{\mathbf{S}_2^i}) + \frac{1}{2} Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i) \\ &\leq Pr(\overline{\mathbf{S}_1^i} \wedge \overline{\mathbf{S}_2^i}) + Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i) \\ &= Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i}) \end{aligned}$$

With $m_0 = \frac{16}{\alpha}(4V \log(\frac{16}{\alpha}) + 2\log(\frac{8(s+1)}{\delta}))$, using Lemma 1 we have $Pr(\overline{\mathbf{S}_1^0}) \leq \frac{\alpha}{16}$ and $Pr(\overline{\mathbf{S}_2^0}) \leq \frac{\alpha}{16}$ with probability $1 - \frac{\delta}{4(s+1)}$. Generally, we have that an arbitrary S_j^i $(j = 1, 2)$ being consistent with the examples in $\mathcal{L}$ has an error rate at most $\frac{\alpha}{16}$ with probability $1 - \frac{\delta}{4(s+1)}$. So we have $Pr(\mathbf{S}_1^i \wedge \mathbf{S}_2^i) \geq 1 - \frac{\alpha}{8}$ with probability $1 - \frac{\delta}{2(s+1)}$. Without loss of generality, consider $0 < \alpha \leq 1$ and therefore $1 - \frac{\alpha}{8} > \frac{1}{2}$. Thus the α-*expansion* condition suggests

$$Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i) \geq \alpha Pr(\overline{\mathbf{S}_1^i} \wedge \overline{\mathbf{S}_2^i}). \tag{3}$$

For $i \geq 1$, the learners ask the user to label m_i unlabeled examples drawn randomly from $S_1^{i-1} \oplus S_2^{i-1}$ according to the target concept c and obtain two new classifiers S_1^i and S_2^i. Similarly, if $m_i = \frac{16}{\alpha}(4V \log(\frac{16}{\alpha}) + 2\log(\frac{8(s+1)}{\delta}))$, using Lemma 1 we have

$$Pr(\overline{\mathbf{S}_j^i} \mid \mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) \leq \frac{\alpha}{16} \quad (j \in \{1, 2\})$$

with probability $1 - \frac{\delta}{4(s+1)}$. So we get that

$$Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i} \mid \mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) \leq \frac{\alpha}{8}$$

with probability $1 - \frac{\delta}{2(s+1)}$. Considering Eq. 2 we have

$$Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i} \mid \mathbf{S}_1^{i-1} \wedge \mathbf{S}_2^{i-1}) \leq \frac{\alpha Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1})}{8 Pr(\mathbf{S}_1^{i-1} \wedge \mathbf{S}_2^{i-1})} .$$

Since

$$\begin{aligned} Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i}) = {} & Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i} \mid \overline{\mathbf{S}_1^{i-1}} \wedge \overline{\mathbf{S}_2^{i-1}}) \\ & \cdot Pr(\overline{\mathbf{S}_1^{i-1}} \wedge \overline{\mathbf{S}_2^{i-1}}) \\ & + Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i} \mid \mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) \\ & \cdot Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) \\ & + Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i} \mid \mathbf{S}_1^{i-1} \wedge \mathbf{S}_2^{i-1}) \\ & \cdot Pr(\mathbf{S}_1^{i-1} \wedge \mathbf{S}_2^{i-1}), \end{aligned}$$

we have

$$Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i}) \leq \frac{\alpha}{4} Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) + Pr(\overline{\mathbf{S}_1^{i-1}} \wedge \overline{\mathbf{S}_2^{i-1}}) .$$

From Eq. 3 we can get that

$$Pr(\overline{\mathbf{S}_1^{i-1}} \wedge \overline{\mathbf{S}_2^{i-1}}) \leq Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1})/\alpha .$$

Thus, considering

$$Pr(\overline{\mathbf{S}_1^{i-1} \wedge \mathbf{S}_2^{i-1}}) = Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) + Pr(\overline{\mathbf{S}_1^{i-1}} \wedge \overline{\mathbf{S}_2^{i-1}}),$$

we have

$$\begin{aligned} & \frac{Pr(\overline{\mathbf{S}_1^i \wedge \mathbf{S}_2^i})}{Pr(\overline{\mathbf{S}_1^{i-1} \wedge \mathbf{S}_2^{i-1}})} \\ \leq {} & \frac{\frac{\alpha}{4} Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) + Pr(\overline{\mathbf{S}_1^{i-1}} \wedge \overline{\mathbf{S}_2^{i-1}})}{Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) + Pr(\overline{\mathbf{S}_1^{i-1}} \wedge \overline{\mathbf{S}_2^{i-1}})} \\ \leq {} & \frac{\frac{\alpha}{4} Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) + Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1})/\alpha}{Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1}) + Pr(\mathbf{S}_1^{i-1} \oplus \mathbf{S}_2^{i-1})/\alpha} \\ = {} & \frac{\alpha/4 + 1/\alpha}{1 + 1/\alpha} . \end{aligned}$$

Now we get

$$\begin{aligned} Pr(\overline{\mathbf{S}_1^s \wedge \mathbf{S}_2^s}) &\leq (\frac{\alpha/4 + 1/\alpha}{1 + 1/\alpha})^s Pr(\overline{\mathbf{S}_1^0 \wedge \mathbf{S}_2^0}) \\ &\leq \frac{\alpha}{8} (\frac{\alpha/4 + 1/\alpha}{1 + 1/\alpha})^s . \end{aligned}$$

So when $s = \lceil \frac{\log \frac{\alpha}{8\epsilon}}{\log \frac{1}{C}} \rceil$ where C is a constant and $\frac{\alpha/4+1/\alpha}{1+1/\alpha} < 1$, we have $Pr(\overline{\mathbf{S}_1^s \wedge \mathbf{S}_2^s}) \leq \epsilon$. In other words, we get a classifier h^s_{com} whose error rate is no more than ϵ with probability $1 - \delta$. □

From Theorem 1 we know that we only need to label $\sum_{i=0}^{s} m_i = O(\log \frac{1}{\epsilon} \log(\log \frac{1}{\epsilon}))$ examples to get a classifier with error rate no more than ϵ with probability

$1-\delta$. Thus, we achieve an exponential improvement in sample complexity from $\widetilde{O}(\frac{1}{\epsilon})$ to $\widetilde{O}(\log\frac{1}{\epsilon})$ as in Dasgupta et al. (2005) and Balcan et al. (2007). Note that we have not assumed a specific data distribution and a specific hypothesis class which were assumed in the studies of Dasgupta et al. (2005) and Balcan et al. (2007). From the proof of Theorem 1 we can also know that the proportion $\frac{\alpha}{16}$ in Eq. 2 can be relaxed to close to $\frac{\alpha}{2}$. Such relaxation will not affect the exponential improvement, but will reduce the convergence speed.

Further, considering that not every data distribution $\mathbb{D}$ is α-expanding with respect to hypothesis class $\mathcal{H}_1 \times \mathcal{H}_2$, we will give a coarse upper bound of the generalization error for Paradigm 1 for cases when the *α-expansion* assumption does not hold.

Let $Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i) = \alpha_i Pr(\overline{\mathbf{S}_1^i} \wedge \overline{\mathbf{S}_2^i})$ $(i = 0, 1, \cdots)$. If the *α-expansion* assumption does not hold in Paradigm 1, for any $\epsilon > 0$ and any integer $N > 0$, the size of the set $\{\alpha_i\colon\ i > N \wedge \alpha_i < \epsilon\}$ is infinite. We set a parameter $\epsilon_c > 0$ as the stop condition. When $Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i)$ is less than ϵ_c, we terminate the iteration in Paradigm 1. Now we make the definition on *expanded region with respect to ϵ_c*.

Definition 2 *Let γ_{ϵ_c} denote the expanded region with respect to ϵ_c in Paradigm 1,*

$$\gamma_{\epsilon_c} = Pr(\overline{\boldsymbol{S}_1^0} \wedge \overline{\boldsymbol{S}_2^0}) - Pr(\overline{\boldsymbol{S}_1^i} \wedge \overline{\boldsymbol{S}_2^i}),$$

where $i = \min\{i : Pr(\boldsymbol{S}_1^i \oplus \boldsymbol{S}_2^i) < \epsilon_c \wedge i \geq 1\}$.

After i rounds the region in which both classifiers wrongly predict becomes smaller and smaller, from $Pr(\overline{\mathbf{S}_1^0} \wedge \overline{\mathbf{S}_2^0})$ to $Pr(\overline{\mathbf{S}_1^i} \wedge \overline{\mathbf{S}_2^i})$. This *expanded region* can be thought of as an approximation of $\Sigma_{k=1}^{i} Pr(\mathbf{S}_1^k \oplus \mathbf{S}_2^k)$.

Theorem 2 *When the α-expansion assumption does not hold, set $\epsilon_c > 0$ to terminate Paradigm 1. The error rate of h_{com}^i can be smaller than h_{com}^0 for $\gamma_{\epsilon_c} + \frac{1}{2}(Pr(\boldsymbol{S}_1^0 \oplus \boldsymbol{S}_2^0) - \epsilon_c)$.*

Proof. Considering $error_{h_{com}^i} = Pr(\overline{\mathbf{S}_1^i} \wedge \overline{\mathbf{S}_2^i}) + \frac{1}{2}Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i)$ and $Pr(\mathbf{S}_1^i \oplus \mathbf{S}_2^i) < \epsilon_c$, we have that $error_{h_{com}^0} - error_{h_{com}^i}$ is larger than $\gamma_{\epsilon_c} + \frac{1}{2}(Pr(\mathbf{S}_1^0 \oplus \mathbf{S}_2^0) - \epsilon_c)$. □

Theorem 2 implies that Paradigm 1 could not boost the performance to arbitrarily high and gives a coarse upper bound of the error rate, when the *α-expansion* assumption does not hold. The improvement depends on the *expanded region* γ and the disagreement between the initial two classifiers. The larger the *expanded region* γ, the better the improvement of Paradigm 1. Theorem 2 can also be applied to one-shot *co-training* (Balcan et al., 2005).

4. Sample Complexity of Combination of Multi-View Active Learning and Semi-Supervised Learning

We can try to reduce the sample complexity further by combining multi-view active learning with semi-supervised learning. Previously this has been tried in some applications and led to good results (Zhou et al., 2006), yet to the best of our knowledge, there is no theoretical analysis which supports such argument. For computational simplicity, we consider the following case in this section. Suppose that the hypothesis class $\mathcal{H}_j$ is the subset of mappings from X_j to $[-1, 1]$ and $y = sign(c(x))$, $c = (c_1, c_2)$ is the underlying target concept, where c_1 and c_2 is the underlying target concept in each view, respectively. Let $d(f, g)$ denote the probability that the two classifiers $f \in \mathcal{H}_j$ and $g \in \mathcal{H}_j$ predict different labels on an example x_j drawn randomly from X_j, then

$$d(f, g) = Pr_{x_j \in X_j}\Big(sign\big(f(x_j)\big) \neq sign\big(g(x_j)\big)\Big).$$

Suppose that for any $f, g \in \mathcal{H}_j$, there exists some constant $L_1 > 0$ to hold that $|f(x_j) - g(x_j)| \leq L_1 \cdot d(f, g) \cdot \|x_j\|_2$, where $\|x_j\|_2$ denotes the 2-norm of x_j. Without loss of generality, suppose that there exists some constant $L_2 > 0$ to hold that $\|x_j\|_2 \leq L_2$ for $x_j \in X_j$ $(j = 1, 2)$. Now we have the following theorem for Paradigm 2 which combines multi-view active learning with semi-supervised learning.

Theorem 3 *For data distribution $\mathbb{D}$ α-expanding with respect to hypothesis class $\mathcal{H}_1 \times \mathcal{H}_2$, let ϵ and δ denote the final desired accuracy and confidence parameters. If $s = \lceil \frac{\log\frac{\alpha}{8\epsilon}}{\log\frac{1}{C}} \rceil$, $m_0 = \frac{1}{L}(4V\log(\frac{1}{L}) + 2\log(\frac{8(s+1)}{\delta}))$ and $m_i = \frac{16}{\alpha}(4V\log(\frac{16}{\alpha}) + 2\log(\frac{8(s+1)}{\delta}))$ $(i = 1, 2, \cdots,)$, Paradigm 2 will generate a classifier with error rate no more than ϵ with probability $1 - \delta$.*

Here, $V = \max[VC(\mathcal{H}_1), VC(\mathcal{H}_2)]$ where $VC(\mathcal{H})$ denotes the VC-dimension of the hypothesis class $\mathcal{H}$, constant $C = \frac{\alpha/4+1/\alpha}{1+1/\alpha}$ and constant $L = \min[\frac{\alpha}{16}, \frac{1}{16L_1L_2}]$.

Proof. In Paradigm 2, we also use Eq. 1 to combine the two classifiers. With $m_0 = \frac{1}{L}(4V\log(\frac{1}{L}) + 2\log(\frac{8(s+1)}{\delta}))$ where constant $L = \min[\frac{\alpha}{16}, \frac{1}{16L_1L_2}]$, using Lemma 1 we have $Pr(\overline{\mathbf{S}_1^0}) \leq \frac{1}{L}$ and $Pr(\overline{\mathbf{S}_2^0}) \leq \frac{1}{L}$ with probability $1 - \frac{\delta}{4(s+1)}$. Generally, we have that an

Input:

Unlabeled data set $\mathcal{U} = \{x^1, x^2, \cdots, \}$, where each example x^t is given as a pair (x_1^t, x_2^t)

Threshold thr

Process:

Ask the user to label m_0 unlabeled examples drawn randomly from $\mathbb{D}$ to compose the labeled data set $\mathcal{L}$

Iterate $i = 0, 1, \cdots, s$

Set counter n_1^{i+1} to 0. If $\mathbb{D}$ is expanding, set counter n_2^{i+1} to $+\infty$; Otherwise, set counter n_2^{i+1} to 0;

Train two classifiers h_1^i and h_2^i consistent with $\mathcal{L}$ in each view, respectively;

Apply h_1^i and h_2^i to the unlabeled data set $\mathcal{U}$ and find out the contention points set $\mathcal{Q}_i$;

for $k = 1, \cdots, m_{i+1}$

Draw an example $x^k = (x_1^k, x_2^k)$ randomly from $\mathcal{Q}_i$;

if $|h_1^i(x_1^k)| > thr$ **then** $y^k = sign(h_1^i(x_1^k))$;

else if $|h_2^i(x_2^k)| > thr$ **then** $y^k = sign(h_2^i(x_2^k))$;

else ask the user to label x^k and $n_1^{i+1} = n_1^{i+1} + 1$;

Add (x^k, y^k) into $\mathcal{L}$ and delete it from $\mathcal{U}$ and $\mathcal{Q}_i$.

end for

for $w = 1, 2, \cdots$

if $n_2^{i+1} \geq m_{i+1} - n_1^{i+1}$ **break**;

Draw an example $x^w = (x_1^w, x_2^w)$ randomly from $\mathcal{U} - \mathcal{Q}_i$;

if $|h_1^i(x_1^w)| > thr$ **then** $y^w = sign(h_1^i(x_1^w))$;

else if $|h_2^i(x_2^w)| > thr$ **then** $y^w = sign(h_2^i(x_2^w))$;

else ask the user to label x^w and $n_2^{i+1} = n_2^{i+1} + 1$;

Add (x^w, y^w) into $\mathcal{L}$ and delete it from $\mathcal{U}$.

end for

Output:

$h_{final} = \text{combine}(h_1^s, h_2^s)$

Table 2. Paradigm 2: Combination of multi-view active learning and semi-supervised learning

arbitrary S_j^i $(j = 1, 2)$ being consistent with the examples in $\mathcal{L}$ has an error rate at most $\frac{1}{L}$ with probability $1 - \frac{\delta}{4(s+1)}$. So, for any example $x = (x_1, x_2)$,

$$|h_j^i(x_j) - c_j(x_j)| \leq L_1 \cdot L_2 \cdot d(h_j^i, c_j) \leq \frac{1}{16} .$$

We can set the threshold thr in Paradigm 2 to $\frac{1}{16}$. If $|h_j^i(x_j)| > \frac{1}{16}$, h_j^i and c_j make the same prediction on x_j. When $s = \lceil \frac{\log \frac{\alpha}{8\epsilon}}{\log \frac{1}{C}} \rceil$, from the proof of Theorem 1 we have $Pr(\overline{\mathbf{S}_1^s \wedge \mathbf{S}_2^s}) \leq \epsilon$. Thus we get a classifier h_{com}^s whose error rate is no more than ϵ with probability $1 - \delta$ using Paradigm 2. □

The sample complexity of Paradigm 2 is $m_0 + \sum_{i=1}^{s} n_1^i$, which is much smaller than that of Paradigm 1. From Theorem 3 we know that the sample complexity can be further reduced by combining multi-view active learning with semi-supervised learning, however, it needs a stronger assumption on the hypothesis class $\mathcal{H}_1 \times \mathcal{H}_2$. If this assumption holds, in contrast to Paradigm 1, when α-*expansion* does not hold, we can query $\sum_{i=1}^{s}(m_i - n_1^i)$ more examples on which both classifiers have small margin, which can help to reduce the size of the region $\overline{S_1} \wedge \overline{S_2}$.

5. Empirical Study

In this section we empirically study the performance of the Paradigms 1 and 2 on a real-world data set, i.e., the *course* data set (Blum & Mitchell, 1998). This data set has two views (*pages* view and *links* view) and contains 1,051 examples each corresponds to a web page, and the task is to predict whether an unseen web page is a course page or not. There are 230 positive examples (roughly 22%). We randomly use 25% data as the test set and use the remaining 75% data as the unlabeled set $\mathcal{U}$ in Tables 1 and 2. Then, we randomly draw 10 positive and 30 negative examples from $\mathcal{U}$ to generate the initial m_0 labeled examples.

In practice, the thr in Paradigm 2 can be determined by cross validation on labeled examples. Here in our experiments, for the ease of comparison, we do not set thr and instead, we fix the number of examples to be queried in both Paradigms. Thus, we can study their performance under the same number of queries. In detail, in the i-th round, Paradigm 1 picks out two contention points randomly to query; while Paradigm

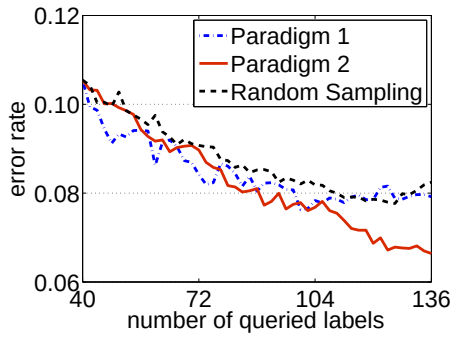

Figure 1. Comparison of the performances

2 picks out the example with the smallest absolute sum of the two classifiers' outputs from $\mathcal{Q}_i$ and $\mathcal{U}-\mathcal{Q}_i$ respectively to query, and picks out the example with the largest absolute sum of the two classifiers' outputs from $\mathcal{Q}_i$ and $\mathcal{U}-\mathcal{Q}_i$ respectively to label as $sign\big(h_1^i(x_1)+h_2^i(x_2)\big)$. That is, the two examples to be queried in Paradigm 2 are $\arg\min_{x\in\mathcal{Q}_i}\big(|h_1^i(x_1)+h_2^i(x_2)|\big)$ and $\arg\min_{x\in\mathcal{U}-\mathcal{Q}_i}\big(|h_1^i(x_1)+h_2^i(x_2)|\big)$, while the two examples Paradigm 2 labels for itself by semi-supervised learning are $\arg\max_{x\in\mathcal{Q}_i}\big(|h_1^i(x_1)+h_2^i(x_2)|\big)$ and $\arg\max_{x\in\mathcal{U}-\mathcal{Q}_i}\big(|h_1^i(x_1)+h_2^i(x_2)|\big)$. We use Random Sampling as the baseline and implement the classifiers with SMO in WEKA (Witten & Frank, 2005). The experiments are repeated for 20 runs and Figure 1 plots the average error rates of the three methods against the number of examples that have been queried.

It can be found from Figure 1 that with the same number of queried examples, although there are some fluctuation, the performance of Paradigm 1 is generally better than that of Random Sampling, while the performance of Paradigm 2 is better than that of the others. In particular, the advantage of Paradigm 2 becomes more prominent as the number of queries increases. This is not difficult to understand since with more labeled data the learners become stronger and thus the labels obtained from the semi-supervised learning process become more helpful.

Overall, the empirical study verifies that comparing with pure active learning, the combination of multi-view active learning and semi-supervised learning can reduce the sample complexity.

6. Conclusion

In this paper, we first characterize the sample complexity of multi-view active learning and get an exponential improvement in the sample complexity from $\widetilde{O}(\frac{1}{\epsilon})$ to $\widetilde{O}(\log\frac{1}{\epsilon})$. The α-*expansion* assumption we employed is weaker than assumptions taken by previous theoretical studies on active learning, such as that the data is distributed uniformly over the unit sphere in $\mathbb{R}^d$ and that the hypothesis class is linear separators through the origin. We also give an upper bound of the error rate for cases where the α-*expansion* assumption does not hold. Then, we analyze the combination of multi-view active learning with semi-supervised learning and get that such a combination can reduce the sample complexity further, which is verified by an empirical study. This provides an explanation to that why the method described in (Zhou et al., 2006) can lead to good results.

Our work is the first theoretical analysis on the sample complexity of realizable multi-view active learning. Recently, *non-realizable* active learning, where there does not exist a hypothesis perfectly separating the data, starts to attract attention (Balcan et al., 2006; Balcan et al., 2007; Dasgupta et al., 2008). Extending our work to non-realizable multi-view active learning is a future work.

Abstract

In this paper we study how to improve nearest neighbor classification by learning a Mahalanobis distance metric. We build on a recently proposed framework for distance metric learning known as large margin nearest neighbor (LMNN) classification. Our paper makes three contributions. First, we describe a highly efficient solver for the particular instance of semidefinite programming that arises in LMNN classification; our solver can handle problems with billions of large margin constraints in a few hours. Second, we show how to reduce both training and testing times using metric ball trees; the speedups from ball trees are further magnified by learning low dimensional representations of the input space. Third, we show how to learn different Mahalanobis distance metrics in different parts of the input space. For large data sets, the use of locally adaptive distance metrics leads to even lower error rates.

1. Introduction

Many algorithms for pattern classification and machine learning depend on computing distances in a multidimensional input space. Often, these distances are computed using a Euclidean distance metric—a choice which has both the advantages of simplicity and generality. Notwithstanding these advantages, though, the Euclidean distance metric is not very well adapted to most problems in pattern classification.

Viewing the Euclidean distance metric as overly simplistic, many researchers have begun to ask how to learn or adapt the distance metric itself in order to achieve better results (Xing et al., 2002; Chopra et al., 2005; Frome et al., 2007). Distance metric learning is an emerging area of statistical learning in which the goal is to induce a more powerful distance metric from labeled examples. The simplest instance of this problem arises in the context of k-nearest neighbor (kNN) classification using Mahalanobis distances. Mahalanobis distances are computed by linearly transforming the input space, then computing Euclidean distances in the transformed space. A well-chosen linear transformation can improve kNN classification by decorrelating and reweighting elements of the feature vector. In fact, significant improvements have been observed within several different frameworks for this problem, including neighborhood components analysis (Goldberger et al., 2005), large margin kNN classification (Weinberger et al., 2006), and information-theoretic metric learning (Davis et al., 2007).

These studies have established the general utility of distance metric learning for kNN classification. However, further work is required to explore its promise in more difficult regimes. In particular, larger data sets raise new and important challenges in scalability. They also present the opportunity to learn more adaptive and sophisticated distance metrics.

In this paper, we study these issues as they arise in the recently proposed framework of large margin nearest neighbor (LMNN) classification (Weinberger et al., 2006). In this framework, a Mahalanobis distance metric is trained with the goal that the k-nearest neighbors of each example belong to the same class while examples from different classes are separated by a large margin. Simple in concept, useful in practice, the ideas behind LMNN classification have also inspired other related work in machine learning and computer vision (Torresani & Lee, 2007; Frome et al., 2007).

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

The role of the margin in LMNN classification is inspired by its role in support vector machines (SVMs). Not surprisingly, given these roots, LMNN classification also inherits various strengths and weaknesses of SVMs (Schölkopf & Smola, 2002). For example, as in SVMs, the training procedure in LMNN classification reduces to a convex optimization based on the hinge loss. However, as described in section 2, naïve implementations of this optimization do not scale well to larger data sets.

Addressing the challenges and opportunities raised by larger data sets, this paper makes three contributions. First, we describe how to optimize the training procedure for LMNN classification so that it can readily handle data sets with tens of thousands of training examples. In order to scale to this regime, we have implemented a special-purpose solver for the particular instance of semidefinite programming that arises in LMNN classification. In section 3, we describe the details of this solver, which we have used to tackle problems involving billions of large margin constraints. To our knowledge, problems of this size have yet to be tackled by other recently proposed methods (Goldberger et al., 2005; Davis et al., 2007) for learning Mahalanobis distance metrics.

As the second contribution of this paper, we explore the use of metric ball trees (Liu et al., 2005) for LMNN classification. These data structures have been widely used to accelerate nearest neighbor search. In section 4, we show how similar data structures can be used for faster training and testing in LMNN classification. Ball trees are known to work best in input spaces of low to moderate dimensionality. Mindful of this regime, we also show how to modify the optimization in LMNN so that it learns a low-rank Mahalanobis distance metric. With this modification, the metric can be viewed as projecting the original inputs into a lower dimensional space, yielding further speedups.

As the third contribution of this paper, we describe an important extension to the original framework for LMNN classification. Specifically, in section 5, we show how to learn different Mahalanobis distance metrics for different parts of the input space. The novelty of our approach lies in learning a collection of different local metrics to maximize the margin of correct kNN classification. The promise of this approach is suggested by recent, related work in computer vision that has achieved state-of-the-art results on image classification (Frome et al., 2007). Our particular approach begins by partitioning the training data into disjoint clusters using class labels or unsupervised methods. We then learn a Mahalanobis distance metric for each cluster. While the training procedure couples the distance metrics in different clusters, the optimization remains a convex problem in semidefinite programming. The globally coupled training of these metrics also distinguishes our approach from earlier work in adaptive distance metrics for kNN classification (Hastie & Tibshirani, 1996). To our knowledge, our approach yields the best kNN test error rate on the extensively benchmarked MNIST data set of handwritten digits that does not incorporate domain-specific prior knowledge (LeCun et al., 1998; Simard et al., 1993). Thus, our results show that we can exploit large data sets to learn more powerful and adaptive distance metrics for kNN classification.

2. Background

Of the many settings for distance metric learning, the simplest instance of the problem arises in the context of kNN classification using Mahalanobis distances. A Mahalanobis distance metric computes the squared distances between two points $\vec{x}_i$ and $\vec{x}_j$ as:

$$d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) = (\vec{x}_i - \vec{x}_j)^\top \mathbf{M} (\vec{x}_i - \vec{x}_j), \qquad (1)$$

where $\mathbf{M} \succeq 0$ is a positive semidefinite matrix. When $\mathbf{M}$ is equal to the identity matrix, eq. (1) reduces to the Euclidean distance metric. In distance metric learning, the goal is to discover a matrix $\mathbf{M}$ that leads to lower kNN error rates than the Euclidean distance metric.

Here we briefly review how Mahalanobis distance metrics are learned for LMNN classification (Weinberger et al., 2006). Let the training data consist of n labeled examples $\{(\vec{x}_i, y_i)\}_{i=1}^n$ where $\vec{x}_i \in \mathcal{R}^d$ and $y_i \in \{1, \ldots, c\}$, where c is the number of classes. For LMNN classification, the training procedure has two steps. The first step identifies a set of k similarly labeled *target neighbors* for each input $\vec{x}_i$. Target neighbors are selected by using prior knowledge (if available) or by simply computing the k nearest (similarly labeled) neighbors using Euclidean distance. We use the notation $j \rightsquigarrow i$ to indicate that $\vec{x}_j$ is a target neighbor of $\vec{x}_i$. The second step adapts the Mahalanobis distance metric so that these target neighbors are closer to $\vec{x}_i$ than all other differently labeled inputs. The Mahalanobis distance metric is estimated by solving a problem in semidefinite programming. Distance metrics obtained in this way were observed to yield consistent and significant improvements in kNN error rates.

The semidefinite program in LMNN classification arises from an objective function which balances two terms. The first term penalizes large distances between inputs and their target neighbors. The second term penalizes small distances between differently la-

beled inputs; specifically, a penalty is incurred if these distances do not exceed (by a finite margin) the distances to the target neighbors of these inputs. The terms in the objective function can be made precise with further notation. Let $y_{ij} \in \{0, 1\}$ indicate whether the inputs $\vec{x}_i$ and $\vec{x}_j$ have the same class label. Also, let $\xi_{ijl} \geq 0$ denote the amount by which a differently labeled input $\vec{x}_l$ invades the "perimeter" around input $\vec{x}_i$ defined by its target neighbor $\vec{x}_j$. The Mahalanobis distance metric $\mathbf{M}$ is obtained by solving the following semidefinite program:

Minimize $\sum_{j \rightsquigarrow i} \left[d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) + \mu \sum_l (1 - y_{il}) \xi_{ijl} \right]$
subject to:
(a) $d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_l) - d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) \;\geq\; 1 - \xi_{ijl}$
(b) $\xi_{ijl} \geq 0$
(c) $\mathbf{M} \succeq 0$.

The constant μ defines the trade-off between the two terms in the objective function; in our experiments, we set $\mu = 1$. The constraints of type **(a)** encourage inputs ($\vec{x}_i$) to be at least one unit closer to their k target neighbors ($\vec{x}_j$) than to any other differently labeled input ($\vec{x}_l$). When differently labeled inputs $\vec{x}_l$ invade the local neighborhood of $\vec{x}_i$, we refer to them as *impostors*. Impostors generate positive slack variables ξ_{ijl} which are penalized in the second term of the objective function. The constraints of type **(b)** enforce nonnegativity of the slack variables, and the constraint **(c)** enforces that $\mathbf{M}$ is positive semidefinite, thus defining a valid (pseudo)metric. Noting that the squared Mahalanobis distances $d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_j)$ are linear in the matrix $\mathbf{M}$, the above optimization is easily recognized as an semidefinite program.

3. Solver

The semidefinite program in the previous section grows in complexity with the number of training examples (n), the number of target neighbors (k), and the dimensionality of the input space (d). In particular, the objective function is optimized with respect to $O(kn^2)$ large margin constraints of type **(a)** and **(b)**, while the Mahalanobis distance metric $\mathbf{M}$ itself is a $d \times d$ matrix. Thus, for even moderately large and/or high dimensional data sets, the required optimization (though convex) cannot be solved by standard off-the-shelf packages (Borchers, 1999).

In order to tackle larger problems in LMNN classification, we implemented our own special-purpose solver. Our solver was designed to exploit the particular structure of the semidefinite program in the previous section. The solver iteratively re-estimates the Mahalanobis distance metric $\mathbf{M}$ to minimize the objective function for LMNN classification. The amount of computation is minimized by careful book-keeping from one iteration to the next. The speed-ups from these optimizations enabled us to work comfortably on data sets with up to $n = 60,000$ training examples.

Our solver works by eliminating the slack variables ξ_{ijl} from the semidefinite program for LMNN classification, then minimizing the resulting objective function by sub-gradient methods. The slack variables are eliminated by folding the constraints **(a)** and **(b)** into the objective function as a sum of "hinge" losses. The hinge function is defined as $[z]_+ = z$ if $z > 0$ and $[z]_+ = 0$ if $z < 0$. In terms of this hinge function, we can express ξ_{ijl} as a function of the matrix $\mathbf{M}$:

$$\xi_{ijl}(\mathbf{M}) \;=\; \left[1 + d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) - d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_l)\right]_+ \qquad (2)$$

Finally, writing the objective function only in terms of the matrix $\mathbf{M}$, we obtain:

$$\varepsilon(\mathbf{M}) = \sum_{j \rightsquigarrow i} \left[d^2_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) + \mu \sum_l (1 - y_{il}) \xi_{ijl}(\mathbf{M}) \right]. \qquad (3)$$

This objective function is not differentiable due to the hinge losses that appear in eq. (2). Nevertheless, because it is convex, we can compute its sub-gradient and use standard descent algorithms to find its minimum. At each iteration of our solver, the optimization takes a step along the sub-gradient to reduce the objective function, then projects the matrix $\mathbf{M}$ back onto the cone of positive semidefinite matrices. Iterative methods of this form are known to converge to the correct solution, provided that the gradient step-size is sufficiently small (Boyd & Vandenberghe, 2004).

The gradient computation can be done most efficiently by careful book-keeping from one iteration to the next. As simplifying notation, let $\mathbf{C}_{ij} = (\vec{x}_i - \vec{x}_j)(\vec{x}_i - \vec{x}_j)^\top$. In terms of this notation, we can express the squared Mahalanobis distances in eq. (8) as:

$$d_{\mathbf{M}}(\vec{x}_i, \vec{x}_j) = \mathrm{tr}(\mathbf{C}_{ij}\mathbf{M}). \qquad (4)$$

To evaluate the gradient, we denote the matrix $\mathbf{M}$ at the t^{th} iteration as $\mathbf{M}^t$. At each iteration, we also define a set $\mathcal{N}^t$ of triplet indices such that $(i, j, l) \in \mathcal{N}^t$ if and only if the triplet's corresponding slack variable exceeds zero: $\xi_{ijl}(\mathbf{M}^t) > 0$. With this notation, we can write the gradient $\mathbf{G}^t = \frac{\partial \varepsilon}{\partial \mathbf{M}}\big|_{\mathbf{M}^t}$ at the t^{th} iteration as:

$$\mathbf{G}^t \;=\; \sum_{j \rightsquigarrow i} \mathbf{C}_{ij} + \mu \sum_{(i,j,l) \in \mathcal{N}^t} (\mathbf{C}_{ij} - \mathbf{C}_{il}). \qquad (5)$$

Computing the gradient requires computing the outer products in $\mathbf{C}_{ij}$; it thus scales quadratically in the

input dimensionality. As the set $\mathcal{N}^t$ is potentially large, a naïve computation of the gradient would be extremely expensive. However, we can exploit the fact that the gradient contribution from each active triplet (i, j, l) does not depend on the degree of its margin violation. Thus, the changes in the gradient from one iteration to the next are determined entirely by the differences between the sets $\mathcal{N}^t$ and $\mathcal{N}^{t+1}$. Using this fact, we can derive an extremely efficient update that relates the gradient at one iteration to the gradient at the previous one. The update subtracts the contributions from triples that are no longer active and adds the contributions from those that just became active:

$$\mathbf{G}^{t+1} = \mathbf{G}^t - \mu \sum_{(i,j,l)\in\mathcal{N}^t-\mathcal{N}^{t+1}} (\mathbf{C}_{ij} - \mathbf{C}_{il}) + \mu \sum_{(i,j,l)\in\mathcal{N}^{t+1}-\mathcal{N}^t} (\mathbf{C}_{ij} - \mathbf{C}_{il}) \tag{6}$$

For small gradient step sizes, the set $\mathcal{N}^t$ changes very little from one iteration to the next. In this case, the right hand side of eq. (6) can be computed very fast.

To further accelerate the solver, we adopt an active set method. This method is used to monitor the large margin constraints that are actually violated. Note that computing the set $\mathcal{N}^t$ at each iteration requires checking every triplet (i, j, l) with $j \rightsquigarrow i$ for a potential margin violation. This computation scales as $O(nd^2 + kn^2d)$, making it impractical for large data sets. To avoid this computational burden, we observe that the great majority of triples do not incur margin violations: in particular, for each training example, only a very small fraction of differently labeled examples typically lie nearby in the input space. Consequently, a useful approximation is to check only a subset of likely triples for margin violations per gradient computation and only occasionally perform the full computation. We set this active subset to the list of all triples that have ever violated the margin, ie $\bigcup_{i=1}^{t-1} \mathcal{N}^i$. When the optimization converges, we verify that the working set $\mathcal{N}^t$ does contain all active triples that incur margin violations. This final check is needed to ensure convergence to the correct minimum. If the check is not satisfied, the optimization continues with the newly expanded active set.

Table 1 shows how quickly the solver works on problems of different sizes. The results in this table were generated by learning a Mahalanobis distance metric on the MNIST data set of 28×28 grayscale handwritten digits (LeCun et al., 1998). The digits were preprocessed by principal component analysis (PCA) to reduce their dimensionality from $d = 784$ to $d = 169$. We experimented by learning a distance metric from different subsets of the training examples. The experiments were performed on a standard desktop machine with a 2.0 GHz dual core 2 processor. For each experiment, the table shows the number of training examples, the CPU time to converge, the number of active constraints, the total number of constraints, and the kNN test error (with $k = 3$). Note that for the full MNIST training set, the semidefinite program has over three billion large margin constraints. Nevertheless, the active set method converges in less than four hours—from a Euclidean distance metric with 2.33% test error to a Mahalanobis distance metric with 1.72% test error.

N	time	|active set|	|total set|	train error	test error
60	**9s**	**844**	**3.2K**	**0%**	**29.37%**
600	**37s**	**6169**	**323K**	**0%**	**10.79%**

Table 1. Statistics of the solver on subsets of the data set of MNIST handwritten digits. See text for details.

4. Tree-Based Search

Nearest neighbor search can be accelerated by storing training examples in hierarchical data structures (Liu et al., 2005). These data structures can also be used to reduce the training and test times for LMNN classification. In this section, we describe how these speedups are obtained using metric ball trees.

4.1. Ball trees

We begin by reviewing the use of ball trees (Liu et al., 2005) for fast kNN search. Ball trees recursively partition the training inputs by projecting them onto directions of large variance, then splitting the data on the mean or median of these projected values. Each subset of data obtained in this way defines a hypersphere (or "ball") in the multidimensional input space that encloses its training inputs. The distance to such a hypersphere can be easily computed for any test input; moreover, this distance provides a lower bound on the test input's distance to any of the enclosed training inputs. This bound is illustrated in Fig. 1. Let S be the set of training inputs inside a specific ball with radius r. The distance from a test input $\vec{x}_t$ to any training input $\vec{x}_i \in S$ is bounded from below by:

$$\forall \vec{x}_i \in S \quad \|\vec{x}_t - \vec{x}_i\| \geq \max(\|\vec{x}_t - \vec{c}\|_2 - r, 0). \tag{7}$$

These bounds can be exploited in a tree-based search for nearest neighbors. In particular, if the distance to the currently k^{th} closest input $\vec{x}_j$ is smaller than the bound from eq. (7), then all inputs inside the ball S can be pruned away. This pruning of unexplored subtrees can significantly accelerate kNN search. The same basic strategy can also be applied to kNN search

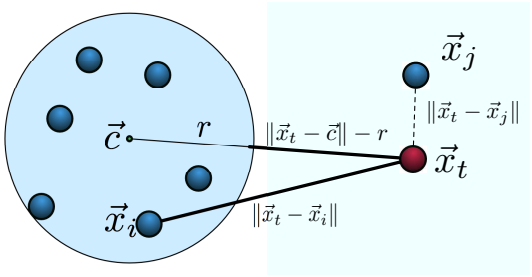

Figure 1. How ball trees work: for any input $\vec{x}_i \in S$, the distance $\|\vec{x}_t - \vec{x}_i\|$ is bounded from below by eq. (7) . If a training example $\vec{x}_j$ is known to be closer to $\vec{x}_t$, then the inputs inside the ball can be ruled out as nearest neighbors.

under a Mahalanobis distance metric.

4.2. Speedups

We first experimented with ball trees to reduce the *test* times for LMNN classification. In our experiments, we observed a factor of $3x$ speed-up for 40-dimensional data and a factor of $15x$ speedup for 15-dimensional data. Note that these speedups were measured relative to a highly optimized baseline implementation of kNN search. In particular, our baseline implementation rotated the input space to align its coordinate axes with the principal components of the data; the coordinate axes were also sorted in decreasing order of variance. In this rotated space, distance computations were terminated as soon as any partially accumulated results (from leading principal components) exceeded the currently smallest k distances from the kNN search in progress.

We also experimented with ball trees to reduce the *training* times for LMNN classification. To reduce training times, we integrated ball trees into our special-purpose solver. Specifically, ball trees were used to accelerate the search for so-called "impostors". Recall that for each training example $\vec{x}_i$ and for each of its similarly labeled target neighbors $\vec{x}_j$, the impostors consist of all differently labeled examples $\vec{x}_l$ with $d_M(\vec{x}_i, \vec{x}_l)^2 \leq d_M(\vec{x}_i, \vec{x}_j)^2 + 1$. The search for impostors dominates the computation time in the training procedure for LMNN classification. To reduce the amount of computation, the solver described in section 3 maintains an active list of previous margin violations. Nevertheless, the overall computation still scales as $O(n^2 d)$, which can be quite expensive. Note that we only need to search for impostors among training examples with different class labels. To speed up training, we built one ball tree for the training examples in each class and used them to search for impostors (as the ball-tree creation time is negligible in comparison with the impostor search, we re-built it in every iteration). We observed the ball trees to yield speedups ranging from a factor of $1.9x$ with 10-dimensional data to a factor of $1.2x$ with 100 dimensional data.

4.3. Dimensionality reduction

Across all our experiments, we observed that the gains from ball trees diminished rapidly with the dimensionality of the input space. This observation is consistent with previous studies of ball trees and NN search. When the data is high dimensional, NN search is plagued by the so-called "curse of dimensionality". In particular, distances in high dimensions tend to be more uniform, thereby reducing the opportunities for pruning large subtrees.

The curse of dimensionality is often addressed in ball trees by projecting the stored training inputs into a lower dimensional space. The most commonly used methods for dimensionality reduction are random projections and PCA. Despite their widespread use, however, neither of these methods is especially geared to preserve (or improve) the accuracy of kNN classification.

We experimented with two methods for dimensionality reduction in the particular context of LMNN classification. Both methods were based on learning a low-rank Mahalanobis distance metric. Such a metric can be viewed as projecting the original inputs into a lower dimensional space. In our first approach, we performed a singular value decomposition (SVD) on the full rank solution to the semidefinite program in section 2. The full rank solution for the distance metric was then replaced by a low rank approximation based on its leading eigenvectors. We call this approach LMNN-SVD. In our second approach, we followed a suggestion from previous work on LMNN classification (Torresani & Lee, 2007). In this approach, we explicitly parameterized the Mahalanobis distance metric as a low-rank matrix, writing $\mathbf{M} = \mathbf{L}^\top \mathbf{L}$, where $\mathbf{L}$ is a rectangular matrix. To obtain the distance metric, we optimized the same objective function as before, but now in terms of the explicitly low-rank linear transformation $\mathbf{L}$. The optimization over $\mathbf{L}$ is not convex unlike the original optimization over $\mathbf{M}$, but a (possibly local) minimum can be computed by standard gradient-based methods. We call this approach LMNN-RECT.

Fig. 2 shows the results of kNN classification from both these methods on the MNIST data set of handwritten digits. For these experiments, the raw MNIST images (of size 28× 28) were first projected onto their 350 leading principal components. The training procedure for LMNN-SVD optimized a full-rank distance metric in this 350 dimensional space, then extracted a low-rank distance metric from its leading eigenvectors.

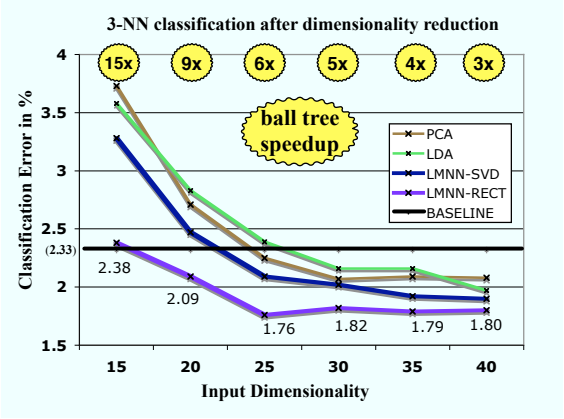

Figure 2. Graph of kNN error rate (with $k = 3$) on different low dimensional representations of the MNIST data set.

The training procedures for LMNN-RECT optimized a low-rank rectangular matrix of size $r \times 350$, where r varied from 15 to 40. Also shown in the figure are the results from further dimensionality reduction using PCA, as well as the baseline kNN error rate in the original (high dimensional) space of raw images. The speedup from ball trees is shown at the top of the graph. The amount of speedup depends significantly on the amount of dimensionality reduction, but very little on the particular method of dimensionality reduction. Of the three methods compared in the figure, LMNN-RECT is the most effective, improving significantly over baseline kNN classification while operating in a much lower dimensional space. Overall, these results show that aggressive dimensionality reduction can be combined with distance metric learning.

5. Multiple Metrics

The originally proposed framework for LMNN classification has one clear limitation: the same Mahalanobis distance metric is used to compute distances everywhere in the input space. Writing the metric as $\mathbf{M} = \mathbf{L}^\top \mathbf{L}$, we see that Mahalanobis distances are equivalent to Euclidean distances after a global linear transformation $\vec{x} \rightarrow \mathbf{L}\vec{x}$ of the input space. Such a transformation cannot adapt to nonlinear variabilities in the training data.

In this section, we describe how to learn different Mahalanobis distance metrics in different parts of the input space. We begin by simply describing how such a collection of local distance metrics is used at test time. Assume that the data set is divided into p disjoint partitions $\{P_\alpha\}_{\alpha=1}^p$, such that $P_\alpha \cap P_\beta = \{\}$ for any $\alpha \neq \beta$ and $\bigcup_\alpha P_\alpha = \{\vec{x}_i\}_{i=1}^n$. Also assume that each partition P_α has its own Mahalanobis distance metric $\mathbf{M}_\alpha$ for use in kNN classification. Given a test vector $\vec{x}_t$, we compute its squared distance to a training input $\vec{x}_i$ in partition α_i as:

$$d^2_{\mathbf{M}_{\alpha_i}}(\vec{x}_t, \vec{x}_i) = (\vec{x}_t - \vec{x}_i)^\top \mathbf{M}_{\alpha_i}(\vec{x}_t - \vec{x}_i). \qquad (8)$$

These distances are then sorted as usual to determine nearest neighbors and label the test input. Note, however, how different distance metrics are used for training inputs in different partitions.

We can also use these metrics to compute distances between training inputs, with one important caveat. Note that for inputs belonging to different partitions, the distance between them will depend on the particular metric used to compute it. This asymmetry does not present any inherent difficulty since, in fact, the dissimilarity measure in kNN classification is not required to be symmetric. Thus, even on the training set, we can use multiple metrics to measure distances and compute meaningful leave-one-out kNN error rates.

5.1. Learning algorithm

In this section we describe how to learn multiple Mahalanobis distance metrics for LMNN classification. Each of these metrics is associated with a particular cluster of training examples. To derive these clusters, we experimented with both unsupervised methods, such as the k-means algorithm, and fully supervised methods, in which each cluster contains the training examples belonging to a particular class.

Before providing details of the learning algorithm, we make the following important observation. Multiple Mahalanobis distance metrics for LMNN classification cannot be learned in a decoupled fashion—that is, by solving a collection of simpler, independent problems of the type already considered (e.g., one within each partition of training examples). Rather, the metrics must be learned in a coordinated fashion so that the distances from different metrics can be meaningfully compared for kNN classification. In our framework, such comparisons arise whenever an unlabeled test example has potential nearest neighbors in two or more different clusters of training examples.

Our learning algorithm for multiple local distance metrics $\{\mathbf{M}_\alpha\}_{\alpha=1}^p$ generalizes the semidefinite program for ordinary LMNN classification in section 2. First, we modify the objective function so that the distances to target neighbors $\vec{x}_j$ are measured under the metric $\mathbf{M}_{\alpha_j}$. Next, we modify the large margin constraints in **(a)** so that the distances to potential impostors $\vec{x}_l$ are measured under the metric $\mathbf{M}_{\alpha_l}$. Finally, we replace the single positive semidefinite constraint in **(c)**

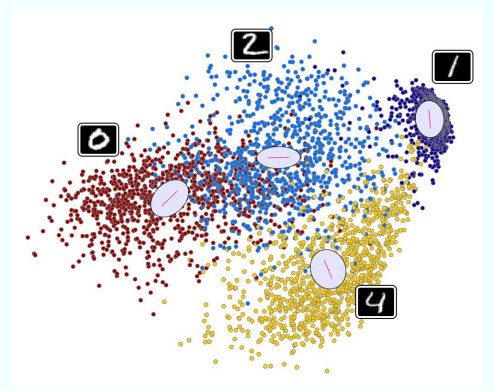

Figure 3. Visualization of multiple local distance metrics for MNIST handwritten digits. See text for details.

by multiple such constraints, one for each local metric $\mathbf{M}_\alpha$. Taken together, these steps lead to the new semidefinite program:

Minimize $\sum_{j \rightsquigarrow i} \left[d^2_{\mathbf{M}_{\alpha_j}}(\vec{x}_i, \vec{x}_j) + \mu \sum_l (1 - y_{il}) \xi_{ijl} \right]$
subject to:
(a) $d^2_{\mathbf{M}_{\alpha_l}}(\vec{x}_i, \vec{x}_l) - d^2_{\mathbf{M}_{\alpha_j}}(\vec{x}_i, \vec{x}_j) \;\geq\; 1 - \xi_{ijl}$
(b) $\xi_{ijl} \geq 0$
(c) $\mathbf{M}_\alpha \succeq 0$.

Note how the new constraints in **(a)** couple the different Mahalanobis distance metrics. By jointly optimizing these metrics to minimize a single objective function, we ensure that the distances they compute can be meaningfully compared for kNN classification.

5.2. Results

We evaluated the performance of this approach on five publicly available data sets: the MNIST data set[1] of handwritten digits ($n = 60000$, $c = 10$), the 20-Newsgroups data set[2] of text messages ($n = 18827$, $c = 20$), the Letters data set[3] of distorted computer fonts ($n = 14000$, $c = 26$), the Isolet data set[4] of spoken letters ($n = 6238$, $c = 26$), and the YaleFaces[5] data set of face images ($n = 1690$, $c = 38$). The data sets were preprocessed by PCA to reduce their dimensionality. The amount of dimensionality reduction varied with each experiment, as discussed below.

To start, we sought to visualize the multiple metrics learned in a simple experiment on MNIST handwritten digits of zeros, ones, twos, and fours. For ease of visualization, we worked with only the leading two principal components of the MNIST data set. Fig. 3 shows these two dimensional inputs, color-coded by class label. With these easily visualized inputs, we minimized the objective function in section 5.1 to learn a specialized distance metric for each type of handwritten digit. The ellipsoids in the plot reveal the directions amplified by the local distance metric of each digit class. Notably, each distance metric learns to amplify the direction perpendicular to the decision boundary for the nearest, competing class of digits.

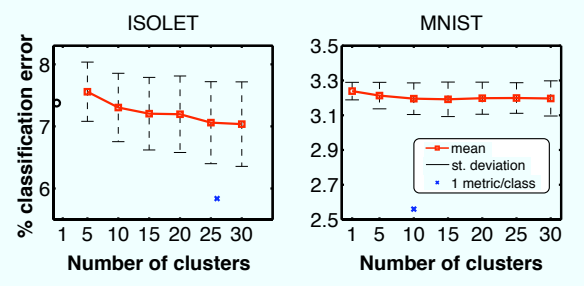

Figure 4. Test kNN error rates on the Isolet and MNIST data sets as a function of the number of distance metrics.

Our next experiments examined the performance of LMNN classification as a function of the number of distance metrics. In these experiments, we used PCA to reduce the input dimensionality to $d = 50$; we also only worked with a subset of $n = 10000$ training examples of MNIST handwritten digits. To avoid overfitting, we used an "early stopping" approach while monitoring the kNN error rates on a held-out validation set consisting of 30% of the training data.

Fig. 4 shows the test kNN error rates on the Isolet and MNIST data sets as a function of the number of distance metrics. In these experiments, we explored both unsupervised and supervised methods for partitioning the training inputs as a precursor to learning local distance metrics. In the unsupervised setting, the training examples were partitioned by k-means clustering, with the number of clusters ranging from 1 to 30 (just 1 cluster is identical to single-matrix LMNN). As k-means clustering is prone to local minima, we averaged these results over 100 runs. The figure shows the average test error rates in red, as well as their standard deviations (via error bars). In the supervised setting, the training examples were partitioned by their class labels, resulting in the same number of clusters as classes. The test error rates in these experiments are shown as blue crosses. In both the unsupervised and supervised settings, the test error rates decreased with the use of multiple metrics. However, the improvements were far greater in the supervised setting.

Figure 5. The classification train- and testerror rates with one metric (LMNN) and multiple metrics. The value of k was set by cross validation.

Finally, our last experiments explored the improvement in kNN error rates when one distance metric was learned for the training examples in each class. In these experiments, we used the full number of training examples for each data set. In addition, we used PCA to project the training inputs into a lower dimensional subspace accounting for at least 95% of the data's total variance. Fig. 5 shows generally consistent improvement in training and test kNN error rates, though overfitting is an issue, especially on the 20-NewsGroups and YaleFaces data sets. This overfitting is to be expected from the relatively large number of classes and high input dimensionality of these data sets: the number of model parameters in these experiments grows linearly in the former and quadratically in the latter. On these data sets, only the use of a validation set prevents the training error from vanishing completely while the test error skyrockets. On the other hand, a significant improvement in the test error rate is observed on the largest data set, that of MNIST handwritten digits. On this data set, multiple distance metrics yield a 1.18% test error rate—a highly competitive result for a method that does not take into account prior domain knowledge (LeCun et al., 1998).

6. Discussion

In this paper, we have extended the original framework for LMNN classification in several important ways: by describing a solver that scales well to larger data sets, by integrating metric ball trees into the training and testing procedures, by exploring the use of dimensionality reduction for further speedups, and by showing how to train different Mahalanobis distance metrics in different parts of the input space. These extensions should prove useful in many applications of kNN classification. More generally, we also hope they spur further work on problems in distance metric learning and large-scale semidefinite programming, both areas of great interest in the larger field of machine learning.

Abstract

We show how nonlinear embedding algorithms popular for use with *shallow* semi-supervised learning techniques such as kernel methods can be applied to deep multilayer architectures, either as a regularizer at the output layer, or on each layer of the architecture. This provides a simple alternative to existing approaches to *deep* learning whilst yielding competitive error rates compared to those methods, and existing *shallow* semi-supervised techniques.

1. Introduction

Embedding data into a lower dimensional space or the related task of clustering are unsupervised dimensionality reduction techniques that have been intensively studied. Most algorithms are developed with the motivation of producing a useful analysis and visualization tool.

Recently, the field of semi-supervised learning (Chapelle et al., 2006), which has the goal of improving generalization on supervised tasks using unlabeled data, has made use of many of these techniques. For example, researchers have used nonlinear embedding or cluster representations as features for a supervised classifier, with improved results.

Most of these architectures are *disjoint* and *shallow*, by which we mean the unsupervised dimensionality reduction algorithm is trained on unlabeled data separately as a first step, and then its results are fed to a supervised classifier which has a shallow architecture such as a (kernelized) linear model. For example, several methods learn a clustering or a distance measure based on a nonlinear manifold embedding as a first step (Chapelle et al., 2003; Chapelle & Zien, 2005). Transductive Support Vector Machines (TSVMs) (Vapnik, 1998) (which employs a kind of clustering) and LapSVM (Belkin et al., 2006) (which employs a kind of embedding) are examples of methods that are *joint* in their use of unlabeled data and labeled data, but their architecture is still *shallow*.

Deep architectures seem a natural choice in hard AI tasks which involve several *sub-tasks* which can be coded into the layers of the architecture. As argued by several researchers (Hinton et al., 2006; Bengio et al., 2007) semi-supervised learning is also natural in such a setting as otherwise one is not likely to ever have enough labeled data to perform well.

Several authors have recently proposed methods for using unlabeled data in deep neural network-based architectures. These methods either perform a greedy layer-wise pre-training of weights using unlabeled data alone followed by supervised fine-tuning (which can be compared to the *disjoint* shallow techniques for semi-supervised learning described before), or learn unsupervised encodings at multiple levels of the architecture jointly with a supervised signal. Only considering the latter, the basic setup we advocate is simple:

1. Choose an unsupervised learning algorithm.
2. Choose a model with a deep architecture.
3. The unsupervised learning is plugged into any (or all) layers of the architecture as an *auxiliary task*.
4. Train supervised and unsupervised tasks using the same architecture *simultaneously*.

The aim is that the unsupervised method will improve accuracy on the task at hand. However, the unsupervised methods so far proposed for deep architectures are in our opinion somewhat complicated and

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

restricted. They include a particular kind of generative model (a restricted Boltzmann machine) (Hinton et al., 2006), autoassociators (Bengio et al., 2007), and a method of sparse encoding (Ranzato et al., 2007). Moreover, in all cases these methods are not compared with, and appear on the surface to be completely different to, algorithms developed by researchers in the field of semi-supervised learning.

In this article we advocate simpler ways of performing deep learning by leveraging *existing* ideas from semi-supervised algorithms so far developed in *shallow* architectures. In particular, we focus on the idea of combining an *embedding*-based regularizer with a supervised learner to perform semi-supervised learning, such as is used in Laplacian SVMs (Belkin et al., 2006). We show that this method can be: (i) generalized to multi-layer networks and trained by stochastic gradient descent; and (ii) is valid in the *deep* learning framework given above.

Our experimental evaluation is then split into three parts: (i) stochastic training of semi-supervised multi-layered architectures is compared with existing semi-supervised approaches on several benchmarks, with positive results; (ii) a demonstration of how to use semi-supervised regularizers in *deep* architectures by plugging them into any layer of the architecture is shown on the well-known MNIST dataset; and (iii) a case-study is presented using these techniques for deep-learning of semantic role labeling of English sentences.

The rest of the article is as follows. In Section 2 we describe existing techniques for semi-supervised embedding. In Section 3 we describe how to generalize these techniques to the task of *deep learning*. Section 4 reviews existing techniques for deep learning, Section 5 gives an experimental comparison between all these approaches, and Section 6 concludes.

2. Semi-Supervised Embedding

A key assumption in many semi-supervised algorithms is the structure assumption[1]: points within the same structure (such as a cluster or a manifold) are likely to have the same label. Given this assumption, the aim is to use unlabeled data to uncover this structure. In order to do this many algorithms such as cluster kernels (Chapelle et al., 2003), LDS (Chapelle & Zien, 2005), label propagation (Zhu & Ghahramani, 2002) and LapSVM (Belkin et al., 2006), to name a few, make use of regularizers that are directly related to unsupervised embedding algorithms. To understand these methods we will first review some relevant approaches to linear and nonlinear embedding.

[1]This is often referred to as the cluster assumption or the manifold assumption (Chapelle et al., 2006).

2.1. Embedding Algorithms

We will focus on a rather general class of embedding algorithms that can be described by the following type of optimization problem: given the data $x_1, \ldots, x_U$ find an embedding $f(x_i)$ of each point x_i by minimizing

$$\sum_{i,j=1}^{U} L(f(x_i, \alpha), f(x_j, \alpha), W_{ij})$$

w.r.t. α, subject to

Balancing constraint.

This type of optimization problem has the following main ingredients:

- $f(x) \in \mathbb{R}^n$ is the embedding one is trying to learn for a given example $x \in \mathbb{R}^d$. It is parametrized by α. In many techniques $f(x_i) = f_i$ is a lookup table where each example i is assigned an independent vector f_i.
- L is a loss function between pairs of examples.
- The matrix W of weights W_{ij} specifying the similarity or dissimilarity between examples x_i and x_j. This is supplied in advance and serves as a kind of label for the loss function.
- A balancing constraint is often required for certain objective functions so that a trivial solution is not reached.

Many well known algorithms fit into this framework.

Multidimensional scaling (MDS) is a classical algorithm that attempts to preserve the distance between points, whilst embedding them in a lower dimensional space, e.g. by using the loss function

$$L(f_i, f_j, W_{ij}) = (||f_i - f_j|| - W_{ij})^2$$

MDS is equivalent to PCA if the metric is Euclidean (Williams, 2001).

ISOMAP (Tenenbaum et al., 2000) is a nonlinear embedding technique that attempts to capture manifold structure in the original data. It works by defining a similarity metric that measures distances along the manifold, e.g. W_{ij} is defined by the shortest path on the neighborhood graph. One then uses those distances to embed using conventional MDS.

Laplacian Eigenmaps (Belkin & Niyogi, 2003) learn manifold structure by emphasizing the preservation of *local distances*. One defines the distance metric between the examples by encoding them in the Laplacian $L = W - D$, where $D_{ii} = \sum_j W_{ij}$ is diagonal. Then, the following optimization is used:

$$\sum_{ij} L(f_i, f_j, W_{ij}) = \sum_{ij} W_{ij} ||f_i - f_j||^2 = f^\top L f \quad (1)$$

subject to the balancing constraint:

$$f^\top D f = I \text{ and } f^\top D 1 = 0. \quad (2)$$

Siamese Networks (Bromley et al., 1993) are also a classical method for nonlinear embedding. Neural networks researchers think of such models as a network with two identical copies of the same function, with the same weights, fed into a "distance measuring" layer to compute whether the two examples are similar or not, given labeled data. In fact, this is exactly the same as the formulation given at the beginning of this Section.

Several loss functions have been proposed for *siamese networks*, here we describe a margin-based loss proposed by the authors of (Hadsell et al., 2006):

$$L(f_i, f_j, W_{ij}) = \begin{cases} ||f_i - f_j||^2 & \text{if } W_{ij} = 1, \\ \max(0, m - ||f_i - f_j||^2) & \text{if } W_{ij} = 0 \end{cases} \quad (3)$$

which encourages similar examples to be close, and dissimilar ones to have a distance of at least m from each other. Note that no balancing constraint is needed with such a choice of loss as the margin constraint inhibits a trivial solution. Compared to using constraints like (2) this is much easier to optimize by gradient descent.

2.2. Semi-Supervised Algorithms

Several *semi-supervised* classification algorithms have been proposed which take advantage of the algorithms described in the last section. Here we assume the setting where one is given $L + U$ examples x_i, but only the first L have a known label y_i.

Label Propagation (Zhu & Ghahramani, 2002) adds a Laplacian Eigenmap type regularization to a nearest-neighbor type classifier:

$$\min_f \sum_{i=1}^{L} ||f_i - y_i||^2 + \lambda \sum_{i,j=1}^{L+U} W_{ij} ||f_i - f_j||^2 \quad (4)$$

The algorithm tries to give two examples with large weighted edge W_{ij} the same label. The neighbors of neighbors tend to also get the same label as each other by transitivity, hence the name *label propagation*.

LapSVM (Belkin et al., 2006) uses the Laplacian Eigenmaps type regularizer with an SVM: minimize

$$||w||^2 + \gamma \sum_{i=1}^{L} H(y_i f(x_i)) + \lambda \sum_{i,j=1}^{L+U} W_{ij} ||f(x_i) - f(x_j)||^2 \quad (5)$$

where $H(x) = \max(0, 1 - x)$ is the hinge loss.

Other Methods In (Chapelle & Zien, 2005) a method called *graph* is suggested which combines a modified version of ISOMAP with an SVM. The authors also suggest to combine modified ISOMAP with TSVMs rather than SVMs, and call it *Low Density Separation* (LDS).

3. Semi-supervised Embedding for Deep Learning

We would like to use the ideas developed in semi-supervised learning for *deep learning*. Deep learning consists of learning a model with several layers of non-linear mapping. In this article we will consider multi-layer networks with M layers of hidden units that give a C-dimensional output vector:

$$f_i(x) = \sum_{j=1}^{d} w_j^{O,i} \; h_j^M(x) + b^{O,i}, \quad i = 1, \ldots, C \quad (6)$$

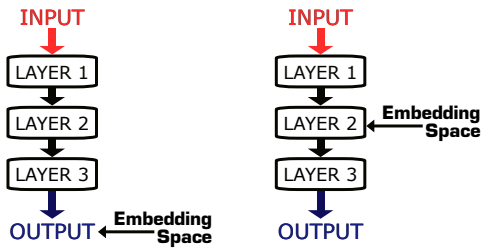
where w^O are the weights for the output layer, and typically the k^{th} layer is defined as

$$h_i^k(x) = S\left(\sum_j w_j^{k,i} \; h_j^{k-1}(x) + b^{k,i} \right), \; k > 1 \quad (7)$$

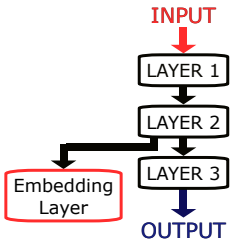
$$h_i^1(x) = S\left(\sum_j w_j^{1,i} \; x_j + b^{1,i} \right) \quad (8)$$

and S is a non-linear squashing function such as tanh. Here, we describe a standard *fully connected* multi-layer network but prior knowledge about a particular problem could lead one to other network designs. For example in sequence and image recognition time delay and convolutional networks (TDNNs and CNNs) (LeCun et al., 1998) have been very successful. In those approaches one introduces layers that apply convolutions on their input which take into account locality information in the data, i.e. they learn features from image patches or windows within a sequence.

The general method we propose for *semi-supervised deep learning* is to add a semi-supervised regularizer in deep architectures in one of three different modes, as shown in Figure 1:



(a) Output (b) Internal



(c) Auxiliary

Figure 1. Three modes of embedding in deep architectures.

(a) Add a semi-supervised loss (regularizer) to the supervised loss on the entire network's output (6):

$$\sum_{i=1}^{L} \ell(f(x_i), y_i) + \lambda \sum_{i,j=1}^{L+U} L(f(x_i), f(x_j), W_{ij}) \quad (9)$$

This is most similar to the *shallow* techniques described before, e.g. equation (5).

(b) Regularize the k^{th} hidden layer (7) directly:

$$\sum_{i=1}^{L} \ell(f(x_i), y_i) + \lambda \sum_{i,j=1}^{L+U} L(f^k(x_i), f^k(x_j), W_{ij}) \quad (10)$$

where $f^k(x) = (h_1^k(x), \ldots, h_{N_k}^k(x))$ is the output of the network up to the k^{th} hidden layer.

(c) Create an auxiliary network which shares the first k layers of the original network but has a new final set of weights:

$$g_i(x) = \sum_j w_j^{AUX,i} \; h_j^k(x) + b^{AUX,i} \quad (11)$$

We train this network to *embed* unlabeled data simultaneously as we train the original network on *labeled* data.

In our experiments we use the loss function (3) for embedding, and the hinge loss

$$\ell(f(x), y) = \sum_{c=1}^{C} H(y(c) f_c(x)),$$

Algorithm 1 *Embed*NN

Input: labeled data (x_i, y_i), $i = 1, \ldots, L$, unlabeled data x_i, $i = L+1, \ldots, U$, set of functions $f(\cdot)$, and embedding functions $g^k(\cdot)$, see Figure 1 and equations (9), (10) and (11).
repeat
  Pick a random *labeled* example (x_i, y_i)
  Make a gradient step to optimize $\ell(f(x_i), y_i)$
  for each embedding function $g^k(\cdot)$ **do**
    Pick a random pair of neighbors x_i, x_j.
    Make a gradient step for $\lambda L(g^k(x_i), g^k(x_j), 1)$
    Pick a random unlabeled example x_n.
    Make a gradient step for $\lambda L(g^k(x_i), g^k(x_n), 0)$
  end for
until stopping criteria is met.

for labeled examples, where $y(c) = 1$ if $y = c$ and -1 otherwise. For neighboring points, this is the same regularizer as used in LapSVM and Laplacian Eigenmaps. For non-neighbors, where $W_{ij} = 0$, this loss "pulls" points apart, thus inhibiting trivial solutions without requiring difficult constraints such as (2). To achieve an embedding *without* labeled data the latter is necessary or all examples would collapse to a single point in the embedding space. We therefore prefer this regularizer to using (1) alone. Pseudocode of our approach is given in Algorithm 1.

Labeling unlabeled data as neighbors Training neural networks online using stochastic gradient descent is fast and can scale to millions of examples. A possible bottleneck with our approach is computation of the matrix W, that is, computing which unlabeled examples are neighbors and have value $W_{ij} = 1$. Embedding algorithms often use k-nearest neighbor for this task, and although many methods for its fast computation do exist, this could still be slower than we would like. One possibility is to approximate it with sampling techniques.

However, there are also many other ways of collecting neighboring unlabeled data, notably if one is given *sequence* data such as in audio, video or text problems. For example, one can take images from two consecutive frames of video as a neighboring pair with $W_{ij} = 1$. Such pairs are likely to have the same label, and are collected cheaply. In Section 5 we apply this kind of idea to text and train a semi-supervised semantic role labeler using an unlabeled set of 631 million words.

When do we expect this approach to work? One can see our approach as an instance of multi-task learning (Caruana, 1997) using unsupervised auxiliary

tasks. In common with other semi-supervised learning approaches, and indeed other deep learning approaches, we only expect this to work if $p(x)$ is useful for the supervised task $p(y|x)$, i.e. if the structure assumption is true. We believe many natural tasks have this property.

We note that an alternative multi-task learning scheme is presented in (Ando & Zhang, 2005) and applied to neural networks in (Ahmed et al., 2008) which instead constructs auxiliary *supervised* tasks from unlabeled data by constructing tasks with labels y^*. This is useful when $p(y^*|x)$ is correlated to $p(y|x)$, however an expert must engineer a useful target y^*.

4. Existing Approaches to Deep Learning

Hinton and coworkers (2006) proposed the Deep Belief Net (DBN) which is a multi-layered network first trained as a generative model with unlabeled data before being subsequently trained in supervised mode. It is based around iteratively training Restricted Boltzmann machines (RBMs) for each layer. An RBM is a two-layer network in which visible, binary stochastic pixels v are connected to hidden binary stochastic feature detectors h. The probability assigned to an example x is:

$$P(x) = \sum_{h \in \mathcal{H}} P(x,h) = \sum_{h \in \mathcal{H}} \frac{e^{-E(x,h)}}{Z}$$

$$E(x,h) = -\sum_{i \in \text{pixels}} w_i^P v_i - \sum_{j \in \text{features}} w_j^F h_j - \sum_{i,j} v_j h_j w_{ij}$$

The idea is to obtain large values for the training examples, and small values elsewhere just as in any maximum likelihood density estimator. This is trained with a procedure called contrastive divergence whereby one pushes up the energy on training data and pushes down the energy on samples generated by the model. The authors used this method to pretrain a deep neighborhood component analysis model (DBN-NCA) and a regularized version that simultaneously trains an autoencoder (DBN-rNCA) (Salakhutdinov & Hinton, 2007).

The authors of (Bengio et al., 2007) suggested a simpler scheme: define an autoencoder that given an input x tries to encode it in a low dimensional space $z = f_{enc}(x)$, and then decode it again to reproduce it as well as possible, e.g. so that

$$||x - f_{dec}(f_{enc}(x))||^2$$

is small. (Actually you can also view RBMs in this way, see (Ranzato et al., 2007).) The idea is to use an autoencoder as a regularizer which is trained on unlabeled data. If the autoencoder is linear it corresponds to PCA (Japkowicz et al., 2000) and hence also MDS, making a clear link to the embedding algorithms we discussed in Section 2.1. The authors claim that autoassociators have the advantage "that almost any parametrizations of the layers are possible, as long as the training criterion is continuous in the parameters [...] the class of probabilistic models for which [DBNs] can be applied is currently more limited."

Finally, recently the authors of (Ranzato et al., 2007) introduced another method of deep learning which also amounts to a kind of encoder/decoder architecture, called SESM. In this case they choose to learn large, sparse codes as they believe these are good for classification. They choose an encoder $f_{enc}(x) = w^\top x + b_{enc}$ and a decoder with shared weights $f_{dec}(z) = wS(z) + b_{dec}$. They then optimize the following loss:

$$\alpha_e ||z - f_{enc}(x)||_2^2 + ||x - f_{dec}(z)||_2^2 + \alpha_s h(z) + \alpha_r ||w||_1$$

where the first term makes the output of the encoder close to the code z (which is also learnt), the second term makes the decoder try to reproduce the input, and the third and fourth terms sparsify the codes z and the weights of the encoder and decoder w. α_e, α_s and α_r are all hyperparameters. The training requires an online coordinate descent scheme because both z and w are being optimized.

We believe all of the methods just described are significantly more complicated than our approach. Our embedding approach can also be seen as an encoder $f_{enc}(x)$ that embeds data into a low dimensional space. However we do not need to decode during training (or indeed at all). Further, if the data is high dimensional and sparse there is a significant speedup from not having to decode.

Finally, existing approaches advocate greedy layer-wise training, followed by a "fine-tuning" step using the supervised signal. The intention is that the unsupervised learning provides a better initialization for supervised learning, and hence a better final local minimum. Our approach does not use a pre-training step, but instead *directly* optimizes our new objective function. We advocate that it is the new choice of objective that can provide improved results.

5. Experimental Evaluation

We test our approach on several datasets summarized in Table 1.

Small-scale experiments g50c, Text and Uspst are small-scale datasets often used for semi-supervised

Table 1. Datasets used in our experiments. The first three are small scale datasets used in the same experimental setup as found in (Chapelle & Zien, 2005; Sindhwani et al., 2005; Collobert et al., 2006). The following six datasets are large scale. The Mnist 1h,6h,1k,3k and 60k variants are MNIST with a labeled subset of data, following the experimental setup in (Collobert et al., 2006). SRL is a Semantic Role Labeling task (Pradhan et al., 2004) with one million labeled training examples and 631 million unlabeled examples.

data set	classes	dims	points	labeled
g50c	2	50	500	50
Text	2	7511	1946	50
Uspst	10	256	2007	50
Mnist1h	10	784	70k	100
Mnist6h	10	784	70k	600
Mnist1k	10	784	70k	1000
Mnist3k	10	784	70k	3000
Mnist60k	10	784	70k	60000
SRL	16	-	631M	1M

learning experiments (Chapelle & Zien, 2005; Sindhwani et al., 2005; Collobert et al., 2006). We followed the same experimental setup, averaging results of ten splits of 50 labeled examples where the rest of the data is unlabeled. In these experiments we test the embedding regularizer on the output of a neural network (see equation (9) and Figure 1(a)). We define a two-layer neural network (NN) with hu hidden units. We define W so that the 10 nearest neighbors of i have $W_{ij} = 1$, and $W_{ij} = 0$ otherwise. We train for 50 epochs of stochastic gradient descent and fixed $\lambda = 1$, but for the first 5 we optimized the supervised target alone (without the embedding regularizer). This gives two free hyperparameters: the number of hidden units $hu = \{0, 5, 10, 20, 30, 40, 50\}$ and the learning rate $lr = \{0.1, 0.05, 0.01, 0.005, 0.001, 0.0005, 0.0001\}$.

We report the optimum choices of these values optimized by 5-fold cross validation and by optimizing on the test set in Table 2. Note the datasets are very small, so cross validation is unreliable. Several methods from the literature optimized their hyperparameters using the test set (those that are not marked with (cv)). Our *Embed*NN is competitive with state-of-the-art semi-supervised methods based on SVMs, even outperforming them in some cases.

MNIST experiments We compare our method in all three different modes (Figure 1) with conventional semi-supervised learning (TSVM) using the same data split and validation set as in (Collobert et al., 2006). We also compare to several deep learning methods: RBMs, SESM and DBN-NCA and DBN-rNCA (however, they are trained on a different data split). In

Table 2. Results on Small-Scale Datasets. We report the best test error over the hyperparameters of our method, *Embed*NN, as in the methodology of (Chapelle & Zien, 2005) as well as the error when optimizing the parameters by cross-validation, *Embed*NN$^{(cv)}$. LDS$^{(cv)}$ and LapSVM$^{(cv)}$ also use cross-validation.

	g50c	Text	Uspst
SVM	8.32	18.86	23.18

Table 4. Mnist1h dataset with deep networks of 2, 6, 8, 10 and 15 layers; each hidden layer has 50 hidden units. We compare classical NN training with *Embed*NN where we either learn an embedding at the output layer (^{O}) or an auxiliary embedding on all layers at the same time (^{ALL}). .

	2	4	6	8	10	15
NN	26.0	26.1	27.2	28.3	34.2	47.7
Embed^{O}NN	19.7	15.1	15.1	15.0	13.7	11.8
Embed^{ALL}NN	18.2	12.6	7.9	8.5	6.3	9.3

Table 5. Full Mnist60k dataset with deep networks of 2, 6, 8, 10 and 15 layers, using either 50 or 100 hidden units. We compare classical NN training with $Embed^{ALL}$NN where we learn an auxiliary embedding on all layers at the same time.

	2	4	6	8	10	15
NN (HUs=50)	2.9	2.6	2.8	3.1	3.1	4.2
$Embed^{ALL}$NN	2.8	1.9	2.0	2.2	2.4	2.6
NN (HUs=100)	2.0	1.9	2.0	2.2	2.3	3.0
$Embed^{ALL}$NN	1.9	1.5	1.6	1.7	1.8	2.4

these experiments we consider 2-layer networks (NN) and 6-layer convolutional neural nets (CNN) for embedding. We optimize the parameters of NN ($hu = \{50, 100, 150, 200, 400\}$ hidden units and learning rates as before) on the validation set. The CNN architecture is fixed: 5 layers of image patch-type convolutions, followed by a linear layer of 50 hidden units, similar to (LeCun et al., 1998). The results given in Table 3 show the effectiveness of embedding in all three modes, with both NNs and CNNs.

Deeper MNIST experiments We then conducted a similar set of experiments but with very deep architectures – up to 15 layers, where each hidden layer has 50 hidden units. Using Mnist1h, we first compare conventional NNs to $Embed^{ALL}$NN where we learn an auxiliary nonlinear embedding (50 hidden units and a 10 dimensional embedding space) on each layer, as well as $Embed^{O}$NN where we only embed the outputs. Results are given in Table 4. When we increase the number of layers, NNs trained with conventional backpropagation overfit and yield steadily *worse* test error (although they are easily capable of achieving zero training error). In contrast, $Embed^{ALL}$NN *improves* with increasing depth due to the semi-supervised "regularization". Embedding on *all* layers of the network has made *deep learning* possible. $Embed^{O}$NN (embedding on the outputs) also helps, but not as much.

We also conducted some experiments using the full MNIST dataset, Mnist60k. Again using deep networks of up to 15 layers using either 50 or 100 hidden units $Embed^{ALL}$NN outperforms standard NN. Results are given in Table 5. Increasing the number of hidden units is likely to improve these results further, e.g. using 4 layers and 500 hidden units on each layer, one obtains 1.27% using $Embed^{ALL}$NN.

Semantic Role Labeling The goal of semantic role labeling (SRL) is, given a sentence and a relation of interest, to label each word with one of 16 tags that indicate that word's semantic role with respect to the action of the relation. For example the sentence *"The cat eats the fish in the pond"* is labeled in the following way: *"The*$_{ARG0}$ *cat*$_{ARG0}$ *eats*$_{REL}$ *the*$_{ARG1}$ *fish*$_{ARG1}$ *in*$_{ARGM-LOC}$ *the*$_{ARGM-LOC}$ *pond*$_{ARGM-LOC}$*"* where ARG0 and ARG1 effectively indicate the subject and object of the relation "eats" and ARGM-LOC indicates a locational modifier. The PropBank dataset includes around 1 million labeled words from the Wall Street Journal. We follow the experimental setup of (Collobert & Weston, 2007) and train a 5-layer convolutional neural network for this task, where the first layer represents the input sentence words as 50-dimensional vectors. Unlike (Collobert & Weston, 2007), we do not give any prior knowledge to our classifier. In that work words were stemmed and clustered using their parts-of-speech. Our classifier is trained using only the original input words.

Table 6. A deep architecture for Semantic Role Labeling with no prior knowledge outperforms state-of-the-art systems ASSERT and SENNA that incorporate knowledge about parts-of-speech and parse trees. A convolutional network (CNN) is improved by learning an auxiliary embedding ($Embed^{A1}$CNN) for words represented as 100-dimensional vectors using the entire Wikipedia website as unlabeled data.

Method	Test Error
ASSERT (Pradhan et al., 2004)	16.54%
SENNA (Collobert & Weston, 2007)	16.36%
CNN [no prior knowledge]	18.40%
$Embed^{A1}$CNN [no prior knowledge]	14.55%

We attempt to improve this system by, as before, learning an *auxiliary embedding* task. Our embedding is learnt using unlabeled sentences from the Wikipedia web site, consisting of 631 million words in total using the scheme described in Section 3. The same lookup table of word vectors as in the supervised task is used as input to an 11 word window around a given word, yielding 550 features. Then a linear layer projects these features into a 100 dimensional embedding space. All windows of text from Wikipedia are considered neighbors, and non-neighbors are constructed by replacing the middle word in a sentence window with a random word. Our lookup table indexes the most frequently used 30,000 words, and all other words are assigned index 30,001.

The results in Table 6 indicate a clear improvement when learning an auxiliary embedding. ASSERT (Pradhan et al., 2004) is an SVM parser-based system with many hand-coded features, and SENNA is a NN which uses part-of-speech information to build its word vectors. In contrast, our system is the only state-

of-the-art method that does not use prior knowledge in the form of features derived from parts-of-speech or parse tree data. This application will be described in more detail in a forthcoming paper.

6. Conclusion

In this work, we showed how one can improve supervised learning for deep architectures if one jointly learns an embedding task using unlabeled data. Our results both confirm previous findings and generalize them. Researchers using *shallow* architectures already showed two ways of using embedding to improve generalization: (i) embedding unlabeled data as a *separate* pre-processing step (i.e., first layer training) and; (ii) using embedding as a regularizer (i.e., at the output layer). More importantly, we generalized these approaches to the case where we train a semi-supervised embedding *jointly* with a supervised *deep* multi-layer architecture on any (or all) layers of the network, and showed this can bring real benefits in complex tasks.

Efficiently Learning Linear-Linear Exponential Family Predictive Representations of State

David Wingate WINGATED@UMICH.EDU
Satinder Singh BAVEJA@UMICH.EDU
Computer Science and Engineering, University of Michigan, 2260 Hayward, Ann Arbor, MI 48109

Abstract

Exponential Family PSR (EFPSR) models capture stochastic dynamical systems by representing state as the parameters of an exponential family distribution over a short-term window of future observations. They are appealing from a learning perspective because they are fully observed (meaning expressions for maximum likelihood do not involve hidden quantities), but are still expressive enough to both capture existing models and predict new models. While maximum-likelihood learning algorithms for EFPSRs exist, they are not computationally feasible. We present a new, computationally efficient, learning algorithm based on an approximate likelihood function. The algorithm can be interpreted as attempting to induce stationary distributions of observations, features and states which match their empirically observed counterparts. The approximate likelihood, and the idea of matching stationary distributions, may apply to other models.

1. Introduction

One of the basic problems in modeling controlled, partially observable, stochastic dynamical systems is representing and tracking state. In a reinforcement learning context, the state of the system is important because it can be used to make predictions about the future, or to control the system optimally. Often, state is viewed as an unobservable, latent variable, but models with *predictive representations of state* (Littman et al., 2002) propose an alternative: PSRs represent state as *statistics about the future*.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

The original PSR models used the probability of specific, detailed futures called *tests* as the statistics of interest. Recent work has introduced the more general notion of using parameters that model the distribution of length n futures as the statistics of interest (Rudary et al., 2005; Wingate, 2008). To clarify this, consider an agent interacting with the system. It observes a series of observations $o_1...o_t$, which we call a *history* h_t (where subscripts denote time). Given any history, there is some distribution over the next n observations: $p(O_{t+1}...O_{t+n}|h_t) \equiv p(F^n|h_t)$ (where O_{t+i} is the random variable representing an observation i steps in the future, and F^n is a mnemonic for *future*). We emphasize that this distribution directly models observable quantities in the system.

The *Exponential Family PSR* is a new family of models of partially observable, stochastic dynamical systems. EFPSR models assume that the distribution $p(F^n|h_t)$ has an exponential family form, and that the parameters of that distribution are the state of the system (Wingate, 2008). This idea has been shown to unify a number of existing models of dynamical systems: for example, if $p(F^n|h_t)$ is assumed to be Gaussian (and certain other choices are made), the model can capture any domain modeled by a Kalman filter.

Existing algorithms for learning EFPSR models from data are based on maximizing exact likelihood, but the algorithms are slow. This paper presents an efficient algorithm for one particular EFPSR, named the Linear-Linear EFPSR. We begin by presenting an approximate likelihood function, and then show that the terms needed to maximize it can be efficiently computed by virtue of the linearity of the Linear-Linear EFPSR's state update. The resulting algorithm is computationally efficient, and can be interpreted in terms of stationary distributions of observations, features and states. It allows us to begin to learn models of domains which are too large (in terms of the amount of data required, and in terms of the complexity of the observation space) to tackle with any other EFPSR.

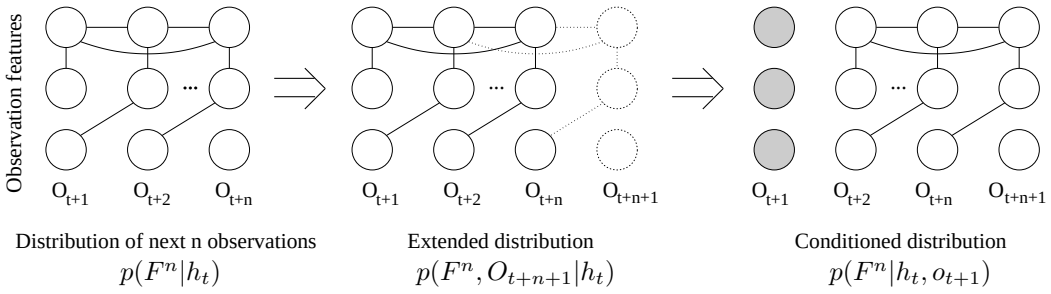

Figure 1. An illustration of extending and conditioning.

2. The Exponential Family PSR

We first review the EFPSR family of models, including how state is represented and how it is maintained.

State. The EFPSR defines state as the parameters of an exponential family distribution modeling $p(F^n|h_t)$, which is a window of n future observations. To emphasize that these parameters represent state, we will refer to them as s_t. The form of the distribution is:

$$p(F^n = f^n|h_t; s_t) = \exp\left\{s_t^\top \phi(f^n) - \log Z(s_t)\right\}, \quad (1)$$

with both $\{\ \phi(f^n),\ s_t\ \} \in \mathbb{R}^{l\times 1}$. The vector $\phi(f^n)$ is a feature vector which controls the particular form of the distribution. For example, $\phi(X) = [X, X^2]$, yields a Gaussian, but $\phi(X) = [X, \log(X)]$ yields a gamma. Since the distribution is over the future, ϕ can be thought of as *features of the future*.

As the agent interacts with the system, $p(F^n|h_t)$ changes because h_t changes; therefore the parameters s_t and hence state change. The feature vector $\phi(f^n)$ does not change over time.

Maintaining State. In addition to selecting the form of $p(F^n|h_t)$, there is a dynamical component: given the parameters of $p(F^n|h_t)$, how can we incorporate a new observation to find the parameters of $p(F^n|h_t, o_{t+1})$? That is, how can we update state? Our strategy is to *extend and condition*.

Extend. We assume that we have the parameters of $p(F^n|h_t)$, denoted s_t. We *extend* the distribution of $F^n|h_t$ to include O_{t+n+1}, which forms a new variable $F^{n+1}|h_t$, and we assume it has the distribution $p(F^n, O_{t+n+1}|h_t) = p(F^{n+1}|h_t)$. This is a temporary distribution over $(n+1)$ observations.

To perform the extension, we define an *extension function* which maps the current state vector to the parameters of the extended distribution:

$$s_t^+ = \text{extend}(s_t; \theta),$$

where θ is a vector of parameters controlling the extension function (and hence, the overall dynamics).

The extension function helps govern the kinds of dynamics that the model can capture. For example, in the PLG family of work, a linear extension allows the model to capture linear dynamics (Rudary et al., 2005), while a non-linear extension allows the model to capture non-linear dynamics (Wingate, 2008).

Condition. Once we have extended the distribution to model the $n+1$'st observation in the future, we then condition on the *actual* observation o_{t+1}, which results in the parameters of $p(F^n|h_{t+1})$:

$$s_{t+1} = \text{condition}(s_t^+, o_{t+1}),$$

which is our state at time $t+1$.

The entire process of extending and conditioning is illustrated in Fig. 1. We have drawn graphs to suggest that there can be structure in the distributions, and to informally hint at the fact that the form of the distribution does not change over time. This, and other constraints on the features and extension function, are discussed in detail elsewhere (Wingate, 2008).

2.1. The Linear-Linear EFPSR

The EFPSR is a family of models. Specific members of the family are chosen by selecting two things: the features ϕ, and an extension function. For example, if $p(F^n|h_t)$ is Gaussian, and a special extension function is chosen, the predictively defined version of a linear dynamical system (Kalman filter) is recovered.

The Linear-Linear EFPSR chooses features and an extension function designed to make it both analytically tractable and efficiently approximable. The extension function is linear, and features are chosen such that conditioning is always a linear operation (hence the name, "Linear-Linear"). In this paper, we also assume the base observations are vectors of binary random variables. If they are not, we assume that binary features are extracted from the observations, and discard the original observations (we call these *atomic* features, to distinguish them from the higher-order features defined by ϕ).

Features. Let each base observation O_t be a vector $\in \{0,1\}^d$; therefore, each $F^n|h_t \in \{0,1\}^{nd}$. We restrict all features comprising the feature vector ϕ to be conjunctions of the atomic binary variables in the base observations. For example, if each $O_t \in \{0,1\}^3$, there could be a feature $\phi(o_t)_k$ which is a conjunction of the second and third components of the observation: $\phi(o_t)_k = (o_t)_2(o_t)_3$. By selecting features this way, the resulting distribution can be conditioned with an operator that is nonlinear in the observation o_{t+1}, but linear in the state s_t. We therefore define the linear conditioning operator $G(o_{t+1})$ to be a matrix which transforms s_t^+ into s_{t+1}: $s_{t+1} = G(o_{t+1})s_t^+$. See (Wingate, 2008) for details.

Extension function. We choose a linear extension:

$$s_t^+ = As_t + B.$$

$A \in \mathbb{R}^{k\times l}$ and $B \in \mathbb{R}^{k\times 1}$ are our model parameters.

The combination of a linear extension and a linear conditioning operator means that the entire extend-and-condition operation (ie, state update) is a linear operation:

$$s_{t+1} = G(o_{t+1})\left(As_t + B\right).$$

This will be critical in the sequel.

3. Learning with Exact Likelihood

We now briefly sketch how to learn a Linear-Linear EFPSR model from data by maximizing exact likelihood. We do this to point out the two primary computational bottlenecks that motivate this paper.

We assume we are given a sequence of T observations, $[o_1 \cdots o_T]$, which we stack to create a sequence of samples from the $F^n|h_t$'s: $f_t|h_t = [o_{t+1} \cdots o_{t+n}|h_t]$. The likelihood of the training data is $p(o_1, o_2 ... o_T) = \prod_{t=1}^T p(o_t|h_t)$, but we will find it more convenient to measure the likelihood of the corresponding f_t's: $p(o_1, o_2 ... o_T) \approx n\prod_{t=1}^T p(f_t|h_t)$ (maximizing this is equivalent to maximizing the standard likelihood).

The expected log-likelihood of the training f_t's under the model defined in Eq. 1 is

$$\mathcal{LL} = \frac{1}{T}\left(\sum_{t=1}^{T} -s_t^\top \phi(f_t) - \log Z(s_t)\right) \qquad (2)$$

Our goal is to maximize this quantity. Any optimization method can be used to maximize the log-likelihood. Two popular choices are gradient ascent and quasi-Newton methods, such as (L-)BFGS, which require the gradient of the likelihood with respect to the parameters, which we will now compute.

We can differentiate with respect to our parameters:

$$\frac{\partial \mathcal{LL}}{\partial \{A, B\}} = \sum_{t=1}^{T} \frac{\partial \mathcal{LL}}{\partial s_t}^\top \frac{\partial s_t}{\partial \theta} \qquad (3)$$

and with respect to each state:

$$\begin{aligned}\frac{\partial \mathcal{LL}}{\partial s_t} &= \frac{\partial}{\partial s_t}\left[-s_t^\top \phi(f_t) - \log Z(s_t)\right] \\ &= \mathrm{E}_{s_t}[\phi(F^n|h_t)] - \phi(f_t) \qquad (4)\end{aligned}$$

where $\mathrm{E}_{s_t}[\phi(F^n|h_t)] \in \mathbb{R}^{l\times 1}$ is the vector of expected sufficient statistics at time t.

The gradient of s_t with respect to A is given by

$$\frac{\partial s_t}{\partial A} = G(o_{t+1})\left(A\frac{\partial s_{t-1}}{\partial A} + s_{t-1}^\top \otimes I\right),$$

where $\otimes$ is the Kronecker product, and I is an identity matrix the same size as A. The gradient of the state with respect to B is

$$\frac{\partial s_t}{\partial B} = G(o_{t+1})\left(A\frac{\partial s_{t-1}}{\partial B} + I\right).$$

Note that the gradients at time t are temporally recursive – they depend all previous gradients.

There are two bottlenecks which motivate this paper:

1. Computing $\mathrm{E}_{s_t}[\phi(F^n|h_t)]$ is a standard inference problem in exponential family models, and is computationally expensive because it scales exponentially with the number of atomic observation variables included in the domain of $p(F^n|h_t)$. Even approximate inference is NP-hard (Dagum & Luby, 1993), and it must be done T times.

2. The gradients are temporally recursive, but can be computed in a single pass through the data. However, the process is expensive. For the discussion, assume that we have l features in $\phi(f_t)$, and that we have k features in the extended distribution. This means that the matrix $A \in \mathbb{R}^{k\times l}$, that the vector $s_t \in \mathbb{R}^l$, and that there are kl total parameters describing A. The term $\partial s_t/\partial A$ is a matrix, with l rows and kl columns. Given $\partial s_{t-1}/\partial A$, part of computing $\partial s_t/\partial A$ involves multiplying $\partial s_t/\partial A$ by A. This is an expensive matrix-matrix multiplication, which scales poorly as the number of features in the model grows, and it must be performed T times to get the true gradient of the likelihood, which scales poorly as the size of the training set grows.

To summarize, the exact learning algorithm does not scale well with either the number of training samples T, the dimension of the observations, the window size n, or the number of features $|\phi|$.

4. Approximate Likelihood

We now turn to the main contribution of this paper. In order to achieve an efficient learning algorithm, we will present an approximate expression for likelihood, named $\widehat{\mathcal{LL}}$, and show that its gradient can be efficiently computed. We will also examine what happens in the limit as $T \to \infty$. The quantity $\widehat{\mathcal{LL}}$ could be used with any model, not just the Linear-Linear EFPSR, but we will show that the Linear-Linear EFPSR allows us to compute the needed terms easily.

We now present our approximate log-likelihood $\widehat{\mathcal{LL}}$, which is an approximate lower bound on the exact likelihood. To begin, we will make one central assumption:

Assumption 4.1. We assume that $\text{Cov}[s_t, \phi(f_t)] = 0$ and that $\text{Cov}[s_t, o_t] = 0$, $\forall t$.

This assumes that the state does not covary with observable quantities. It implies that $\text{E}[s_t^\top \phi(f_t)] = \text{E}[s_t]^\top \text{E}[\phi(f_t)]$, which will be repeatedly used in the following derivation. This is not as severe of an assumption as it may appear to be – in particular, that this does not imply that s_t and $\phi(f_t)$ are independent.

We derive $\widehat{\mathcal{LL}}$ using Assumption 4.1 and a lower bound based on Jensen's inequality:

$$\begin{aligned}
\mathcal{LL} &= \frac{1}{T}\left(\sum_{t=1}^{T} -s_t^\top \phi(f_t) - \log Z(s_t)\right) \\
&= \text{E}_T\left[-s_t^\top \phi(f_t) - \log Z(s_t)\right] \\
&= \text{E}_T\left[-s_t^\top \phi(f_t)\right] - \text{E}_T\left[\log Z(s_t)\right] \\
&\approx \text{E}_T\left[-s_t\right]^\top \text{E}_T\left[\phi(f_t)\right] - \text{E}_T\left[\log Z(s_t)\right] \\
&\geq \text{E}_T\left[-s_t\right]^\top \text{E}_T\left[\phi(f_t)\right] - \log Z(\text{E}_T\left[s_t\right]) \\
&\equiv \widehat{\mathcal{LL}}
\end{aligned}$$

where we have defined the operator

$$\text{E}_T[X] \equiv \frac{1}{T}\sum_{t=1}^{T} X.$$

The fourth line in the derivation follows because of Assumption 4.1. The fifth line is obtained by a double application of Jensen's inequality:

$$\begin{aligned}
\text{E}[-\log Z(s_t)] &= \text{E}\left[-\log(\int \exp(-s_t^\top \phi(F))dF)\right] \\
&\geq -\log(\text{E}\left[\int \exp(-s_t^\top \phi(F))dF\right]) \\
&\geq -\log(\int \exp(\text{E}\left[-s_t^\top \phi(F)\right])dF) \\
&\approx -\log(\int \exp(\text{E}\left[-s_t\right]^\top \text{E}\left[\phi(F)\right])dF) \\
&= -\log Z(\text{E}[s_t]).
\end{aligned}$$

Algorithm 1 LEARN-EFPSRS-W-APPROX-LL

Input: $\text{E}_T[o_t]$, $\text{E}_T[\phi(f_t)]$
Initialize $A = 0$, $B = 0$.
repeat
  $(\widehat{\mathcal{LL}}, \nabla_A \widehat{\mathcal{LL}}, \nabla_B \widehat{\mathcal{LL}})$=GRADS-OF-APPROX-LL($\text{E}_T[o_t], \text{E}_T[\phi(f_t)], A, B$)
  // Use the gradients in an optimizer. Steepest
  // descent would look like this:
  $A = A + \alpha \nabla_A \widehat{\mathcal{LL}}$
  $B = B + \alpha \nabla_B \widehat{\mathcal{LL}}$
until $\widehat{\mathcal{LL}}$ is maximized
Return A, B

The second and third lines follow because of the convexity of the functions $-\log$ and exp, and the fourth line follows by Assumption 4.1.

The approximate log-likelihood involves several new terms, which we now explain. Consider $\text{E}_T[s_t]$. Because this is an unconditional expectation, as $T \to \infty$, this can be interpreted as the stationary distribution of states induced by a particular setting of the parameters of the model.

At first glance, this term would appear to defeat the point of our approximations: it appears to depend on T and on the model parameters, which means that we would have to recompute it, at cost T, every time the parameters change (as they would inside any sort of optimization loop). Fortunately, because it is the stationary distribution of states, it can be efficiently computed in the case of the Linear-Linear EFPSR as the solution to a linear system of equations in a way that does not depend on T.

The other terms have similar interpretations. $\text{E}_T[\phi(f_t)]$ is empirically observed stationary distribution of features of n-step windows of observations. Since it does not depend on the model parameters, it can be computed once at the beginning of learning in a single pass through the data. The quantity $\log Z(\text{E}_T[s_t])$ is the log partition function Z computed using the vector $\text{E}_T[s_t]$, and can be computed in the same way as the partition function associated with any ordinary state s_t.

4.1. Computing the Approximate Likelihood

Can the approximate log-likelihood $\widehat{\mathcal{LL}}$ and its derivatives be computed efficiently? The answer is yes: Appendix A shows that in the case of the Linear-Linear EFPSR, both $\widehat{\mathcal{LL}}$ and the derivative of $\widehat{\mathcal{LL}}$ with respect to the model parameters can be computed efficiently. The computation does not depend on T (the amount

of training data), and only involves the solution to two sparse linear systems of equations. Inference must be performed on the graphical model only once. In addition, the expensive matrix-matrix multiplications are completely eliminated.

4.2. Algorithm Summary

Let us pause for a brief summary. The exact log-likelihood $\mathcal{LL}$ in Eq. 2 is intractable to maximize. However, we have introduced $\widehat{\mathcal{LL}}$, and shown that it and its derivatives can be computed efficiently. Putting everything together, we see that this learning algorithm is attempting:

- to find a setting of the parameters A and B
- which generate a stationary distribution of states $\mathrm{E}_T[s_t]$,
- based on a transition operator defined using the stationary distribution of observations $\mathrm{E}_T[o_t]$,
- which imply a stationary distribution of features of length n trajectories $\mathrm{E}_{\mathrm{E}_T[s_t]}[\phi(F^n|h_t)]$ as close as possible to the empirically observed stationary distribution of features of length n trajectories $\mathrm{E}_T[\phi(f_t)]$.

With gradients in hand, any optimization method may be used to find the optimal settings for A and B. The final gradient algorithm is shown in Algorithm 2 (in Appendix A), and a simple companion steepest descent optimizer is shown in Algorithm 1.

5. A Low-Rank Parameterization

We briefly turn our attention to the parameter matrices A and B. So far, we have implicitly assumed that the matrix A is reasonably sized, but this assumption is false in the case of a large number of features.

To clarify this, recall that our state s_t is a vector $\in \mathbb{R}^{l\times 1}$, where l is the number of features of the future. When we extend and condition, we implicitly compute s_t^+, which is a vector of parameters describing $n+1$ observations: $s_t^+ = As_t + B$. If we assume that there are k extended features, the A matrix is $\in \mathbb{R}^{k\times l}$.

One of the goals of EFPSRs is to be able to use many features in order to capture state. If the number of features l is very large (say, tens of thousands, or even millions), the number of extended features k will be even larger, and the matrix A will be too large to work with. For example, if there are 10,000 features, and if the extended distribution has 15,000 features, the matrix $A \in \mathbb{R}^{15{,}000\times 10{,}000}$, which is simply too large.

$\widehat{\mathcal{LL}}$ has another property which suggests a solution

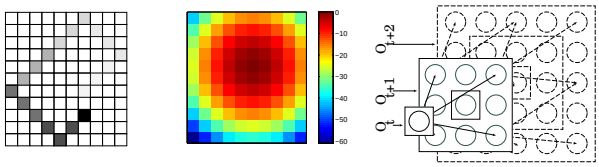

Figure 2. The setup of the bouncing ball problem.

to this problem: the gradients $\nabla_A \widehat{\mathcal{LL}}$ have a natural rank-one form, and therefore mesh well with singular value decomposition (SVD) update algorithms (Brand, 2006). Instead of maintaining the full matrix A, we can maintain a low-rank SVD of A. Given the SVD of A and a rank-one gradient update, the parameters of the updated SVD can be efficiently computed. The entire process can be meshed with a rank-aware line search. The advantage is that the full matrix A is never computed, but exact line searches can be conducted. See (Wingate, 2008) for more details.

6. Experiments and Results

We now evaluate the quality of our approximations. For large problems, we cannot compute the exact likelihoods to compare with, and since we are using approximate likelihoods, it is not clear what a comparison would mean. Instead, we use reinforcement learning to help measure the quality of the model: we use the states generated by the EFPSR as the input to an reinforcement learning planner. We conclude that our model is good if the RL agent is able to use it generate performance comparable to that of the true model. For comparison, we also tested RL using the raw observations as state (called the "reactive," or first-order Markov policy), and a random policy.

6.1. Planning in the EFPSR

We used the Natural Actor Critic (or NAC) algorithm (Peters et al., 2005) to test our model. NAC requires two things: a stochastic, parameterized policy and the gradients of the log probability of that policy. We used a softmax function of a linear projection of the state: the probability of taking action a_i from state s_t given the policy parameters θ is $p(a_i; s_t, \theta) = \exp\left\{s_t^\top \theta_i\right\} / \sum_{j=1}^{|\mathcal{A}|} \exp\left\{s_t^\top \theta_j\right\}$, where θ is to be learned. See (Wingate, 2008) for details.

6.2. Bouncing Ball

The first test domain is called the Bouncing Ball domain. In this domain, the observations are factored in a way that is closely related to the dynamics of the system. This domain was hand-crafted to be compatible with the EFPSR: the domain has significant structure

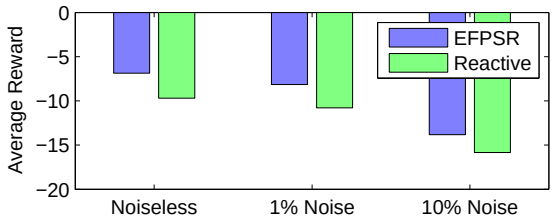

Figure 3. Results on the bouncing ball domain.

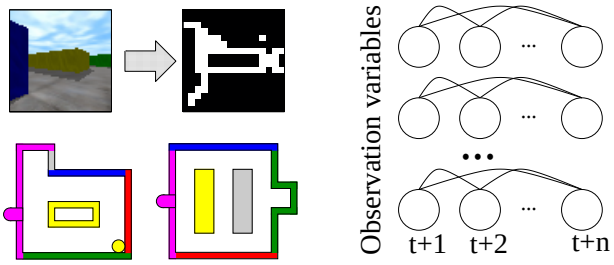

Figure 4. Setup of the vision domain.

in the observations, and basically requires the use of a model which is able to capture that structure.

Figure 2 describes the domain pictorially. The left figure shows the the ball bouncing. At each timestep, the agent observes an 11x10 array of pixels which may be black or white. One of these pixels represents the "ball," which bounces diagonally around the box (shown as a gray trail in the figure). The agent has two actions: 0 means "do nothing," and 1 means "reverse the direction of the ball." The reward signal is shown in the middle. This domain is episodic: every 50 timesteps, the ball is reset to a random position. We define three different versions of the domain. In the noiseless version, the agent sees the exact position of the ball. This domain is second-order Markov with $11 \times 10 = 110$ observations. The second version adds a p=1% chance of flipping white pixels to black. This domain is no longer second-order Markov, and has 2^{110} possible observations. The third version uses p=10%.

Figure 2 shows the features we used, which are hand-coded to correspond with the known dynamics. We set $n = 2$ and added singleton features for each observation. Pairwise features were added for each variable to its diagonal neighbors in the next timestep (to capture the diagonal motion of the ball). The extended distribution $p(F^3|h_t)$ used quartets consisting of an action and observation at time t, and diagonal observations at time $t+1$ and $t+2$. There were 584 features describing $p(F^2|h_t)$ and 1,292 features describing $p(F^3|h_t)$.

We used the timeless gradients, the low rank approximation of A, and 100,000 training samples. Figure 3 collects the results. The EFPSR is able to consistently improve over the best reactive policy, generating a policy with 30% higher reward in the noiseless version, a policy with 25% higher reward when p=1%, and a policy with 13% higher reward when p=10%. It is an open question as to whether different feature sets would improve these results further.

6.3. Robot Vision Domain

Together, the combination of the Linear-Linear EFPSR, the approximate maximum likelihood objective function, and the low-rank decomposition of the parameter matrix allow experimentation on domains with hundreds of observation variables and tens of thousands of features, which is larger than any other model with a predictive representation of state. Here, we apply the entire suite of techniques to the task of visual navigation, where a robot must navigate a maze using only features of camera images as observations.

Figure 4 explains the setup. The latent state space consists of a position x, y and orientation θ. The experiments used two different maps (bottom left). The agent has four actions: move forward, move backward, turn left and turn right. We tested two kinds of dynamics: in the "coarse" dynamics, the agent took large steps and turns, and in the "fine" dynamics, the agent took small steps and turns. The initial observations are 64x64 color images, from which binary features are extracted (upper left). We tried two different sets of binary features. The first set consisted of 884 features like edges, corners and colors, and the second feature set was a post-processed version of the first. The idea of the second set was to create higher-order features which represented things like walls and hallways. To do this, images from Maze #1 were clustered according to the latent states, and then the binary features were averaged together to create a sort of filter. New images were tested against each filter, triggering if the response exceeded a threshold. There were 373 of these features. Note that while the images were all taken from Maze #1, they were also used in Maze #2, where the colors, hall geometry, etc. were all different.

We set $n = 3$. For the feature vector $\phi()$, we used "streamer features." These connect each observation variable only to its temporal successors (Fig. 4, right). There were between 12,000 and 50,000 total features in the final feature set. We trained on 200,000 samples generated with a random policy. For the NAC parameters, we used a TD rate of $\lambda = 0.85$, a step-size $\alpha = 10.0$, gradient termination test $\epsilon = 0.001$ and remembering factor $\beta = 0.0$.

Figure 5 shows the results. The random policy performed the same in both domains, regardless of map or dynamics. Higher rewards were obtained in general

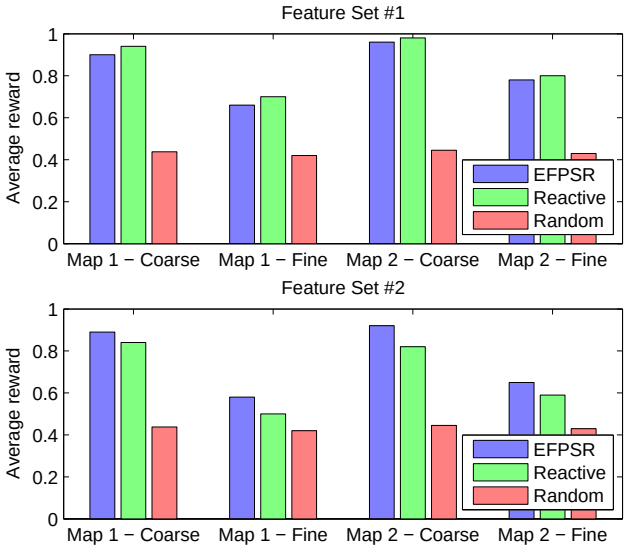

Figure 5. Results on the vision domain.

with coarse dynamics, regardless of map, feature set, or learning algorithm (presumably because the agent can reach high-reward regions more quickly).

The difference between the two feature sets that is most interesting. Using feature set #1, the EFPSR performs just under the performance of the reactive policy, regardless of map or dynamics. Perhaps this means that the EFPSR was unable to capture any meaningful dynamics, and instead learned to predict the identity function, with some noise. This would result in a policy equivalent to the reactive policy.

The results are reversed for feature set #2. Here, the EFPSR consistently outperforms the reactive policy. Together, these observations imply a coherent story. For both feature sets, we used the same set of streamer features. One plausible explanation for the results is that low-order conjunctions of more abstract features gives more modeling benefit than low-order conjunctions of granular, low-level features. It is easy to imagine that low-order conjunctions of granular features is insufficient to capture useful abstract structure in the domain. For example, to represent the corner of a wall, the agent might need a conjunction of 10 features, but we only had fourth order conjunctions. This was part of the motivation for feature set #2: because the camera images were clustered according to latent states, they were typically images of the same thing, from slightly different positions and angles. Using this feature set, the highest-order conjunction was still four or five, but these conjunctions may represent more abstract knowledge: if one feature represents "pink wall" and another represents "pink corner," perhaps a low-order conjunction could express "I'm looking at a pink wall, but if I turn left, I'll see a pink corner." The idea that low-order conjunctions of more abstract features gives more modeling benefit than low-order conjunctions of granular, low-level features suggests several directions for future improvement of these results.

Not reflected in the performance graphs is the computation required. Learning the model was relatively easy, taking only about 30 seconds. Because of the intensive rendering and relatively large size of the domains, the NAC algorithm required about a day to generate the policies to be reported. Informal calculations indicated that it would take about a week to get a single gradient with exact likelihood.

7. Conclusions and Future Work

We have presented a computationally efficient learning algorithm for the Linear-Linear EFPSR model and illustrated it on two domains. Our main contribution is an approximate likelihood, and the insight that maximizing it is equivalent to attempting to match stationary distributions. This idea may find traction in other learning problems. While evaluation of the model and learning algorithm is challenging, it is only by virtue of these approximations that we were able to attempt at all domains like the Bouncing Ball or the Robot Vision domain, which have continuous state spaces, rich observations, and tens of thousands of features. For both domains, we obtained better-than-reactive control policies, suggesting that information from history has successfully been incorporated into the state representation. This is a positive result considering the size of the data set and the number of features involved. Future work needs to address the problem of learning good atomic features and the graphical structure, since these appear to be key factors affecting performance.

A. Computing $\widehat{\mathcal{LL}}$ and Its Derivatives

To compute $\widehat{\mathcal{LL}}$ we must compute three terms: $\mathrm{E}_T[s_t]$ (the stationary distribution of states), $\mathrm{E}_T[\phi(f_t)]$ (which is computed once from data), and the log partition function $\log Z(\mathrm{E}_T[s_t])$. We begin with $\mathrm{E}_T[s_t]$. Recall that our goal is to compute this term in a way that is independent of T. This will be possible using Assumption 4.1, the linearity of the state update, and an insight related to stationary distributions:

$$\begin{aligned}
\mathrm{E}_T[s_t] &= \mathrm{E}_T\left[G(o_t)\left(As_{t-1}+B\right)\right] \\
&\approx \mathrm{E}_T\left[G(o_t)A\right]\mathrm{E}_T\left[s_{t-1}\right] + \mathrm{E}_T\left[G(o_t)\right]B \\
&= \mathrm{E}_T\left[G(o_t)A\right]\mathrm{E}_T\left[s_t\right] + B_G \\
&= G(\mathrm{E}_T[o_t])A\mathrm{E}_T\left[s_t\right] + B_G \\
&= \left(I - G(\mathrm{E}_T[o_t])A\right)^{-1} B_G \qquad (5)
\end{aligned}$$

where I is an appropriately sized identity matrix, and where $B_G = G(\mathrm{E}_T[o_t])B$. The second line follows by Assumption 4.1.

The third and fourth lines are both interesting for different reasons. The fourth line follows by the linearity of the operator $G(\cdot)$. The matrix $G(\mathrm{E}[o_t])$ can be interpreted as the expected transition operator, and is a simple function of the stationary distribution of observations $\mathrm{E}_T[o_t]$. The third line follows by the limiting properties of our expectations: we assume that $\mathrm{E}_T[s_t] = \mathrm{E}_T[s_{t-1}]$ because as $T \to \infty$, both represent the stationary distribution of states.

The result is that $\mathrm{E}_T[s_t]$ can be computed as the solution to a linear system of equations. Note that $G(E_T[o_t])$ will typically be very sparse, and a designer may force the A part to be sparse or low-rank. If so, a matrix-vector product can be computed efficiently, and an iterative solver should be used to solve Eq. 5.

Computing Derivatives. We now compute the derivatives of $\widehat{\mathcal{LL}}$ with respect to A and B:

$$\frac{\partial \widehat{\mathcal{LL}}}{\partial \{A, B\}} = \frac{\partial \widehat{\mathcal{LL}}}{\partial \mathrm{E}_T[s_t]}^\top \frac{\partial \mathrm{E}_T[s_t]}{\partial \{A, B\}}$$

We begin with the left-hand term:

$$\frac{\partial \widehat{\mathcal{LL}}}{\partial \mathrm{E}_T[s_t]} = \mathrm{E}_{\mathrm{E}_T[s_t]}[\phi(F)] - \mathrm{E}_T[\phi(f_t)] \equiv \Delta$$

This result has an appealing intuitive interpretation. $\mathrm{E}_{\mathrm{E}_T[s_t]}[\phi(F)]$ can be interpreted as the expected features that would be obtained if inference were performed using $\mathrm{E}_T[s_t]$ as the state – in other words, it represents the stationary distribution of features under the model. Since $\mathrm{E}_T[\phi(f_t)]$ represents the empirically observed stationary distribution, we see that the gradient wishes to match the two. If we use a variational method to compute the log partition function $\log Z(\mathrm{E}_T[s_t])$, which is needed to determine the value of the log-likelihood, then the expected features $\mathrm{E}_{\mathrm{E}_T[s_t]}[\phi(F)]$ are available as a byproduct of the optimization. This is a pleasing efficiency.

However, we are not done. We still must find the transition parameters which allow us to move the expected sufficient statistics closer:

$$\frac{\partial \mathrm{E}_T[s_t]}{\partial A} = (I - G(\mathrm{E}[o_t])A)^{-1} \left(\frac{\partial}{\partial A} G(\mathrm{E}[o_t])A\right) \mathrm{E}_T[s_t]$$

We now find it convenient to remember that the full derivative also includes the term $\partial \widehat{\mathcal{LL}} / \partial \mathrm{E}_T[s_t] \equiv \Delta$, which is a column vector. Let $\Gamma \equiv \Delta^\top (I - G(\mathrm{E}[o_t])A)^{\top -1} G(\mathrm{E}[o_t])$. Then:

$$\Delta^\top \frac{\partial \mathrm{E}_T[s_t]}{\partial A} = \frac{\partial}{\partial A} \Gamma A \mathrm{E}_T[s_t] = \Gamma^\top \mathrm{E}_T[s_t]^\top$$

Algorithm 2 GRADS-OF-APPROX-LL

Input: $\mathrm{E}_T[o_t]$, $\mathrm{E}_T[\phi(f_t)]$, A, B

// Compute stationary distribution of states
$\mathrm{E}_T[s_t] = (I - G(\mathrm{E}_T[o_t])A)^{-1} B$

// Use $\mathrm{E}_T[s_t]$ to perform inference
Compute $\mathrm{E}_{\mathrm{E}_T[s_t]}[\phi(F)]$ and $\log Z(\mathrm{E}_T[s_t])$

// Compute the approximate log-likelihood:
$\widehat{\mathcal{LL}} = -\mathrm{E}_T[s_t]^\top \mathrm{E}_{\mathrm{E}_T[s_t]}[\phi(F)] - \log Z(\mathrm{E}_T[s_t])$.

// Compute the gradient:
$\Delta = \mathrm{E}[\phi(f_t)] - \mathrm{E}_{\mathrm{E}_T[s_t]}[\phi(F)]$.
$\Gamma = \Delta^\top (I - G(\mathrm{E}[o_t])A)^{\top -1} G(\mathrm{E}[o_t])$
$\nabla_A \widehat{\mathcal{LL}} = \Gamma^\top \mathrm{E}_T[s_t]^\top$ ← note: a rank-one matrix
$\nabla_B \widehat{\mathcal{LL}} = G(\mathrm{E}_T[o_t])^\top \Delta$

Return $\widehat{\mathcal{LL}}, \nabla_A \widehat{\mathcal{LL}}, \nabla_B \widehat{\mathcal{LL}}$

The derivative with respect to B is similar:

$$\begin{aligned} \Delta^\top \frac{\partial \mathrm{E}_T[s_t]}{\partial B} &= \Delta^\top \frac{\partial}{\partial B} [G(\mathrm{E}[o_t])(A\mathrm{E}_T[s_t] + B)] \\ &= \frac{\partial}{\partial B} \Delta^\top G(\mathrm{E}[o_t])B = \Delta^\top G(\mathrm{E}[o_t]) \end{aligned}$$

The completed algorithm is shown in Algorithm 2.

Fully Distributed EM for Very Large Datasets

Abstract

In EM and related algorithms, E-step computations distribute easily, because data items are independent given parameters. For very large data sets, however, even storing all of the parameters in a single node for the M-step can be impractical. We present a framework that fully distributes the entire EM procedure. Each node interacts only with parameters relevant to its data, sending messages to other nodes along a junction-tree topology. We demonstrate improvements over a MapReduce topology, on two tasks: word alignment and topic modeling.

1. Introduction

With dramatic recent increases in both data scale and multi-core environments, it has become increasingly important to understand how machine learning algorithms can be efficiently parallelized. Many computations, such as the calculation of expectations in the E-step of the EM algorithm, decompose in obvious ways, allowing subsets of data to be processed independently. In some such cases, the MapReduce framework (Dean & Ghemawat, 2004) is appropriate and sufficient (Chu et al., 2006). Specifically, MapReduce is suitable when its centralized reduce operation can be carried out efficiently. However, this is not always the case. For example, in modern machine translation systems, many millions of words of example translations are aligned using unsupervised models trained with EM (Brown et al., 1994). In this case, one quickly gets to the point where no single compute node can store the model parameters (expectations over word pairs in this case) for all of the data at once, and communication required for a centralized reduce operation dominates computation time. The common solutions in practice are either to limit the total training data or to process manageable chunks independently. Either way, the complete training set is not fully exploited.

In this paper, we propose a general framework for distributing EM and related algorithms in which not only is the computation distributed, as in the map and reduce phases of MapReduce, but the storage of parameters and expected sufficient statistics is also fully distributed and maximally localized. No single node needs to store or manipulate all of the data or all of the parameters. We describe a range of network topologies and discuss the tradeoffs between communication bandwidth, communication latency, and per-node memory requirements. In addition to a general presentation of the framework, a primary focus of this paper is the presentation of experiments in two application cases: word alignment for machine translation (using standard EM) and topic modeling with LDA (using variational EM). We show empirical results on the scale-up of our method for both applications, across several topologies.

Previous related work in the sensor network literature has discussed distributing estimation of Gaussian mixtures using a tree-structured topology (Nowak, 2003); this can be seen as a special case of the present approach. Paskin et al. (2004) present an approximate message passing scheme that uses a junction tree topology in a related way, but for a different purpose. In addition, Newman et al. (2008) present an asynchronous sampling algorithm for LDA; we discuss this work further, below. None of these papers have discussed the general case of distributing and decoupling parameters in M-step calculations, the main contribution of the current work.

2. Expectation Maximization

Although our framework is more broadly applicable, we focus on the EM algorithm (Dempster et al., 1977), a technique for finding maximum likelihood param-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

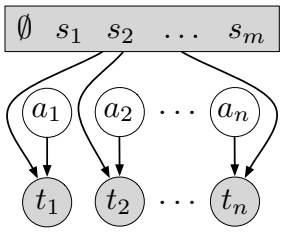

Figure 1: IBM Model 1 word alignment model. The top sentence is the source, and the bottom sentence is the target. Each target word is generated by a source word determined by the corresponding alignment variable.

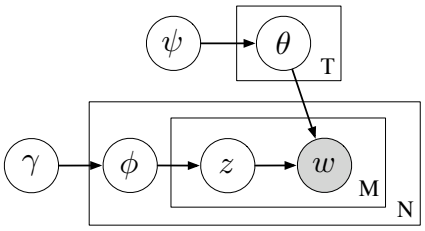

Figure 2: Latent Dirichlet Allocation model. Each word is generated from a topic vocabulary distribution and each topic is generated from a document topic distribution.

eters of a probabilistic model with latent or hidden variables. In this setting, each datum d_i consists of a pair (x_i, h_i) where x_i is the set of observed variables and h_i are unobserved. We assume a joint model over $P(x_i, h_i|\theta)$ with parameters θ. Our goal is to find a θ that maximizes the marginal observed log-likelihood $\sum_{i=1}^{m} \log P(x_i|\theta)$. Each iteration consists of two steps:

$$q_i(h_i) \leftarrow P(h_i|x_i, \theta) \qquad \text{[E-Step]}$$

$$\theta \leftarrow \arg\max_{\theta} \sum_{i=1}^{m} \mathbf{E}_{q_i} P(x_i|h_i, \theta) \qquad \text{[M-Step]}$$

where the expectation in the M-Step is taken with respect to the distribution $q(\cdot)$ over the latent variables found in the E-Step. When $P(\cdot|\theta)$ is a member of the exponential family, the M-Step reduces to solving a set of equations involving expected sufficient statistics under the distribution. Thus, the E-Step consists of collecting expected sufficient statistics $\eta = \mathbf{E}_\theta P(\boldsymbol{\eta}|X)$ with respect to q_i for each datum x_i. We briefly present two EM applications we use for experiments.

2.1. Word Alignment

Word alignment is the task of linking words in a corpora of parallel sentences. Each parallel sentence pair consists of a source sentence S and its translation T into a target language.[1] The model we present here is known as IBM Model 1 (Brown et al., 1994).[2] In this model, each word of T is generated from some word of S or from a null word $\emptyset$ prepended to each source sentence. The null word allows words to appear in the target sentence without any evidence in the source. Model 1 is a mixture model, in which each mixture component indicates which source word is responsible for generating the target word (see figure 1).

[1] Sometimes in the word alignment literature the roles of S and T are reversed to reflect the decoding process.

[2] Although there are more sophisticated models for this task, our concern is with efficiency in the presence of many parameters. More complicated models do not contain substantially more parameters.

The formal generative model is as follows: (1) Select a length n for the translation T based upon $|S| = m$ (typically uniform over a large range). (2) For each $j = 1, \ldots, n$, uniformly choose some source alignment position $a_j \in \{0, 1, \ldots, m\}$. (3) For each $j = 1, \ldots, n$, choose target word t_j based on source word s_{a_j} with probability $\theta_{s_{a_j} t_j}$

In the data, the alignment variables a are unobserved, and the parameters are the multinomial distributions $\theta_{s\cdot}$ for each source word s. The expected sufficient statistics are expected alignment counts between each source and target word that appear in a parallel sentence pair. These expectations can be obtained from the posterior probability of each alignment,

$$P(a_j = i|S, T, \theta) = \frac{\theta_{s_i t_j}}{\sum_{i'} \theta_{s_{i'} t_j}}$$

The E-Step computes the above posterior for each alignment variable; these values are added to the current expected counts of (s, t) pairings, denoted by η_{st}. The M-Step consists of the following update: $\theta_{st} \leftarrow \frac{\eta_{st}}{\sum_{t'} \eta_{st'}}$. Section 5.1 describes results for this model on a data set with more than 243 million parameters (i.e., distinct co-occurring word pairs).

2.2. Topic Modeling

We present experiments in topic modeling via the Latent Dirichlet Allocation (Blei et al., 2003) topic model (see figure 2). In LDA, we fix a finite number of topics T and assume a closed vocabulary of size V. We assume that each topic t has a multinomial distribution $\theta_{t\cdot} \sim \text{Dirichlet}(\text{Unif}(V), \psi)$. Each document draws a topic distribution $\phi \sim \text{Dirichlet}(\text{Unif}(T), \gamma)$. For each word position in a document, we draw an unobserved topic index z from ϕ and then draw a word from $\theta_{z\cdot}$.

Our goal is to find the MAP estimate of θ for the observed likelihood where the latent topic indicators and document topic distributions ϕ have been integrated out. In this setting, we can not perform an exact E-Step because of the coupling of latent variables through the integral over parameters. Instead,

we use a variational approximation of the posterior as outlined in Blei et al. (2003), where all parameters and latent variables are marginally independent. The relevant expected sufficient statistics for θ are the expected counts η_{tw} over topic t and word w pairings under the approximate variational distribution. The M-Step, as in the case of our word alignment model in section 2.1, consists of normalizing these counts: $\theta_{tw} = \frac{\eta_{tw}}{\sum_{w'} \eta_{tw'}}$. Section 5.2 describes results for this model. We note that the number of parameters in this model is a linear function of the number of topics T.

3. Distributing EM

Given the amount of data and number of parameters in many EM applications, it is worthwhile to distribute the algorithm across many machines. We will consider the setting in which our data set $\mathcal{D}$ has been divided into k splits $\{\mathcal{D}_1, \ldots, \mathcal{D}_k\}$.

3.1. Distributing the E-Step

Distributing the E-Step is relatively straightforward, since the expected sufficient statistics for each datum can be computed independently given a current estimate of the parameters. Each of k nodes computes expected sufficient statistics for one split of the data,

$$\eta^{(i)} = \mathbf{E}_\theta \left[\eta | \mathcal{D}_i\right] \qquad \text{[Distributed E-Step]}$$

where we use the superscript (i) to emphasize that these counts are partial and reflect only the contributions from split $\mathcal{D}_i$ and not contributions from other partitions. We will also write α_i for the set of sufficient statistic *indices* that have nonzero count in $\eta^{(i)}$, and use $\eta[\alpha_i]$ to indicate the projection of η onto the subspace consisting of just those statistics in α_i.

In order to complete the E-Step, we must aggregate expected counts from all partitions in order to re-estimate parameters. This step involves distributed communication of a potentially large number of statistics. We name this phase the C-Step and will examine how to efficiently perform it in section 4. For the moment, we assume that there is a single computing node which accumulates all partial sufficient statistics,

$$\eta = \sum_{i=1}^{k} \eta^{(i)}[\alpha_i] \qquad \text{[C-Step]}$$

where we write $\eta^{(i)}[\alpha_i]$ to indicate that we only communicate non-zero counts. This is a simple and effective way to achieve near-linear speedup in the E-Step; previous work has utilized it effectively (Blei et al., 2003; Chu et al., 2006; Nowak, 2003).

3.2. Distributing the M-Step

A further possibility, which to our knowledge has not been fully exploited, is distributing the M-Step. Often in EM, it is the case that only a subset of parameters may ever be relevant to a split $\mathcal{D}_i$ of the data. For instance, in the word alignment model of section 2.1, if a word pairing (s, t) is not observed in some $\mathcal{D}_i$, node i will never need the parameter θ_{st}. For our full word alignment data set, when $k = 20$, less than 30 million of the 243 million total parameters are relevant to each node.

We will use β_i to refer to the subset of parameter indices relevant for $\mathcal{D}_i$. In order to distribute the M-Step, each node must receive all expected counts necessary to re-estimate all relevant parameters $\theta[\beta_i]$. In section 4, we develop different schemes for how nodes should communicate their partial expected counts, and show that this choice of C-Step topology can dramatically affect the efficiency of distributed EM.

One difficulty in distributing the M-Step lies in the fact that re-estimating $\theta[\beta_i]$ may require counts not found in $\eta[\alpha_i]$. In the case of the word alignment model, θ_{st} requires the counts $\eta_{st'}$ for all t' appearing with s in a sentence pair, even if t' did not occur in $\mathcal{D}_i$. Often these non-local statistics enter the computation only via normalization terms. This is the case for the word alignment and LDA models explored here. This observation suggests an easy way to get around the problem presented above in the case of discrete latent variables: we simply *augment* the set of sufficient statistics η with a set of redundant *sum* terms that provide the missing information needed to normalize parameter estimates. For the word alignment model, we would include a sufficient statistic $\eta_{s\cdot}$ to represent the sum $\sum_{t:(s,t)\in\mathcal{D}} \eta_{st}$. Then the re-estimated value of θ_{st} would simply be $\frac{\eta_{st}}{\eta_{s\cdot}}$. With these augmented statistics, estimating $\theta[\beta_i]$ requires only η_{st} and $\eta_{s\cdot}$ for all $(s, t) \in \mathcal{D}_i$. It might seem counterintuitive, but adding these extra statistics actually *decreases* the total necessary amount of communication, by trading a large number of sparse statistics for a few dense ones.

4. Topologies for Distributed EM

This section will consider techniques for performing the C-Step of distributed EM, in which a node i obtains the necessary sufficient statistics $\eta[\alpha_i]$ to estimate parameters $\theta[\beta_i]$. We assume that the sets of relevant count indices α_i have been augmented as discussed at the end of section 3 so that $\eta[\alpha_i]$ is sufficient to re-estimate $\theta[\beta_i]$.

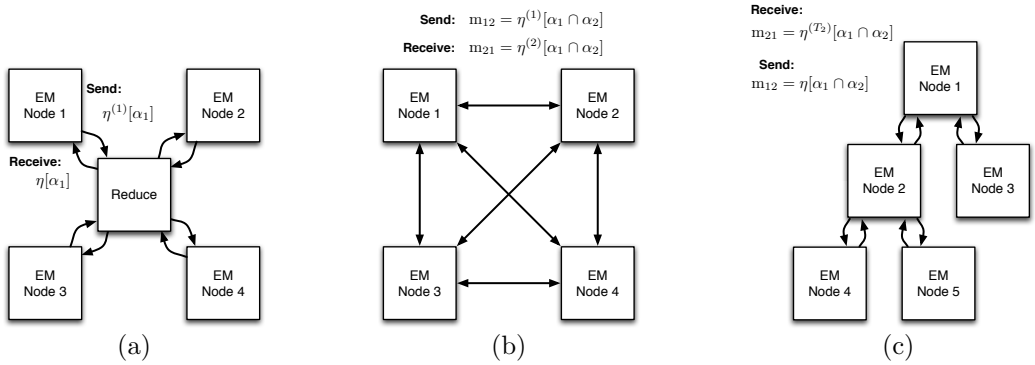

Figure 3: (a) MapReduce: Each node computes partial statistics in a local E-Step, sends these to a central "Reduce" node, and receives back completed statistics relevant for completing its local M-Step. (b) AllPairs: Each node communicates to each other node only the relevant partial sufficient statistics. For many applications, these intersections will be small. (c) JunctionTree: The network topology is a tree, chosen heuristically to optimize any desired criteria (e.g., bandwidth).

4.1. MapReduce Topology

A straightforward way to implement the C-Step is to have each node send its non-zero partial counts $\eta^{(i)}[\alpha_i]$ to a central "Reduce" node for accumulation into η. This central node then returns only the relevant completed counts $\eta[\alpha_i]$ to the nodes so that they can independently perform their local M-Steps. This approach, depicted in figure 3(a), is roughly analogous to the topology used in the MapReduce framework (Dean & Ghemawat, 2004). When parameters are numerous, this will already be more bandwidth-efficient than a naive MapReduce approach, in which the Reduce node would perform a global M-Step and then send *all* of the new parameters θ back to all nodes for the next iteration. To enable sending only relevant counts $\eta[\alpha_i]$, the actual iterations are preceded by a setup phase in which each node constructs an array of relevant count indices α_i and sends this to the Reduce node. This array also fixes an ordering on relevant statistics, so that later messages of counts can be densely encoded.

This MapReduce topology[3] may be a good choice for the C-Step when nodes share most of the same statistics. On the other hand, if sufficient statistics are sparse and numerous, the central reduce node can be a significant bandwidth and memory bottleneck in the distributed EM algorithm. Indeed, in practice, with either Model 1 or LDA, available amounts of training data can and do easily cause the sufficient statistics vectors to exceed the memory of any single node. The MapReduce topology for estimation of LDA has been discussed in related work, notably Newman et al. (2008), though they do not consider the sparse distribution of the M-step, which is necessary for very large data sets.

[3]For the remainder of this paper we will use MapReduce to refer to the *topology* used by the MapReduce system (Dean & Ghemawat, 2004). While the particular details of our implementation will differ substantially from the MapReduce system (e.g., we use a single reduce node), many key results should hold more generally (e.g., the MapReduce approach uses unnecessarily high bandwidth).

4.2. AllPairs Topology

MapReduce takes a completely *centralized* approach to implementing the C-Step, in which the accumulation of η at the Reduce node can be slow or even infeasible. This suggests a *decentralized* approach, in which nodes directly pass relevant counts to one another and no single node need store all of η or θ. This section describes one such approach, AllPairs, which in a sense represents the opposite extreme from MapReduce. In AllPairs, the network graph is a clique on the k nodes, and each node i passes a message $m_{ij} = \eta^{(i)}[\alpha_i \cap \alpha_j]$ to each other node j containing precisely the statistics j needs and nothing more (see figure 3(b)). Each node j then computes its completed set of sufficient statistics with a simple summation:

$$\begin{aligned}\eta[\alpha_i] &= \eta^{(i)} + \sum_{j \neq i} m_{ji} \\ &= \eta^{(i)} + \sum_{j \neq i} \eta^{(j)}[\alpha_i \cap \alpha_j]\end{aligned}$$

AllPairs requires a more complicated setup phase, where each node i calculates, for roughly half of the other nodes, the intersection $\alpha_i \cap \alpha_j$ of its parameters with the other node j's.[4] Node i then sends the contents of this intersection to j.

In each iteration, message passing proceeds asynchronously, and each node begins its local M-Step as

[4]Note that the C-Step time is now sensitive to how our data is partitioned. An interesting area for future work is intelligently partitioning the data so that data split intersections are small.

soon as it has finished sending and receiving the necessary counts. An important point is that, to avoid double counting, a received count cannot be folded into a node's local statistics until the local copy of that count has been incorporated into all outgoing messages.

AllPairs is attractive because it lacks the bandwidth bottleneck of MapReduce, all paths of communication are only one hop long, and each node need only be concerned with precisely those statistics relevant for its local E- and M-steps. On the down side, AllPairs needs a full crossbar connection between nodes, and requires unnecessarily high bandwidth for dense sufficient statistics that are relevant to datums on many nodes. In particular, a statistic that is relevant to k' nodes must be passed $k'(k'-1)$ times, as compared to an optimal value of $2(k'-1)$ (see section 4.3).

4.3. JunctionTree Topology

A tree-based topology related to the junction tree approach used for belief propagation in graphical models (Pearl, 1988) can avoid the bandwidth bottleneck of MapReduce and the bandwidth explosion of AllPairs. In this approach, the k nodes are embedded in an arbitrary tree structure T, and messages are passed along the edges in both directions (see figure 3(c)). We are certainly not the first to exploit such structures for distributing computation; see particularly Paskin et al. (2004), who use it for inference rather than estimation.

We first describe the most bandwidth-efficient method for communicating partial results about a *single* statistic, and then show how this can be extended to produce an algorithm that works for the entire C-Step. Consider a single sufficient statistic η_x (e.g., some η_{st} for Model 1) which is only relevant to E- and M-Steps on some subset of machines S. Before the C-Step, each node has $\eta_x^{(i)}$, and after communication each node should have $\eta_x = \sum_{i \in S} \eta_x^{(i)}$. We cannot hope to accomplish this goal by passing fewer than $2(|S|-1)$ pairwise messages; clearly, it must take at least $|S|-1$ messages before *any* node completes its counts, and then another $|S|-1$ messages for each of the other $|S|-1$ nodes to complete theirs too. This is fewer messages than either MapReduce or AllPairs passes.

This theoretical minimum bandwidth can be achieved by embedding the nodes of S in a tree. After designating an arbitrary node as the root, each node accumulates a partial sum from its *subtree* and then passes it up towards the root. Once the root has accumulated the completed sum η_x, it is recursively passed back down the tree until all nodes have received the completed count, for a total of $2(|S|-1)$ messages.

Of course, each node must obtain a *set* of complete relevant statistics $\eta[\alpha_i]$ rather than a single statistic η_x. One possibility is to pass messages for each sufficient statistic on a separate tree; while this represents the *bandwidth-optimal* solution for the entire C-step, in practice the overhead of managing 240 million different message trees would likely outweigh the benefits.

Instead, we can simply force all statistics to share the *same* global tree T. In each iteration we proceed much as before, designating an arbitrary root node and passing messages up and then down, except that now the message m_{ij} from node i to j conveys the intersection of their relevant statistics $\alpha_i \cap \alpha_j$ rather than a single number. For this to work properly, we require that T has the following *running intersection* property: for each sufficient statistic, all concerned nodes form a *connected subtree* of T. In other words, for all triples of nodes (i, x, j) where x is on the path from i to j, we must have $(\alpha_i \cap \alpha_j) \subseteq \alpha_x$. We can assume that this property holds, by augmenting sets of statistics at interior nodes if necessary.

When the running intersection property holds, the message contents can be expressed as

$$\begin{aligned} m_{ij} &= \eta^{(T_i)}[\alpha_i \cap \alpha_j] && \text{towards root} \\ m_{ji} &= \eta[\alpha_i \cap \alpha_j] && \text{away from root} \end{aligned}$$

where T_i is used to represent the subtree rooted at i, and $\eta^{(T_i)}$ is the sum of statistics from nodes in this subtree. Thus, the single global message passing phase can be thought of as $|\alpha|$ separate single-statistic message passing operations proceeding in parallel, where the root of each such sub-phase is the node in its subtree closest to the global root, and irrelevant operations involving other nodes and statistics can be ignored. In our actual implementation, we instead use an asynchronous message-passing protocol common in probabilistic reasoning systems (Pearl, 1988), which avoids the need to designate a root node in advance.

The setup phase for JunctionTree proceeds as follows: (1) All pairwise intersections of statistics are computed and saved to shared disk. (2) An arbitrary node chooses and broadcasts a directed, rooted tree T on the nodes which optimizes some criterion. (3) Each node (except the root) constructs the set of statistics that must lie on its incoming edge, by taking the union of the intersections of statistics (which can be reread from disk) for all pairs of nodes on opposite sides of the edge.[5] (4) Each node passes the constructed edge set along its incoming edge, fixing future message structures in the process. (5) Each node augments its α_i to

[5] More efficient algorithms are possible, but they require more memory.

include all statistics in local outgoing messages, thus enforcing the running intersection property.

To choose a heuristically good topology, we use the maximum spanning tree (MST) with edge weights equal to the sizes of the intersections $|\alpha_i \cap \alpha_j|$, so that nodes with more shared statistics tend to be closer together. This heuristic has been successfully used in the graphical models literature (Pearl, 1988) to construct junction trees. However, in general one can imagine much better heuristics that also consider, e.g., max degree, tree diameter or underlying network structure.

If statistics tend to be well-clustered within and between nodes, we can expect this MST to require less bandwidth than either alternate topology, and (like AllPairs) there should be no central bandwidth bottleneck. On the other hand, if statistics tend to be shared between only a few nodes and this sharing is not appropriately clustered, bandwidth and memory may increase because many statistics will have to be added to enforce the running intersection property.[6] Furthermore, if the diameter of the tree is large, latency may become an issue as many sequential message sending and incorporation steps will have to be performed. Finally, the setup phase takes longer because choosing the tree topology and enforcing the running intersection property may be expensive. Despite these potential drawbacks, we will see that MST generally performs best of the three topologies investigated here in terms of both bandwidth and total running time.

As a final note, if T is a "hub and spoke" graph, and the hub's statistics are augmented to contain all of η, a MapReduce variant is recovered as a special case of JunctionTree. This is the version of MapReduce we actually implemented; it differs from the version described in section 4.1 only in that the role of reduce node is assigned to one of the workers rather than a separate node, which reduces bandwidth usage.

5. Experiments

We performed experiments using the word alignment model from section 2.1 and the LDA topic model from section 2.2. For each of these models, we compared the network topologies used to perform the C-Step and how they affect the overall efficiency of EM. We implemented the following topologies (described in section 4): MapReduce, AllPairs, and JunctionTree. Although our implementation was done in Java, every reasonable care was taken to be time and memory efficient in our choice of data structures and in network socket communication. All experiments were performed on a cluster of identical, load-free 3.0 GHz 32-bit Intel machines. Running times per iteration represent the median over 10 runs of the maximum time on any node. We also examine the bandwidth of each topology, measured by the number of counts communicated across the network per iteration.

5.1. Word Alignment Results

We performed Model 1 (see section 2.1) experiments on the UN Arabic English Parallel Text TIDES Version 2 corpus, which consists of about 3 million sentences of translated UN proceedings from 1994 until 2001.[7] For the full data set, there are more than 243 million distinct parameters.

In table 1(a), we present results where the number of sentence-pair datums per node is held constant at 145K and the number of nodes (and thus total training data) is varied. For 10 or more nodes, the MapReduce topology runs out of memory due to the number of statistics that must be stored in memory at the Reduce node.[8] In contrast, both AllPairs and JunctionTree complete training for the full data set distributed on 20 nodes.

We also experimented with the setting where we fix the total amount of data at 200K sentences, but add more nodes to distribute the work. Figure 4 gives iteration times for all three topologies broken down according to E-, C-, and M-Steps. The MapReduce graph (figure 4(a)) shows that the C-Step begins dominating run time as the number of nodes increases. This effect reduces the benefit from distributing EM for larger numbers of nodes. Both AllPairs and JunctionTree have substantially smaller C-Steps, which contributes to much faster per-iteration times and also allows larger numbers of nodes to be effective.

On the full dataset, JunctionTree outperforms AllPairs, but not by a substantial margin. Although the two topologies have roughly comparable running times, they have different network behaviors. Figure 5, which compares bandwidth usage in billions of counts transferred over the network per iteration, shows that AllPairs uses substantially more bandwidth than either MapReduce or JunctionTree. This is due to the $O(k^2)$ number of messages sent per iteration. In contrast, JunctionTree typically has a higher la-

[6] This could be avoided by using different trees for different sets of statistics; we leave this for future work.

[7] LDC catalog #LDC2004E13. See `http://projects.ldc.upenn.edu/TIDES/index.html`.

[8] This issue could be sidestepped by using multiple Reduce nodes as in the MapReduce system; however, the fundamental inefficiency of the MapReduce topology would remain.

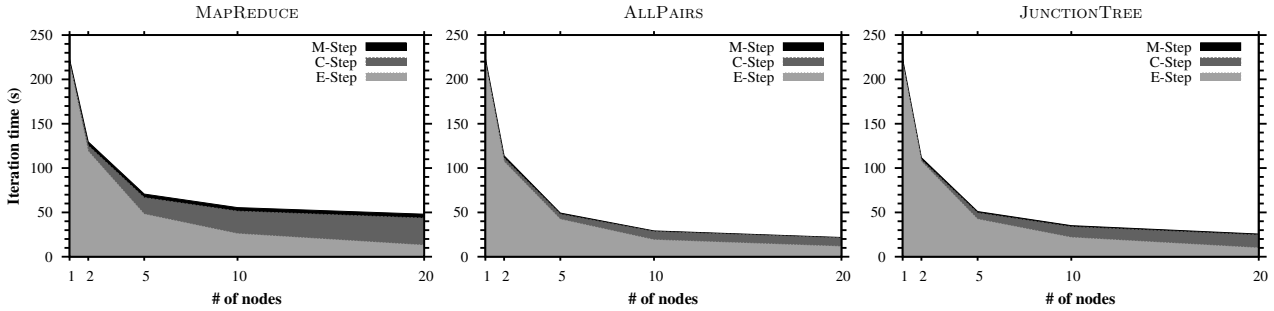

Figure 4: Speedup of median iteration time for three topologies as a function of the number of nodes, training Model 1 on 200k total sentence pairs. Time for each iteration is broken down into E-, C-, and M-Step time. The M-Step is present but difficult to see due to its brevity.

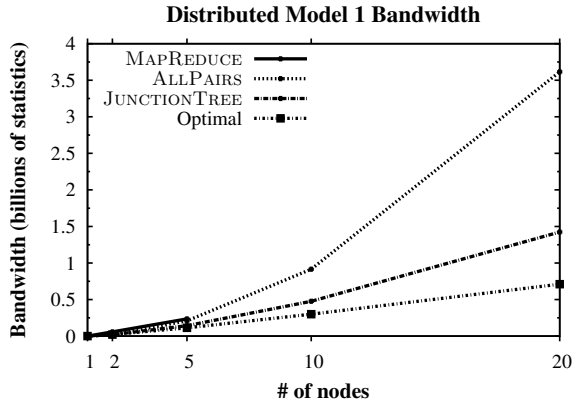

Figure 5: Bandwidth usage for three topologies compared to optimal, as a function of the number of nodes, training on Model 1 with 145k sentence pairs per node. MapReduce ran out of memory when run on more than 5 nodes.

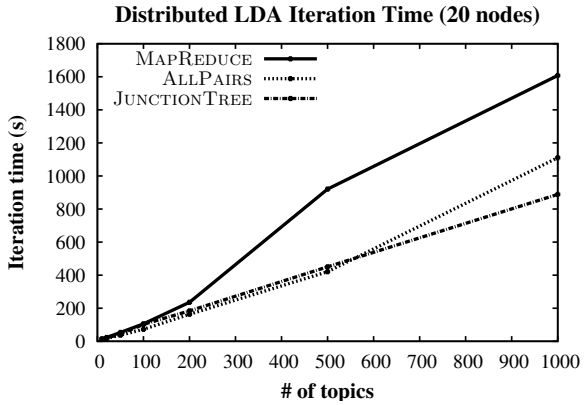

Figure 6: Median iteration time for three topologies, as a function of the number of topics, training on LDA with 20 nodes and all 804k documents.

tency due to the fact that nodes must wait to receive messages before they can send their own. AllPairs and JunctionTree with the MST heuristic represent a bandwidth and latency tradeoff, and the choice of which to use depends on the properties of the particular network.

5.2. Topic Modeling Results

We present results for the variational EM LDA topic model presented in section 2.2. Our results are on the Reuters Corpus Volume 1 (Lewis et al., 2004). This corpus consists of 804,414 newswire documents, where all tokens have been stemmed and stopwords removed.[9] There are approximately 116,000 unique word types after pre-processing. The number of parameters of interest is therefore 116,000T, where T is the number of topics that we specify.

We experimented with this model on the entire corpus and varied the number of topics. The largest number of topics we used was $T = 1{,}000$, which yields 116 million unique parameters. Our results on iteration time are presented in figure 6. Note that the number of parameters depends linearly on the number of topics, which can roughly be seen in figure 6. This figure demonstrates that the efficiency of the AllPairs and JunctionTree topologies as the number of parameters increases. We see that JunctionTree edges out AllPairs for a larger number of topics.

Table 1(b) shows detailed results for the experiment depicted in figure 6. Besides the difference in iteration times for the three algorithms as the number of topics (and statistics) grows, there are at least two other salient points. First, while the number of total statistics grows similarly to in the word alignment experiments, here the number of unique statistics is significantly smaller (i.e., each statistic, on average, is relevant to more nodes). This leads to significantly worse performance, especially in terms of bandwidth, for AllPairs. A second point is that setup times are much lower than for word alignment, because sets of relevant *words* can be determined first, and only then expanded to $(word, topic)$ pairs.

[9] We used the processed version of the corpus provided by Lewis et al. (2004).

(b)

Table 1: (a) Results for scaling up number of nodes, training Model 1 with 145k sentence pairs per node. (b) Results for scaling up number of topics, training LDA with all 804k documents on 20 nodes. All times are measured in seconds, statistics are counted in millions, and bandwidths are measured in millions of statistics passed per iteration. # unique stats measures $|\alpha|$, whereas # total stats measures $\sum_i |\alpha_i|$. Opt bandwidth is theoretically optimal bandwidth (see section 4.3). Setup time includes all time until all nodes started the first E-Step. Median total time per iteration is given, as well as a breakdown into E-, C-, and M-Steps. Max hops is the diameter of the graph. Bottleneck is maximum bandwidth in and out of any single node. (*) indicates an out-of-memory error.

We note that the total bandwidth is actually *lower* for MapReduce than JunctionTree since the MST only heuristically minimizes the *number* of disconnected statistic components, rather than the true cost of enforcing the running intersection property. Despite this, the bandwidth bottleneck for JunctionTree is still much lower than for MapReduce.

6. Conclusion

We have demonstrated theoretically and empirically that a distributed EM system can function successfully, allowing for both significant speedup and scaling up to computations that would be too large to fit in the memory of a single machine. Future work will consider applications to other machine learning methods, alternative junction tree heuristics, and more general graph topologies.

Abstract

This paper aims to conduct a study on the listwise approach to learning to rank. The listwise approach learns a ranking function by taking individual lists as instances and minimizing a loss function defined on the predicted list and the ground-truth list. Existing work on the approach mainly focused on the development of new algorithms; methods such as RankCosine and ListNet have been proposed and good performances by them have been observed. Unfortunately, the underlying theory was not sufficiently studied so far. To amend the problem, this paper proposes conducting theoretical analysis of learning to rank algorithms through investigations on the properties of the loss functions, including consistency, soundness, continuity, differentiability, convexity, and efficiency. A sufficient condition on consistency for ranking is given, which seems to be the first such result obtained in related research. The paper then conducts analysis on three loss functions: likelihood loss, cosine loss, and cross entropy loss. The latter two were used in RankCosine and ListNet. The use of the likelihood loss leads to the development of a new listwise method called ListMLE, whose loss function offers better properties, and also leads to better experimental results.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.
*The work was performed when the first author was an intern at Microsoft Research Asia.

1. Introduction

Ranking, which is to sort objects based on certain factors, is the central problem of applications such as information retrieval (IR) and information filtering. Recently machine learning technologies called 'learning to rank' have been successfully applied to ranking, and several approaches have been proposed, including the pointwise, pairwise, and listwise approaches.

The listwise approach addresses the ranking problem in the following way. In learning, it takes ranked lists of objects (e.g., ranked lists of documents in IR) as instances and trains a ranking function through the minimization of a listwise loss function defined on the predicted list and the ground truth list. The listwise approach captures the ranking problems, particularly those in IR in a conceptually more natural way than previous work. Several methods such as RankCosine and ListNet have been proposed. Previous experiments demonstrate that the listwise approach usually performs better than the other approaches (Cao et al., 2007)(Qin et al., 2007).

Existing work on the listwise approach mainly focused on the development of new algorithms, such as RankCosine and ListNet. However, there was no sufficient theoretical foundation laid down. Furthermore, the strength and limitation of the algorithms, and the relations between the proposed algorithms were still

not clear. This largely prevented us from deeply understanding the approach, more critically, from devising more advanced algorithms.

In this paper, we aim to conduct an investigation on the listwise approach.

First, we give a formal definition of the listwise approach. In ranking, the input is a set of objects, the output is a permutation of the objects[1], and the model is a ranking function which maps a given input to an output. In learning, the training data is drawn i.i.d. according to an unknown but fixed joint probability distribution between input and output. Ideally we would minimize the expected $0-1$ loss defined on the predicted list and the ground truth list. Practically we instead manage to minimize an empirical surrogate loss with respect to the training data.

Second, we evaluate a surrogate loss function from four aspects: (a) consistency, (b) soundness, (c) mathematical properties of continuity, differentiability, and convexity, and (d) computational efficiency in learning. We give analysis on three loss functions: likelihood loss, cosine loss, and cross entropy loss. The first one is newly proposed in this paper, and the last two were used in RankCosine and ListNet, respectively.

Third, we propose a novel method for the listwise approach, which we call ListMLE. ListMLE formalizes learning to rank as a problem of minimizing the likelihood loss function, equivalently maximizing the likelihood function of a probability model. Due to the nice properties of the loss function, ListMLE stands to be more effective than RankCosine and ListNet.

Finally, we have experimentally verified the correctness of the theoretical findings. We have also found that ListMLE can significantly outperform RankCosine and ListNet.

The rest of the paper is organized as follows. Section 2 introduces related work. Section 3 gives a formal definition to the listwise approach. Section 4 conducts theoretical analysis of listwise loss functions. Section 5 introduces the ListMLE method. Experimental results are reported in Section 6 and the conclusion and future work are given in the last section.

2. Related Work

Existing methods for learning to rank fall into three categories. The pointwise approach (Nallapati, 2004) transforms ranking into regression or classification on single objects. The pairwise approach (Herbrich et al., 1999) (Freund et al., 1998) (Burges et al., 2005) transforms ranking into classification on object pairs. The advantage for these two approaches is that existing theories and algorithms on regression or classification can be directly applied, but the problem is that they do not model the ranking problem in a straightforward fashion. The listwise approach can overcome the drawback of the aforementioned two approaches by tackling the ranking problem directly, as explained below.

For instance, Cao et al. (2007) proposed one of the first listwise methods, called ListNet. In ListNet, the listwise loss function is defined as cross entropy between two parameterized probability distributions of permutations; one is obtained from the predicted result and the other is from the ground truth. Qin et al. (2007) proposed another method called RankCosine. In the method, the listwise loss function is defined on the basis of cosine similarity between two score vectors from the predicted result and the ground truth[2]. Experimental results show that the listwise approach usually outperforms the pointwise and pariwise approaches.

In this paper, we aim to investigate the listwise approach to learning to rank, particularly from the viewpoint of loss functions. Actually similar investigations have also been conducted for classification. For instance, in classification, consistency and soundness of loss functions are well studied. Consistency forms the basis for the success of a loss function. It is known that if a loss function is consistent, then the learned classifier can achieve the optimal Bayes error rate in the large sample limit. Many well known loss functions such as hinge loss, exponential loss, and logistic loss are all consistent (cf., (Zhang, 2004)(Bartlett et al., 2003)(Lin, 2002)). Soundness of a loss function guarantees that the loss can represent well the targeted learning problem. That is, an incorrect prediction should receive a larger penalty than a correct prediction, and the penalty should reflect the confidence of prediction. For example, hinge loss, exponential loss, and logistic loss are sound for classification. In contrast, square loss is sound for regression but not for classification (Hastie et al., 2001).

3. Listwise Approach

We give a formal definition of the listwise approach to learning to rank. Let X be the input space whose

[1] In this paper, we use permutation and ranked list interchangeably.

[2] In a broad sense, methods directly optimizing evaluation measures, such as SVM-MAP (Yue et al., 2007) and AdaRank (Xu & Li, 2007) can also be regarded as listwise algorithms. We will, however, limit our discussions in this paper on algorithms like ListNet and RankCosine.

elements are sets of objects to be ranked, Y be the output space whose elements are permutations of objects, and P_{XY} be an unknown but fixed joint probability distribution of X and Y. Let $\mathbf{h} : X \to Y$ be a ranking function, and H be the corresponding function space (i.e., $\mathbf{h} \in H$). Let $\mathbf{x} \in X$ and $\mathbf{y} \in Y$, and let $y(i)$ be the index of object which is ranked at position i. The task is to learn a ranking function that can minimize the expected loss $R(\mathbf{h})$, defined as:

$$R(\mathbf{h}) = \int_{X \times Y} l(\mathbf{h}(\mathbf{x}), \mathbf{y}) dP(\mathbf{x}, \mathbf{y}), \tag{1}$$

where $l(\mathbf{h}(\mathbf{x}), \mathbf{y})$ is the $0-1$ loss function such that

$$l(\mathbf{h}(\mathbf{x}), \mathbf{y}) = \begin{cases} 1, & \text{if } \mathbf{h}(\mathbf{x}) \neq \mathbf{y} \\ 0, & \text{if } \mathbf{h}(\mathbf{x}) = \mathbf{y}, \end{cases} \tag{2}$$

That is to say, we formalize the ranking problem as a new 'classification' problem on permutations. If the permutation of the predicted result is the same as the ground truth, then we have zero loss; otherwise we have one loss. In real ranking applications, the loss can be cost-sensitive, i.e., depending on the positions of the incorrectly ranked objects. We will leave this as our future work and focus on the $0-1$ loss in this paper first. Actually, in the literature of classification, people also studied the $0-1$ loss first, before they eventually moved onto the cost-sensitive case.

It is easy to see that the optimal ranking function which can minimize the expected loss $R(\mathbf{h}_B) = \inf R(\mathbf{h})$ is given by the Bayes rule,

$$\mathbf{h}_B(\mathbf{x}) = \arg\max_{\mathbf{y} \in Y} P(\mathbf{y}|\mathbf{x}), \tag{3}$$

Since P_{XY} is unknown, formula (1) cannot be directly solved and thus $\mathbf{h}_B(\mathbf{x})$ cannot be easily obtained. In practice, we are given independently and identically distributed (i.i.d) samples $S = \{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\}_{i=1}^m \sim P_{XY}$, we instead try to obtain a ranking function $\mathbf{h} \in H$ that minimizes the empirical loss.

$$R_S(\mathbf{h}) = \frac{1}{m} \sum_{i=1}^{m} l(\mathbf{h}(\mathbf{x}^{(i)}), \mathbf{y}^{(i)}). \tag{4}$$

Note that for efficiency consideration, in practice the ranking function usually works on individual objects. It assigns a score to each object (by employing a scoring function g), sorts the objects in descending order of the scores, and finally creates the ranked list. That is to say, $\mathbf{h}(\mathbf{x}^{(i)})$ is decomposable with respect to objects. It is defined as

$$\mathbf{h}(\mathbf{x}^{(i)}) = sort(g(x_1^{(i)}), \ldots, g(x_{n_i}^{(i)})). \tag{5}$$

where $x_j^{(i)} \in \mathbf{x}^{(i)}$, n_i denotes the number of objects in $\mathbf{x}^{(i)}$, $g(\cdot)$ denotes the scoring function, and $sort(\cdot)$ denotes the sorting function. As a result, (4) becomes:

$$R_S(\mathbf{g}) = \frac{1}{m} \sum_{i=1}^{m} l(sort(g(x_1^{(i)}), \ldots, g(x_{n_i}^{(i)})), \mathbf{y}^{(i)}). \tag{6}$$

Due to the nature of the sorting function and the $0-1$ loss function, the empirical loss in (6) is inherently non-differentiable with respect to g, which poses a challenge to the optimization of it. To tackle this problem, we can introduce a surrogate loss as an approximation of (6), following a common practice in machine learning.

$$R_S^{\phi}(\mathbf{g}) = \frac{1}{m} \sum_{i=1}^{m} \phi(\mathbf{g}(\mathbf{x}^{(i)}), \mathbf{y}^{(i)}), \tag{7}$$

where ϕ is a surrogate loss function and $\mathbf{g}(\mathbf{x}^{(i)}) = (g(x_1^{(i)}), \ldots, g(x_{n_i}^{(i)}))$. For convenience in notation, in the following sections, we sometimes write $\phi_{\mathbf{y}}(\mathbf{g})$ for $\phi(\mathbf{g}(\mathbf{x}), \mathbf{y})$ and use bold symbols such as $\mathbf{g}$ to denote vectors since for a given $\mathbf{x}$, $\mathbf{g}(\mathbf{x})$ becomes a vector.

4. Theoretical Analysis

4.1. Properties of Loss Function

We analyze the listwise approach from the viewpoint of surrogate loss function. Specifically, we look at the following properties [3] of it: (a) consistency , (b) soundness, (c) continuity, differentiability, and convexity, and (d) computational efficiency in learning.

Consistency is about whether the obtained ranking function can converge to the optimal one through the minimization of the empirical surrogate loss (7), when the training sample size goes to infinity. It is a necessary condition for a surrogate loss function to be a good one for a learning algorithm (cf., Zhang (2004)).

Soundness is about whether the loss function can indeed represent loss in ranking. For example, an incorrect ranking should receive a larger penalty than a correct ranking, and the penalty should reflect the confidence of the ranking. This property is particularly important when the size of training data is small, because it can directly affect the training results.

4.2. Consistency

We conduct analysis on learning to rank algorithms from the viewpoint of consistency. As far as we know,

[3] In addition, convergence rate is another issue to consider. We leave it as future work.

this is the first work discussing the consistency issue for ranking.

In the large sample limit, minimizing the empirical surrogate loss (7) amounts to minimizing the following expected surrogate loss

$$R^{\phi}(\mathbf{g}) = E_{X,Y}\{\phi_{\mathbf{y}}(\mathbf{g}(\mathbf{x}))\} = E_X\{Q(\mathbf{g}(\mathbf{x}))\} \quad (8)$$
$$\text{where } Q(\mathbf{g}(\mathbf{x})) = \sum_{\mathbf{y}\in Y} P(\mathbf{y}|\mathbf{x})\phi_{\mathbf{y}}(\mathbf{g}(\mathbf{x})).$$

Here we assume $\mathbf{g}(\mathbf{x})$ is chosen from a vector Borel measurable function set, whose elements can take any value from $\Omega \subset R^n$.

When the minimization of (8) can lead to the minimization of the expected $0-1$ loss (1), we say the surrogate loss function is consistent. A equivalent definition can be found in Definition 2. Actually this equivalence relationship has been discussed in related work on the consistency of classification (Zhang, 2004).

Definition 1. *We define $\Lambda_{\mathbf{y}}$ as the space of all possible probabilities on the permutation space Y, i.e., $\Lambda_Y \triangleq \{\mathbf{p} \in R^{|Y|} : \sum_{\mathbf{y}\in Y} p_{\mathbf{y}} = 1, p_{\mathbf{y}} \geq 0\}$.*

Definition 2. *The loss $\phi_{\mathbf{y}}(\mathbf{g})$ is consistent on a set $\Omega \subset R^n$ with respect to the ranking loss (1), if the following conditions hold: $\forall \mathbf{p} \in \Lambda_Y$, assume $\mathbf{y}^* = \arg max_{\mathbf{y}\in Y} p_{\mathbf{y}}$ and $Y^c_{\mathbf{y}^*}$ denotes the space of permutations after removing $\mathbf{y}^*$, we have*

$$\inf_{\mathbf{g}\in\Omega} Q(\mathbf{g}) < \inf_{\mathbf{g}\in\Omega, sort(\mathbf{g})\in Y^c_{\mathbf{y}^*}} Q(\mathbf{g})$$

We next give sufficient conditions of consistency in ranking.

Definition 3. *A permutation probability space Λ_Y is order preserving with respect to object i and j, if the following conditions hold: $\forall \mathbf{y} \in Y_{i,j} \triangleq \{\mathbf{y} \in Y : y^{-1}(i) < y^{-1}(j)\}$ where $y^{-1}(i)$ denotes the position for object i in $\mathbf{y}$, denote $\sigma^{-1}\mathbf{y}$ as the permutation which exchanges the positions of object i and j while hold others unchanged for $\mathbf{y}$, we have $p_{\mathbf{y}} > p_{\sigma^{-1}\mathbf{y}}$.*

Definition 4. *The loss $\phi_{\mathbf{y}}(\mathbf{g})$ is order sensitive on a set $\Omega \subset R^n$, if $\phi_{\mathbf{y}}(\mathbf{g})$ is a non-negative differentiable function and the following two conditions hold:*

1. *$\forall \mathbf{y} \in Y$, $\forall i < j$, denote $\sigma\mathbf{y}$ as the permutation which exchanges the object on position i and that on position j while holds others unchanged for $\mathbf{y}$, if $g_{y(i)} < g_{y(j)}$, then $\phi_{\mathbf{y}}(\mathbf{g}) \geq \phi_{\sigma\mathbf{y}}(\mathbf{g})$ and with at least one $\mathbf{y}$, the strict inequality holds.*
2. *If $g_i = g_j$, then either $\forall \mathbf{y} \in Y_{i,j}$, $\frac{\partial\phi_{\mathbf{y}}(\mathbf{g})}{\partial g_i} \leq \frac{\partial\phi_{\mathbf{y}}(\mathbf{g})}{\partial g_j}$, or $\forall \mathbf{y} \in Y_{i,j}$, $\frac{\partial\phi_{\mathbf{y}}(\mathbf{g})}{\partial g_i} \geq \frac{\partial\phi_{\mathbf{y}}(\mathbf{g})}{\partial g_j}$, and with at least one $\mathbf{y}$, the strict inequality holds.*

Theorem 5. *Let $\phi_{\mathbf{y}}(\mathbf{g})$ be an order sensitive loss function on $\Omega \subset R^n$. $\forall n$ objects, if its permutation probability space is order preserving with respect to $n-1$ objective pairs $(j_1, j_2), (j_2, j_3), \cdots, (j_n - 1, j_n)$. Then the loss $\phi_{\mathbf{y}}(\mathbf{g})$ is consistent with respect to (1).*

Due to space limitations, we only give the proof sketch. First, we can show if the permutation probability space is order preserving with respect to $n-1$ objective pairs $(j_1, j_2), (j_2, j_3), \cdots, (j_n - 1, j_n)$, then the permutation with the maximum probability is $\mathbf{y}^* = (j_1, j_2, \cdots, j_n)$. Second, for an order sensitive loss function, for any order preserving object pairs (j_1, j_2), the vector $\mathbf{g}$ which minimizes $Q(\mathbf{g})$ in (8) should assign a larger score to j_1 than to j_2. This can be proven by the change of loss due to exchanging the scores of j_1 and j_2. Given all these results and Definition 2, we can prove Theorem 5 by means of contradiction.

Theorem 5 gives sufficient conditions for a surrogate loss function to be consistent: the permutation probability space should be order preserving and the function should be order sensitive. Actually, the assumption of order preserving has already been made when we use the scoring function and sorting function for ranking. The property of order preserving has also been explicitly or implicitly used in previous work, such as Cossock and Zhang (2006). The property of order sensitive shows that starting with a ground truth permutation, the loss will increase if we exchange the positions of two objects in it, and the speed of increase in loss is sensitive to the positions of objects.

4.3. Case Studies

We look at the four properties of three loss functions.

4.3.1. Likelihood Loss

We introduce a new loss function for listwise approach, which we call likelihood loss. The likelihood loss function is defined as:

$$\phi(\mathbf{g}(\mathbf{x}), \mathbf{y}) = -\log P(\mathbf{y}|\mathbf{x}; \mathbf{g}) \quad (9)$$
$$\text{where } P(\mathbf{y}|\mathbf{x}; \mathbf{g}) = \prod_{i=1}^{n} \frac{\exp(g(x_{y(i)}))}{\sum_{k=i}^{n} \exp(g(x_{y(k)}))}.$$

Note that we actually define a parameterized exponential probability distribution over all the permutations given the predicted result (by the ranking function), and define the loss function as the negative log likelihood of the ground truth list. The probability distribution turns out to be a Plackett-Luce model (Marden, 1995).

The likelihood loss function has the nice properties as below.

First, the likelihood loss is consistent. The following proposition shows that the likelihood loss is order sensitive. Therefore, according to Theorem 5, it is consistent. Due to the space limitations, we omit the proof.

Proposition 6. *The likelihood loss (9) is order sensitive on* $\Omega \subset R^n$.

Second, the likelihood loss function is sound. For simplicity, suppose that there are two objects to be ranked (similar argument can be made when there are more objects). The two objects receive scores of g_1 and g_2 from a ranking function. Figure 1(a) shows the scores, and the point $\mathbf{g} = (g_1, g_2)$. Suppose that the first object is ranked below the second object in the ground truth. Then the upper left area above line $g_2 = g_1$ corresponds to correct ranking; and the lower right area incorrect ranking. According to the definition of likelihood loss, all the points on the line $g_2 = g_1 + d$ has the same loss. Therefore, we say the likelihood loss only depends on d. Figure 1(b) shows the relation between the loss function and d. We can see the loss function decreases monotonously as d increases. It penalizes negative values of d more heavily than positive ones. This will make the learning algorithm focus more on avoiding incorrect rankings. In this regard, the loss function is a good approximation of the $0-1$ loss.

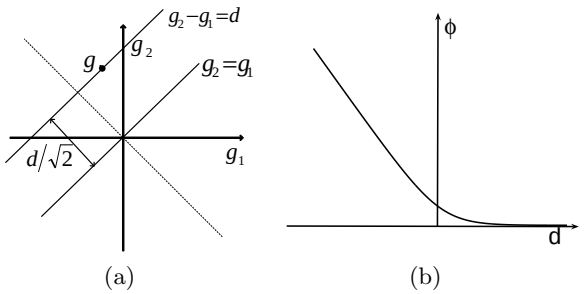

Figure 1. (a) Ranking scores of predicted result; (b) Loss ϕ v.s. d for the likelihood loss.

Third, it is easy to verify that the likelihood loss is continuous, differentiable, and convex (Boyd & Vandenberghe, 2004). Furthermore, the loss can be computed efficiently, with time complexity of linear order to the number of objects.

With the above good properties, a learning algorithm which optimizes the likelihood loss will become powerful for creating a ranking function.

4.3.2. Cosine Loss

The cosine loss is the loss function used in RankCosine (Qin et al., 2007), a listwise method. It is defined on the basis of the cosine similarity between the score vector of the ground truth and that of the predicted result.

$$\phi(\mathbf{g}(\mathbf{x}), \mathbf{y}) = \frac{1}{2}(1 - \frac{\psi_{\mathbf{y}}(\mathbf{x})^T \mathbf{g}(\mathbf{x})}{\|\psi_{\mathbf{y}}(\mathbf{x})\| \|\mathbf{g}(\mathbf{x})\|}). \tag{10}$$

The score vector of the ground truth is produced by a mapping $\psi_{\mathbf{y}}(\cdot) : R^d \to R$, which retains the order in a permutation, i.e, $\psi_{\mathbf{y}}(x_{y(1)}) > \cdots > \psi_{\mathbf{y}}(x_{y(n)})$.

First, we can prove that the cosine loss is consistent, given the following proposition. Due to space limitations, we omit the proof.

Proposition 7. *The cosine loss (10) is order sensitive on* $\Omega \subset R^n$.

Second, the cosine loss is not very sound. Let us again consider the case of ranking two objects. Figure 2(a) shows point $\mathbf{g} = (g_1, g_2)$ representing the scores of the predicted result and point $\mathbf{g}_\psi$ representing the ground truth (which depends on the mapping function ψ). We denote the angle from point $\mathbf{g}$ to line $g_2 = g_1$ as α, and the angle from $\mathbf{g}_\psi$ to line $g_2 = g_1$ as $\alpha_{\mathbf{g}_\psi}$. We investigate the relation between the loss and the angle α. Figure 2(b) shows the cosine loss as a function of α. From this figure, we can see that the cosine loss is not a monotonously decreasing function of α. When $\alpha > \alpha_{\mathbf{g}_\psi}$, it increases quickly, which means that it can heavily penalize correct rankings. Furthermore, the mapping function and thus $\alpha_{\mathbf{g}_\psi}$ can also affect the loss function. Specifically, the curve of the loss function can shift from left to right with different values of $\alpha_{\mathbf{g}_\psi}$. Only when $\alpha_{\mathbf{g}_\psi} = \pi/2$, it becomes a relatively satisfactory representation of loss for the learning problem.

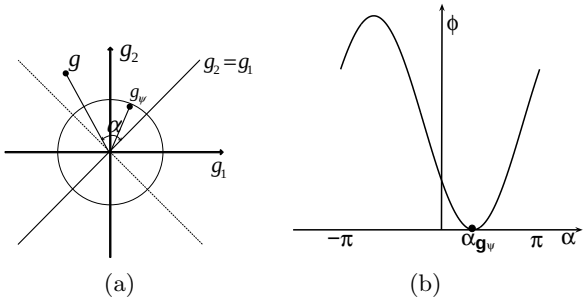

Figure 2. (a) Ranking scores of predicted result and ground truth; (b) Loss ϕ v.s. angle α for the cosine loss.

Third, it is easy to see that the cosine loss is continuous, differentiable, but not convex. It can also be computed in an efficient manner with a time complexity linear to the number of objects.

4.3.3. Cross Entropy Loss

The cross entropy loss is the loss function used in ListNet (Cao et al., 2007), another listwise method. The cross entropy loss function is defined as:

$$\phi(\mathbf{g}(\mathbf{x}), \mathbf{y}) = D(P(\pi|\mathbf{x}; \psi_{\mathbf{y}})||P(\pi|\mathbf{x}; \mathbf{g})) \quad (11)$$

$$\text{where} \quad P(\pi|\mathbf{x}; \psi_{\mathbf{y}}) = \prod_{i=1}^{n} \frac{\exp(\psi_{\mathbf{y}}(x_{\pi(i)}))}{\sum_{k=i}^{n} \exp(\psi_{\mathbf{y}}(x_{\pi(k)}))}$$

$$P(\pi|\mathbf{x}; \mathbf{g}) = \prod_{i=1}^{n} \frac{\exp(g(x_{\pi(i)}))}{\sum_{k=i}^{n} \exp(g(x_{\pi(k)}))}$$

where ψ is a mapping function whose definition is similar to that in RankCosine.

First, we can prove that the cross entropy loss is consistent, given the following proposition. Due to space limitations, we omit the proof.

Proposition 8. *The cross entropy loss (11) is order sensitive on $\Omega \subset R^n$.*

Second, the cross entropy loss is not very sound. Again, we look at the case of ranking two objects. $\mathbf{g} = (g_1, g_2)$ denotes the ranking scores of the predicted result. $\mathbf{g}_\psi$ denotes the ranking scores of the ground truth (depending on the mapping function). Similar to the discussions in the likelihood loss, the cross entropy loss only depends on the quantity d. Figure 3(a) illustrates the relation between $\mathbf{g}$, $\mathbf{g}_\psi$, and d. Figure 3(b) shows the cross entropy loss as a function of d. As can be seen that the loss function achieves its minimum at point $d_{\mathbf{g}_\psi}$, and then increases as d increases. That means it can heavily penalize those correct rankings with higher confidence. Note that the mapping function also affects the penalization. According to mapping functions, the penalization on correct rankings can be even larger than that on incorrect rankings.

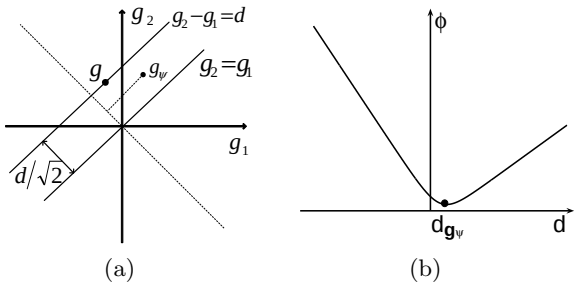

Figure 3. (a) Ranking scores of predicted result and ground truth; (b) Loss ϕ v.s. d for the cross entropy loss.

Third, it is easy to see that the cross entropy loss is continuous and differentiable. It is also convex because the log of a convex function is still convex, and the set of convex function is closed under addition (Boyd & Vandenberghe, 2004). However, it cannot be computed in an efficient manner. The time complexity is of exponential order to the number of objects.

Algorithm 1 ListMLE Algorithm

Input: training data$\{(\mathbf{x}^{(1)}, \mathbf{y}^{(1)}), \ldots, (\mathbf{x}^{(m)}, \mathbf{y}^{(m)})\}$
Parameter: learning rate η, tolerance rate ϵ
Initialize parameter ω
repeat
  for $i = 1$ **to** m **do**
    Input $(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$ to Neural Network and compute gradient $\triangle\omega$ with current ω
    Update $\omega = \omega - \eta \times \triangle\omega$
  end for
  calculate likelihood loss on the training set
until change of likelihood loss is below ϵ
Output: Neural Network model ω

Table 1 gives a summary of the properties of the loss functions. All the three loss functions as aforementioned are consistent, as well as continuous and differentiable. The likelihood loss is better than the cosine loss in terms of convexity and soundness, and is better than the cross entropy loss in terms of time complexity and soundness.

5. ListMLE

We propose a novel listwise method referred to as ListMLE. In learning of ListMLE, we employ the likelihood loss as the surrogate loss function, since it is proven to have all the nice properties as a surrogate loss. On the training data, we actually maximize the sum of the likelihood function with respect to all the training queries.

$$\sum_{i=1}^{m} \log P(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}; \mathbf{g}). \quad (12)$$

We choose Stochastic Gradient Descent (SGD) as the algorithm for conducting the minimization. As ranking model, we choose linear Neural Network (parameterized by ω). Algorithm 1 shows the learning algorithm based on SGD.

6. Experimental Results

We conducted two experiments to verify the correctness of the theoretical findings. One data set is synthetic data, and the other is the LETOR benchmark data for learning to rank (Liu et al., 2007).

Table 1. Comparison between different surrogate losses.

Loss	Consistency	Soundness	Continuity	Differentiability	Convexity	Complexity
Likelihood	√	√	√	√	√	$O(n)$
Cosine	√	×	√	√	×	$O(n)$
Cross entropy	√	×	√	√	√	$O(n! \cdot n)$

6.1. Experiment on Synthetic Data

We conducted an experiment using a synthetic data set. We created the data as follows. First, we randomly sample a point according to the uniform distribution on the square area $[0, 1] \times [0, 1]$. Then we assign to the point a score using the following rule, $y = x_1 + 10x_2 + \epsilon$ where ϵ denotes a random variable normally distributed with mean of zero and standard deviation of 0.005. In total, we generate 15 points and their scores in this way, and create a permutation on the points based on their scores, which forms an instance of ranking. We repeat the process and make 100 training instances, 100 validation instances, and 100 testing instances. We applied RankCosine, ListNet[4], and ListMLE to the data.

We tried different score mapping functions for RankCosine and ListNet, and used five most representative ones, i.e., $log(15-r)$, $\sqrt{15-r}$, $15-r$, $(15-r)^2$ and $\exp(15-r)$, where r denotes the positions of objects. We denote the mapping functions as *log*, *sqrt*, *l*, *q*, and *exp* for simplicity. The experiments were repeated 20 times with different initial values of parameters in the Neural Network model. Table 2 shows the means and standard deviations of the accuracies and Mean Average Precision (MAP)(Baeza-Yates & Ribeiro-Neto, 1999) of the three algorithms. The accuracy measures the proportion of correctly ranked instances and MAP[5] is a commonly used measure in IR.

As shown in the table, ListMLE achieves the best performance among all the algorithms in terms of both accuracy and MAP, owing to good properties of its loss function. The accuracies of RankCosine and ListNet vary according to the mapping functions. Especially, RankCosine achieves an accuracy of only 0.047 when using the mapping function *exp* while 0.917 when using the mapping function *l*. This result indicates that the performances of the cosine loss and the cross entropy loss depend on the mapping functions, while finding a suitable mapping function is not easy. Furthermore, RankCosine has a larger variance than ListMLE and ListNet. The likely explanation is that RankCosine's performance is sensitive to the initial values of parameters due to the non-convexity of its loss function.

[4]The top-1 version of the cross entropy loss was employed as in the original work (Cao et al., 2007).

[5]When calculating MAP, we treated the top-1 items as relevant and the other as irrelevant.

Table 2. The performance of three algorithms on the synthetic data set.

Algorithm	Accuracy	MAP
ListMLE	0.92 ± 0.011	0.999 ± 0.002
ListNet-log	0.905 ± 0.010	0.999 ± 0.002
ListNet-sqrt	0.917 ± 0.009	0.999 ± 0.002
ListNet-l	0.767 ± 0.021	0.995 ± 0.003
ListNet-q	0.868 ± 0.028	0.999 ± 0.002
ListNet-exp	0.832 ± 0.074	0.997 ± 0.004
RankCosine-log	0.180 ± 0.217	0.948 ± 0.034
RankCosine-sqrt	0.080 ± 0.159	0.886 ± 0.056
RankCosine-l	0.917 ± 0.112	0.999 ± 0.002
RankCosine-q	0.102 ± 0.161	0.890 ± 0.060
RankCosine-exp	0.047 ± 0.163	0.746 ± 0.136

6.2. Experiment on OHSUMED Data

We also conducted an experiment on OHSUMED, a benchmark data set for learning to rank provided in LETOR. There are in total 106 queries, and 16,140 query-document pairs upon which relevance judgments are made. The relevance judgments are either definitely relevant, possibly relevant, or not relevant. The data was in the form of feature vector and relevance label. There are in total 25 features. We used the data split provided in LETOR to conduct five-fold cross validation experiments. In evaluation, besides MAP, we adopted another measures commonly used in IR: Normalized Discounted Cumulative Gain (NDCG) (Jarvelin & Kekanainen, 2000).

Note that here the ground truth in the data is given as partial ranking, while the methods need to use total ranking (permutation) in training. To bridge the gap, for RankCosine and ListNet, we adopted the methods proposed in the papers (Cao et al., 2007) (Qin et al., 2007). For ListMLE we randomly selected one perfect permutation for each query from among the possible perfect permutations based on the ground truth.

We applied RankCosine, ListNet, and ListMLE to the data. The results reported below are those averaged over five trials. As shown in Figure 4, ListMLE achieves the best performance among all the algorithms. Especially, on NDCG@1, it has more than

5-point gains over RankCosine which is at the second place. We also conducted the t-test on the improvements of ListMLE over the other two algorithms. The results show that the improvements are statistically significant for NDCG@5, NDCG@7, NDCG@8, NDCG@9, and NDCG@10 (p-value < 0.05).

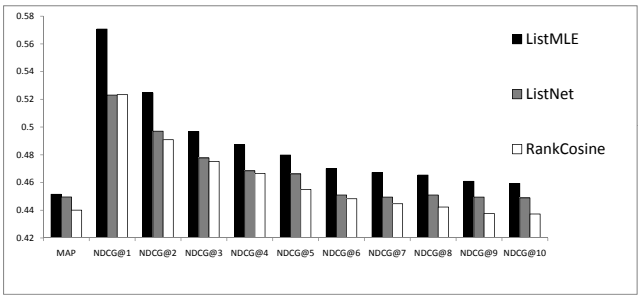

Figure 4. Ranking performance on OHSUMED data.

7. Conclusion

In this paper, we have investigated the theory and algorithms of the listwise approach to learning to rank. We have pointed out that to understand the effectiveness of a learning to rank algorithm, it is necessary to conduct theoretical analysis on its loss function. We propose investigating a loss function from the viewpoints of (a) consistency, (b) soundness, (c) continuity, differentiability, convexity, and (d) efficiency. We have obtained some theoretical results on consistency of ranking. We have conducted analysis on the likelihood loss, cosine loss, and cross entropy loss. The result indicates that the likelihood loss has better properties than the other two losses. We have then developed a new learning algorithm using the likelihood loss, called ListMLE and demonstrated its effectiveness through experiments.

There are several directions which we can further explore. (1) We want to conduct more theoretical analysis on the properties of loss functions, for example, weaker conditions for consistency and the rates of convergence. (2) We plan to study the case where cost-sensitive loss function is used instead of the $0-1$ loss function in defining the expected loss. (3) We plan to investigate other surrogate loss functions with the tools we have developed in this paper.

Abstract

Previous algorithms for learning lexicographic preference models (LPMs) produce a "best guess" LPM that is consistent with the observations. Our approach is more democratic: we do not commit to a single LPM. Instead, we approximate the target using the votes of a *collection* of consistent LPMs. We present two variations of this method—*variable voting* and *model voting*—and empirically show that these democratic algorithms outperform the existing methods. We also introduce an intuitive yet powerful learning bias to prune some of the possible LPMs. We demonstrate how this learning bias can be used with variable and model voting and show that the learning bias improves the learning curve significantly, especially when the number of observations is small.

1. Introduction

Lexicographic preference models (LPMs) are one of the simplest preference representations. An LPM defines an order of importance on the variables that describe the objects in a domain and uses this order to make preference decisions. For example, the meal preference of a vegetarian with a weak stomach could be represented by an LPM such that a vegetarian dish is always preferred over a non-vegetarian dish, and among vegetarian or non-vegetarian items, mild dishes are preferred to spicy ones. Previous work on learning LPMs from a set of preference observations has been limited to autocratic approaches: one of many possible LPMs is picked heuristically and used for future decisions. However, it is highly likely that autocratic methods will produce poor approximations of the target when there are few observations.

In this paper, we present a *democratic* approach to LPM learning, which does not commit to a single LPM. Instead, we approximate a target preference using the votes of a collection of consistent LPMs. We present two variations of this method: *variable voting* and *model voting*. Variable voting operates on the variable level and samples the consistent LPMs implicitly. The learning algorithm based on variable voting learns a partial order on the variables where all linearizations correspond to an LPM consistent with the observations. Model voting explicitly samples the consistent LPMs and employs weighted voting where the weights are computed using Bayesian priors. The additional complexity of voting-based algorithms is tolerable: both algorithms have low-order polynomial time complexity. Our experiments show that these democratic algorithms outperform more than half of the LPMs that can be produced by an autocratic algorithm, greatly increasing the chance of a positive outcome.

To further improve the performance of the learning algorithms when the number of observations is small, we introduce an intuitive yet powerful learning bias. The bias defines equivalence classes on the variables, indicating the most important set of variables, the second most important set, and so on. We demonstrate how this learning bias can be used with variable and model voting and show that the learning bias improves the learning curve significantly on appropriate problems, especially when the number of observations is small.

In the rest of the paper, we give some background on LPMs, then introduce our voting-based methods. We then introduce the learning bias and show how we can generalize the

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

voting methods to utilize such a bias. Finally, we present the results of our experiments, followed by related work and concluding remarks.

2. Lexicographic Decision Models

In this section, we briefly introduce the lexicographic preference model (LPM) and summarize previous results on learning LPMs. Before going into the definition of an LPM, we state that we only consider binary variables whose domain is $\{0, 1\}$.[1] Like others before us, we assume that the preferred value of each variable is known. Without loss of generality, we will assume that 1 is always preferred to 0.

Given a set of variables, $X = \{X_1 \dots X_n\}$, an object A over X is a vector of the form $[x_1, \dots, x_n]$. We use the notation $A(X_i)$ to refer the value of X_i in the object A. A *lexicographic preference model* $\mathcal{L}$ on X is a total order on a subset R of X. We denote this total order with $\sqsubset_{\mathcal{L}}$. Any variable in R is *relevant* with respect to $\mathcal{L}$; similarly, any variable in $X - R$ is *irrelevant* with respect to $\mathcal{L}$. If A and B are two objects, then the preferred object given $\mathcal{L}$ is determined as follows:

- Find the smallest variable X^* in $\sqsubset_{\mathcal{L}}$ such that X^* has different values in A and B. The object that has the value 1 for X^* is the most preferred.
- If all relevant variables in $\mathcal{L}$ have the same value in A and B, then the objects are equally preferred (a tie).

Example 1 *Suppose $X_1 < X_2 < X_3$ is the total order defined by an LPM $\mathcal{L}$, and consider objects $A = [1, 0, 1, 1]$, $B = [0, 1, 0, 0]$, $C = [0, 0, 1, 1]$ and $D = [0, 0, 1, 0]$. A is preferred over B because $A(X_1) = 1$, and X_1 is the most important variable in $\mathcal{L}$. B is preferred over C because $B(X_2) = 1$ and both objects have the same value for X_1. Finally, C and D are equally preferred because they have the same values for the relevant variables.*

An *observation* $o = (A, B)$ is an ordered pair of objects, connoting that A is preferred to B. In many practical applications, however, preference observations are gathered from demonstration of an expert who breaks ties arbitrarily. Thus, for some observations, A and B may actually be tied. An LPM $\mathcal{L}$ is *consistent* with an observation (A, B) iff $\mathcal{L}$ implies that A is preferred to B or that A and B are equally preferred.

The problem of learning an LPM is defined as follows. Given a set of observations, find an LPM $\mathcal{L}$ that is consistent with the observations. Previous work on learning LPMs was limited to the case where all variables are relevant. This assumption entails that, in every observation (A, B), A is strictly preferred to B, since ties can only happen when there are irrelevant attributes.

[1] The representation can easily be generalized to monotonic preferences with ordinal variables such that 1 corresponds to a preference on the increasing order and 0 on decreasing order.

Algorithm 1 *greedyPermutation*

Require: A set of variables X and a set of observations O.
Ensure: An LPM that is consistent with O, if one exists.
1: **for** $i = 1, \dots, n$ **do**
2: Arbitrarily pick one of $X_j \in X$ such that *MISS*$(X_j, O) = \min_{X_k \in X}$ *MISS*(X_k, O)
3: $\pi(X_j) := i$, assign the rank i to X_j
4: Remove X_j from X
5: Remove all observations (A, B) from O such that $A(X_j) \neq B(X_j)$
6: Return the total order $\sqsubset$ on X such that $X_i < X_j$ iff $\pi(X_i) < \pi(X_j)$

Schmitt and Martignon (2006) proposed a greedy algorithm that is guaranteed to find one of the LPMs that is consistent with the observations if one exists. They have also shown that for the noisy data case, finding an LPM that does not violate more than a constant number of the observations is NP-complete. Algorithm 1 is Schmitt and Martignon's greedy variable-permutation algorithm, which we use as a performance baseline. The algorithm refers to a function *MISS*(X_i, O), which is defined as $|\{(A, B) \in O : A(X_i) < B(X_i)\}|$; that is, the number of observations violated in O if the most important variable is selected as X_i. Basically, the algorithm greedily constructs a total order by choosing the variable at each step that causes the minimum number of inconsistencies with the observations. If multiple variables have the same minimum, then one of them is chosen arbitrarily. The algorithm runs in polynomial time, specifically $O(n^2 m)$, where n is the number of variables and m is the number of observations.

Dombi et al. (2007) have shown that if there are n variables, all of which are relevant, then $O(n \log n)$ queries to an oracle suffice to learn an LPM. Furthermore, it is possible to learn any LPM with $O(n^2)$ observations if all pairs differ in only two variables. They proposed an algorithm that can find the unique LPM induced by the observations. In case of noise due to irrelevant attributes the algorithm does not return an answer.

In this paper, we investigate the following problem: Given a set of observations with no noise, but possibly with arbitrarily broken ties, find a rule for predicting preferences that agrees with the target LPM that produced the observations.

3. Voting Algorithms

We propose a democratic approach for approximating the target LPM that produced a set of observations. Instead of finding just one of the consistent LPMs, it reasons with a collection of LPMs that are consistent with the observations. Given two objects, such an approach prefers the one

that a majority of its models prefer. A naive implementation of a voting algorithm would enumerate all LPMs that are consistent with a set of observations. However, since the number of models consistent with a set of observations can be exponential, the naive implementation is infeasible.

In this section, we describe two methods—*variable voting* and *model voting*—that sample the set of consistent LPMs and use voting to predict the preferred object. Unlike existing algorithms that learn LPMs, these methods do not require all variables to be relevant or observations to be tie-free. The following subsections explain the variable voting and model voting methods and summarize some of our theoretical results.

3.1. Variable Voting

Variable voting uses a generalization of the LPM representation. Instead of a total order on the variables, variable voting reasons with a *partial* order ($\preceq$) to find the preferred object in a given pair. Among the variables that are different in both objects, the ones that have the smallest rank (and are hence the most salient) in the partial order vote to choose the preferred object. The object that has the most "1" values for the voting variables is declared to be the preferred one. If the votes are equal, then the objects are equally preferred.

Definition 1 (Variable Voting) *Suppose X is a set of variables and $\preceq$ is a partial order on X. Given two objects, A and B, the variable voting process with respect to $\preceq$ for determining which of the two objects is preferred is:*

- *Define D, the set of variables that differ in A and B.*
- *Define D^*, the set of variables in D that have the smallest rank among D with respect to $\preceq$.*
- *Define N_A as the number of variables in D^* that favor A (i.e., that have value 1 in A and 0 in B) and N_B, as the number of variables in D^* that favor B.*
- *If $N_A > N_B$, then A is preferred. If $N_A < N_B$, then B is preferred. Otherwise, they are equally preferred.*

Example 2 *Suppose $\preceq$ is the partial order $\{X_2, X_3\} < \{X_1\} < \{X_4, X_5\}$. Consider objects $A = [0, 1, 1, 0, 0]$ and $B = [0, 0, 1, 0, 1]$. D is $\{X_2, X_5\}$. D^* is $\{X_2\}$ because X_2 is the smallest ranking variable in D with respect to $\preceq$. X_2 favors A because $A(X_2) = 1$. Thus, variable voting with $\preceq$ prefers A over B.*

Algorithm 2 presents the algorithm *learnVariableRank*, which learns a partial order $\preceq$ on the variables from a set of observations such that variable voting with respect to $\preceq$ will correctly predict the preferred objects in the observations. Specifically, it finds partial orders that define equivalence classes on the set of variables. The algorithm maintains the minimum possible rank for every variable that does not violate an observation with respect to variable voting. Initially, all variables are considered equally important (rank of 1). The algorithm loops over the set of observations until the ranks converge. At every iteration and for every pair, variable voting predicts a winner. If it is correct, then the ranks stay the same. Otherwise, the ranks of the variables that voted for the wrong object are incremented, thus reducing their importance [2]. Finally, the algorithm builds a partial order $\preceq$ based on the ranks such that $x \preceq y$ if and only if x has a lower rank than y.

Algorithm 2 *learnVariableRank*

Require: A set of X of variables, and a set O of observations
Ensure: A partial order on X.
1: $\Pi(x) = 1, \forall\, x \in X$
2: **while** Π can change **do**
3: **for** Every observation $(A, B) \in O$ **do**
4: Let D be the variables that differ in A and B
5: $D^* = \{x \in D | \forall y \in D, \Pi(x) \leq \Pi(y)\}$
6: V_A is the set of variables in D^* that are 1 in A.
7: V_B is the set of variables in D^* that are 1 in B.
8: **if** $|V_B| \geq |V_A|$ **then**
9: **for** $x \in V_B$ such that $\Pi(x) < |X|$ **do**
10: $\Pi(x) = \Pi(x) + 1$;
11: Return partial order $\preceq$ on X such that $x \preceq y$ iff $\Pi(x) < \Pi(y)$.

Table 1. The rank of the variables after each iteration of the for-loop in line 3 of the algorithm *learnVariableRank*.

Observations	X_1	X_2	X_3	X_4	X_5
$Initially$	1	1	1	1	1
$[0, 1, 1, 0, 0], [1, 1, 0, 1, 1]$	2	1	1	2	2
$[0, 1, 1, 0, 1], [1, 0, 0, 1, 0]$	2	1	1	2	2
$[1, 0, 1, 0, 0], [0, 0, 1, 1, 1]$	2	1	1	3	3

Example 3 *Suppose $X = \{X_1, X_2, X_3, X_4, X_5\}$ and O consists of $([0, 1, 1, 0, 0], [1, 1, 0, 1, 1])$, $([0, 1, 1, 0, 1], [1, 0, 0, 1, 0])$ and $([1, 0, 1, 0, 0], [0, 0, 1, 1, 1])$. Table 1 illustrates the ranks of every variable in X after each iteration of the for-loop in line 3 of the algorithm learnVariableRank. The ranks of the variables stay the same during the second iteration of the while-loop, thus, the loop terminates. The partial order $\preceq$ based on ranks of the variables is the same as the order given in Example 2.*

We next summarize our theoretical results about the algorithm *learnVariableRank*.

Correctness: Suppose $\preceq$ is a partial order returned by $learnVariableRank(X, O)$. It can be shown that any LPM $\mathcal{L}$ such that $\sqsubset_{\mathcal{L}}$ is a topological sort of $\preceq$ is consistent with

[2] In our empirical results, we also update the ranks when the prediction was correct but not unanimous. This produces a heuristic speed-up without detracting from the worst case guarantees.

O. Furthermore, $learnVariableRank$ never increments the ranks of the relevant variables beyond their actual rank in the target LPM. The ranks of the irrelevant variables can be incremented as far as the number of variables.

Convergence: *learnVariableRank* has a mistake-bound of $O(n^2)$, where n is the number of variables, because each mistake increases the sum of the potential ranks by at least 1 and the sum of the ranks the target LPM induces is $O(n^2)$. This bound guarantees that given enough observations (as described in the background section), *learnVariableRank* will converge to a partial order $\preceq$ such that every topological sort of $\preceq$ has the same prefix as the total order induced by the target LPM. If all variables are relevant, then $\preceq$ will converge to the total order induced by the target LPM.

Complexity: A very loose upper bound on the time complexity of *learnVariableRank* is $O(n^3m)$, where n is the number of variables and m is the number of observations. This bound holds because the while-loop on line 2 runs at most $O(n^2)$ times and the for-loop in line 3, runs for m observations. The time complexity of one iteration of the for-loop is $O(n)$; therefore, the overall complexity is $O(n^3m)$. We leave the investigation of tighter bounds and the average case analysis for future work.

3.2. Model Voting

The second method we present employs a Bayesian approach. This method randomly generates a sample set, S, of distinct LPMs, that are consistent with the observations. When a pair of objects is presented, the preferred one is predicted using weighted voting. That is, each $\mathcal{L} \in S$ casts a vote for the object it prefers, and this vote is weighted according to its posterior probability $P(\mathcal{L}|S)$.

Definition 2 (Model Voting) *Let U be the set of all LPMs, O be a set of observations, and $S \subset U$ be a set of LPMs that are consistent with O. Given two objects A and B, model voting prefers A over B with respect to S if*

$$\sum_{\mathcal{L}\in U} P(\mathcal{L}|S)V^{\mathcal{L}}_{(A>B)} > \sum_{\mathcal{L}\in U} P(\mathcal{L}|S)V^{\mathcal{L}}_{(B>A)}, \quad (1)$$

where $V^{\mathcal{L}}_{(A>B)}$ is 1 if A is preferred with respect to $\mathcal{L}$, and 0 otherwise. $V^{\mathcal{L}}_{(B>A)}$ is defined analogously. $P(\mathcal{L}|S)$ is the posterior probability of $\mathcal{L}$ being the target LPM given S, calculated as discussed below.

We first assume that all LPMs are equally likely *a priori*. In this case, given a sample S of size k, the posterior probability of an LPM $\mathcal{L}$ will be $1/k$ if and only if $\mathcal{L} \in S$, and 0 otherwise. Note that if S is maximal this case degenerates into the naive voting algorithm. However, it is generally not feasible to have all consistent LPMs—in practice, the sample has to be small enough to be feasible and large enough to be representative.

Algorithm 3 *sampleModels*

Require: A set of variables X, a set of observations O, and rulePrefix, an LPM to be extended.
Ensure: An LPM (possibly aggregated) consistent with O.
1: *candidates* is the set of variables $\{Y : Y \notin rulePrefix \mid \forall(A,B) \in O, A(Y) = 1 \; or A(Y) = B(Y)\}$.
2: **while** *candidates* $\neq \emptyset$ **do**
3: **if** $O = \emptyset$ **then**
4: return (*rulePrefix*, $*$).
5: Randomly remove a variable Z from *candidates* .
6: Remove any observation (C, D) from O such that $C(Z) \neq D(Z)$.
7: Extend *rulePrefix*: *rulePrefix* $=$ (*rulePrefix*, Z).
8: Recompute *candidates*.
9: return *rulePrefix*

In constructing S, we exploit the fact that many consistent LPMs share prefixes in the total order that they define on the variables. We wish to discover and compactly represent such LPMs. To this end, we introduce the idea of *aggregated LPMs*. An aggregated LPM, $(X_1, X_2 \ldots, X_k, *)$, represents a set of LPMs that define a total order with the prefix $X_1 < X_2 < \ldots < X_k$. Intuitively, an aggregated LPM states that any possible completion of the prefix is consistent with the observations. The algorithm *sampleModels* in Algorithm 3 implements a "smart sampling" approach by constructing an LPM that is consistent with the given observations, returning an aggregated LPM when possible. We start with an arbitrary consistent LPM (such as the empty set, which is always consistent) and add more variable orderings extending the input LPM. We first identify the variables that can be used in extending the prefix—that is, all variables X_i such that in every observation, either X_i is 1 in the preferred object or is the same in both objects. We then select one of those variables randomly and extend the prefix. Finally, we remove the observations that are explained with this selection and continue with the rest of the observations. If at any point, no observations remain, then we return the aggregated form of the prefix, since every completion of the prefix will be consistent with the null observation. Running *sampleModels* several times and eliminating duplicates will produce a set of (possibly aggregated) LPMs.

Example 4 *Consider the same set of observations O as in Example 3. Then, the LPMs that are consistent with O are as follows: $()$, (X_2), (X_2, X_3), $(X_2, X_3, X_1, *)$, (X_3), $(X_3, X_1, *)$, (X_3, X_2) and $(X_3, X_2, X_1, *)$. To illustrate the set of LPMs that an aggregate LPM represents, consider $(X_2, X_3, X_1, *)$, which has a total of 5 extensions: (X_2, X_3, X_1), (X_2, X_3, X_1, X_4), (X_2, X_3, X_1, X_5), $(X_2, X_3, X_1, X_4, X_5)$, $(X_2, X_3, X_1, X_5, X_4)$. Every*

time the algorithm sampleModels runs, it will randomly generate one of the aggregated LPMs: $(X_2, X_3, X_1, *)$, $(X_3, X_1, *)$, *or* $(X_3, X_2, X_1, *)$. *Note that the shorter models that are not produced by sampleModels are all sub-prefixes of the aggregated LPMs and it is easy to modify sampleModels to return those models as well.*

An aggregate LPM in a sample saves us from enumerating all possible extensions of a prefix, but it also introduces complications in computing the weights (posteriors) of the LPMs, as well as their votes. For example, when comparing two objects A and B, some extensions of an aggregate LPM might vote for A and some for B. Thus, we need to find the total number of LPMs that an aggregate LPM represents and determine what proportion of them favor A over B (or vice versa), without enumerating all extensions. Suppose there are n variables and $\mathcal{L}$ is an aggregated LPM with a prefix of length k. Then, the number of extensions of $\mathcal{L}$ is denoted by $F_{\mathcal{L}}$ and is equal to f_{n-k}, where f_m is defined to be:

$$f_m = \sum_{i=0}^{m} \binom{m}{i} \times i! = \sum_{i=0}^{m} \frac{(m)!}{(m-i)!}. \qquad (2)$$

Intuitively, f_m counts every possible permutation with at most m items. Note that f_m can be computed efficiently and that the number of all possible LPMs when there are n variables is given by f_n.

Consider a pair of objects A and B. We wish to determine how many extensions of an aggregate LPM $\mathcal{L} = (X_1, X_2, \ldots, X_k, *)$ would vote for one of the objects. We will call the variables $X_1 \ldots X_k$ the *prefix variables*. If A and B have different values for at least one prefix variable, then all extensions will vote in accordance with the smallest such variable. Suppose all prefix variables are tied and m is the set of all non-prefix variables. Then, m is composed of three disjoint sets a, b, and w, such that a is the set of variables that favor A, b is the set of variables that favor B, and w is the set of variables that are neutral (that is, that have the same value in A and B).

An extension $\mathcal{L}'$ of $\mathcal{L}$ will produce a tie iff all variables in a and b are irrelevant in $\mathcal{L}'$. The number of such extensions is $f_{|w|}$. The number of extensions that favor A over B is directly proportional to $|a|/(|a| + |b|)$. The number of extensions of $\mathcal{L}$ that will vote for A over B is denoted by $N^{\mathcal{L}}_{A>B}$, which is given by:

$$N^{\mathcal{L}}_{A>B} = \frac{|a|}{|b| + |a|} \times (f_m - f_{|w|}). \qquad (3)$$

The number of extensions of $\mathcal{L}$ that will vote for B over A is computed similarly. Note that the computation of $N^{\mathcal{L}}_{A>B}$, $N^{\mathcal{L}}_{B>A}$, and $F_{\mathcal{L}}$ can be done in linear time by caching the recurrent values.

Table 2. The posterior probabilities and number of votes of all LPMs in Example 5.

LPMs	$P(L\|S_1)$	$P(L\|S_2)$	$N^{\mathcal{L}}_{A>B}$	$N^{\mathcal{L}}_{B>A}$
$()$	1/31	0	0	0
(X_2)	1/31	0	1	0
(X_2, X_3)	1/31	0	1	0
$(X_2, X_3, X_1, *)$	5/31	5/26	5	0
(X_3)	1/31	0	0	0
$(X_3, X_1, *)$	16/31	16/26	7	7
(X_3, X_2)	1/31	0	1	0
$(X_3, X_2, X_1, *)$	5/31	5/26	5	0

Algorithm 4 *modelVote*

Require: A set of LPMs, S, and two objects, A and B.
Ensure: Returns either one of A or B or tie.

```
Initialize sampleSize to the number of non-aggregated LPMs in S.
for every aggregated LPM L ∈ S do
    sampleSize+=F_L.
Vote(A) = 0; Vote(B) = 0;
for every LPM L ∈ S do
    if L is not an aggregate rule then
        winner is the object L prefers among A and B.
        Increment Vote(winner) by 1/sampleSize.
    else
        if A and B differ in at least one prefix variable of L then
            L* is an extension of L referring only the prefix.
            winner is the object L* prefers among A and B
            Vote(winner) += F_L/sampleSize.
        else
            Vote(A) += N^L_{A>B}/sampleSize.
            Vote(B) += N^L_{B>A}/sampleSize.
if Vote(A) = Vote(B) then
    Return a tie
else
    Return the object obj with the highest Vote(obj).
```

Example 5 *Suppose* X *and* O *are as defined in Example 3. The first column of Table 2 lists all LPMs that are consistent with O. The second column gives the posterior probabilities of these models given the sample* S_1*, which is the set of all consistent LPMs. The third column is the posterior probability of the models given the sample* $S_2 = \{(X_2, X_3, X_1, *), (X_3, X_1, *), (X_3, X_2, X_1, *)\}$. *Given two objects* $A = [0, 1, 1, 0, 0]$ *and* $B = [0, 0, 1, 0, 1]$*, the number of votes for each object based on each LPM is given in the last two columns. Note that the total number of votes for* A *and* B *does not add up to the total number of extensions of* $(X_3, X_1, *)$ *because two of its extensions—*(X_3, X_1) *and* (X_3, X_1, X_4)*—prefer* A *and* B *equally.*

Algorithm 4 describes *modelVote*, which takes a sample of consistent LPMs and a pair of objects as input, and predicts the preferred object using the weighted votes of the LPMs in the sample.

Returning to Example 5, the reader can verify that model voting will prefer A over B. Next, we present our theoretical results on the *sampleModels* and *modelVote* algorithms.

Complexity: The time complexity of *sampleModels* is bounded by $O(n^2m)$, where n is the number of variables and m is the number of observations: the while-loop in line 2 runs at most n times; at each iteration, we have to process every observation, each time performing computations in $O(n)$ time. If we call *sampleModels* s times, then the total complexity of sampling is $O(sn^2m)$. For constant s, this bound is still polynomial. Similarly, the complexity of *modelVote* is $O(sn)$ because it considers each of the s rules in the sample, counting the votes of each rule, which can be done in $O(n)$ time.

Comparison to variable voting: The set of LPMs that is sampled via *learnVariableRank* is a subset of the LPMs that *sampleModels* can produce. The running example in the paper demonstrates that *sampleModels* can generate the LPM $(X_3, X_1, *)$; however, none of its extensions is consistent with the partial order *learnVariableRank* returns.

4. Introducing Bias

In general, when there are not many training examples for a learning algorithm, the space of consistent LPMs is large. In this case, it is not possible to find a good approximation of the target model. To overcome this problem, we can introduce bias (domain knowledge), indicating that certain solutions should be favored over the others. In this section, we propose a bias in the form of equivalence classes over the set of attributes. These equivalence classes indicate the set of most important attributes, second most important attributes, and so on. For example, when buying a used car, most people consider the most important attributes of a car to be the mileage, the year, and the make of the car. The second most important set of attributes is the color, number of doors, and body type. Finally, perhaps the least important properties are the interior color and the wheel covers. We now formally define a learning bias and what it means for an LPM to be consistent with a learning bias.

Definition 3 (Learning Bias) *A learning bias $\mathcal{B}$ for learning a lexicographic preference model on a set of variables X is a total order on a partition of X. $\mathcal{B}$ has the form $E_1 < E_2 < \ldots < E_k$, where $\cup_i E_i = X$. Intuitively, B defines a partial order on X such that for any two variables $x \in E_i$ and $y \in E_j$, $x < y$ iff $E_i < E_j$. We denote this partial order by $\preceq_B$.*

Definition 4 *Suppose that $X = \{X_1, \ldots X_n\}$ is a set of variables, $\mathcal{B}$ a learning bias, and $\mathcal{L}$ an LPM. $\mathcal{L}$ is consistent with $\mathcal{B}$ iff the total order $\sqsubset_{\mathcal{L}}$ is consistent with the partial order $\preceq_{\mathcal{B}}$.*

Intuitively, an LPM that is *consistent* with a learning bias respects the variable orderings induced by the learning bias. The learning bias prunes the space of possible LPMs. The size of the partition determines the strength of the bias; for example, if there is a single variable per set, then the bias defines a specific LPM. In general, the number of LPMs that is consistent with a learning bias of the form $E_1 < E_2 < \ldots < E_k$ can be computed with the following recursive formula:

$$G([e_1, \ldots e_k,]) = f_{e_1} + e_1! \times (G([e_2, \ldots e_k]) - 1), \quad (4)$$

where $e_i = |E_i|$ and the base case for the recursion is $G([]) = 1$. The first term in the formula counts the number of possible LPMs using only the variables in E_1, which are the most important variables. The definition of consistency entails that a variable can appear in $\sqsubset_{\mathcal{L}}$ iff all of the more important variables are already in $\sqsubset_{\mathcal{L}}$, hence the term $e_1!$. Note that the recursion on G is limited to the number of sets in the partition, which is bounded by the number of variables; therefore, it can also be computed in linear time by caching precomputed values of f.

To illustrate the power of a learning bias, consider a learning problem with nine variables. Without a bias, the total number of LPMs is 905,970. If a learning bias partitions the variables into three sets, each with three elements, then the number of LPMs consistent with the bias is only 646. A bias with four sets, where the first set has three variables and the rest have two, limits the number to 190.

We can easily generalize the *learnVariableRank* algorithm to utilize the learning bias, by changing only the first line of *learnVariableRank* which initializes the ranks of the variables. Given a bias of the form $S_1 < \ldots < S_k$, the generalized algorithm assigns the rank 1 (most important rank) to the variables in S_1, rank $|S_1| + 1$ to those in S_2, and so forth. This initialization ensures that an observation (A, B) is used for learning the order of variables in a class S_i only when A and B have the same values for all variables in classes $S_1 \ldots S_{i-1}$ and have different values for at least one variable in S_i.

The algorithm *modelVote* can also be generalized to use a learning bias $\mathcal{B}$. In the sample generation phase, we use *sampleModels* as presented earlier, and then eliminate all rules whose prefixes are not consistent with the bias. Note that even if the prefix of an aggregated LPM $\mathcal{L}$ is consistent with a bias, this may not be the case for every extension of $\mathcal{L}$. Thus, in the algorithm *modelVote*, we need to change any references to $F_{\mathcal{L}}$ and $N^{\mathcal{L}}_{A<B}$ (or $N^{\mathcal{L}}_{B<A}$) with $F^{\mathcal{B}}_{\mathcal{L}}$ and $N^{\mathcal{L},\mathcal{B}}_{A<B}$ (or $N^{\mathcal{L},\mathcal{B}}_{B<A}$), respectively, where:

- $F^{\mathcal{B}}_{\mathcal{L}}$ is the number of extensions of $\mathcal{L}$ that are consistent with $\mathcal{B}$, and

- $N^{\mathcal{L},\mathcal{B}}_{A<B}$ is the number of extensions of $\mathcal{L}$ that are consistent with $\mathcal{B}$ and prefer A. ($N^{\mathcal{L},\mathcal{B}}_{B<A}$ is similar.)

Suppose that $\mathcal{B}$ is a learning bias $E_1 < \ldots < E_m$. Let Y denote the prefix variables of an aggregate LPM $\mathcal{L}$ and E_k be the first set such that at least one variable in E_k is not in Y. Then, $F^{\mathcal{B}}_{\mathcal{L}} = G([|E_k - Y|, |E_{k+1} - Y|, \ldots |E_m - Y|])$.

When counting the number of extensions of $\mathcal{L}$ that are consistent with $\mathcal{B}$ and prefer A, we again need to examine the case where the prefix variables equally prefer the objects. Suppose Y is as defined as above and D_i denotes the set difference between E_i and Y. Let D_j be the first non-empty set and D_k be the first set such that at least one variable in D_k has different values in the two objects. Obviously, only the variables in D_k will influence the prediction of the preferred object. If

- $d_i = |D_i|$, the cardinality of D_i, and
- a is the set of variables in D_k that favor A, b is the set of variables in D_k that favor B, and w is the set of variables in D_k that are neutral,

then $N^{\mathcal{L},\mathcal{B}}_{A>B}$, the number of extensions of $\mathcal{L}$ that are consistent with $\mathcal{B}$ and prefer A, can be computed as follows:

$$N^{\mathcal{L},\mathcal{B}}_{A>B} = \frac{|a|}{|a| + |b|} \times (F^{\mathcal{B}}_{\mathcal{L}} - G([d_j \ldots d_{k-1}, |w|])). \quad (5)$$

5. Experiments

In this section, we explain our experimental methodology and discuss the results of our empirical evaluations. We define the *prediction performance* of an algorithm P with respect to a set of test observations T as:

$$\textit{performance}(P,T) = \frac{\textit{Correct}(P,T) + 0.5 \times \textit{Tie}(P,T)}{|T|} \quad (6)$$

where $\textit{Correct}(P,T)$ is the number of observations in T that are predicted correctly by P and $\textit{Tie}(P,T)$ is the number of observations in T that P predicted as a tie. Note that an LPM returned by *greedyPermutation* never returns a tie. In contrast, variable voting with respect to a partial order in which every variable is equally important will only return ties, so the overall performance will be 0.5, which is no better than randomly selecting the preferred objects. We will use MV, VV, and G to denote the model voting, variable voting, and the greedy approximations of an LPM.

Given sets of training and test observations, (O,T), we measure the *average* and *worst* performances of VV, MV and G. When combined with *learnVariableRank*, VV is a deterministic algorithm, so the average and worst performances of VV are the same. However, this is not the case

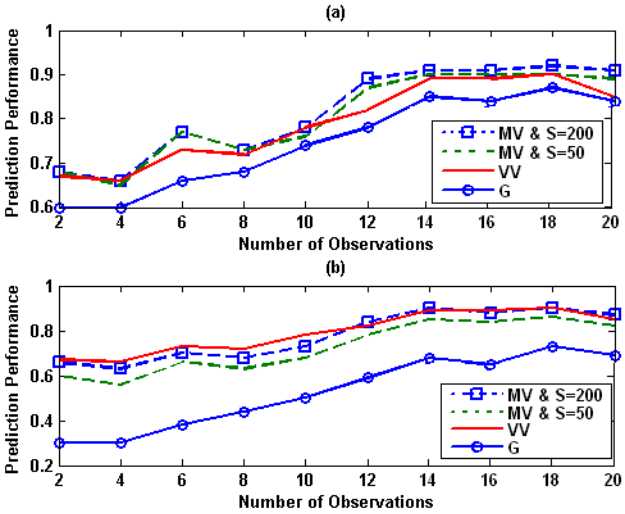

Figure 1. The average and worst prediction performance of the greedy algorithm, variable voting and model voting.

for MV with sampling, because *sampleModels* is randomized. Even for the same training and test data (O,T), the performance of MV can vary. To mitigate this, we ran MV 10 times for each (O,T) pair, and called *sampleModels* S times on each run (thus the sample size is at most S), recording the average and worst of its performance. The greedy algorithm G is also randomized (in line 2, one variable is picked arbitrarily), so we ran G 200 times for every (O,T), recording its average and worst performance.

For our experiments, the control variables are R, the number of relevant variables in the target LPM; I, the number of irrelevant variables; N_O, the number of training observations; and N_T, the number of test observations. For MV experiments we used sample sizes (S) of 50 and 200. Larger sample sizes (e.g. 800) slightly improved performance, but are omitted for space. For fixed values of R and I, an LPM $\mathcal{L}$ is randomly generated. (If a bias B is given, then $\mathcal{L}$ is also consistent with B.) We randomly generated N_O and N_T pairs of objects, each with $I + R$ variables. Finally, we labeled the preferred objects according to $\mathcal{L}$.

Figure 1a shows the average performance of G, MV with two different sample sizes and VV for $R = 15$, $I = 0$, and $N_T = 20$, as N_O ranges from 2 to 20. Figure 1b shows the worst performance for each algorithm. In these figures, the data points are averages over 20 different pairs of training and test sets (O,T). The average performance of VV and MV is better than the average performance of G, and the difference is significant at every data point. Also, note that the worst case performance of G after seeing two observations is around 0.3, which suggests a very poor approximation of the target. VV and MV's worst case performances are much better than the worst case performance of G, justifying the additional complexity of the algorithms MV

and VV. We have observed the same behavior for other values of R and I, and have also witnessed a significant performance advantage for MV over VV in the presence of irrelevant variables when training data is scarce. Space limitations prevent us from presenting these results.

Figure 2 shows the positive effect of learning bias on the performance of voting algorithms for $R = 10$, $I = 0$, and $N_T = 20$, as N_O ranges from 2 to 20. In addition, this experiment aims to show that bias does not undermine the advantage voting algorithms held over the greedy algorithm in the unbiased case. To this end we have trivially generalized G to produce LPMs that are consistent with a given bias. The data points are averages over 20 different pairs of training and test sets (O, T). We have arbitrarily picked two biases: B_1 : $\{X_1, X_2, X_3, X_4, X_5\} < \{X_6, X_7, X_8, X_9, X_{10}\}$ and B_2 : $\{X_1, X_2, X_3\} < \{X_4, X_5\} < \{X_6, X_7, X_8\} < \{X_9, X_{10}\}$. The performance of VV improved greatly with the introduction of learning biases. B_2 is a stronger bias than B_1 and prunes the space of consistent LPMs more than B_1. As a result, the performance gain due to B_2 is greater than that due to B_1. The difference between the bias curves and the non-bias curve is statistically significant except at the last point. Note that the biases are particularly effective when the number of training observations is small. The worst case performance of G with biases B_1 and B_2 are also shown in Figure 2. For both biases, the worst case performance of G is significantly lower than the performance of VV with the corresponding bias. We obtained very similar results with MV but due to space constraints we can not include them in this paper.

6. Related Work

Lexicographic orders and other preference models have been utilized in several research areas, including multicriteria optimization (Bertsekas & Tsitsiklis, 1997), linear programming , and game theory (Quesada, 2003). The lexicographic model and its applications were surveyed by Fishburn (1974). The most relevant existing work for learning and/or approximating LPMs is by Schmitt and Martignon (2006) and Dombi et al. (2007), which were summarized in Section 2. Another analogy, described by Schmitt and Martignon (2006), is between LPMs and decision lists (Rivest, 1987). Specifically, it was shown that LPMs are a special case of 2-decision lists, and that the algorithms for learning these two classes of models are not directly applicable to each other.

7. Conclusions and Future Work

In this paper, we presented democratic approximation methods for learning a lexicographic preference model (LPM) given a set of preference observations. Instead of committing to just one of the consistent LPMs, we maintain a set of models and predict based on the majority of votes. We described two such methods: *variable voting* and *model voting*. We showed that both methods can be implemented in polynomial time and exhibit much better worst- and average-case performance than the existing methods. Finally, we have defined a learning bias that can improve performance when the number of observations is small and incorporated this bias into the voting-based methods, significantly improving their empirical performance.

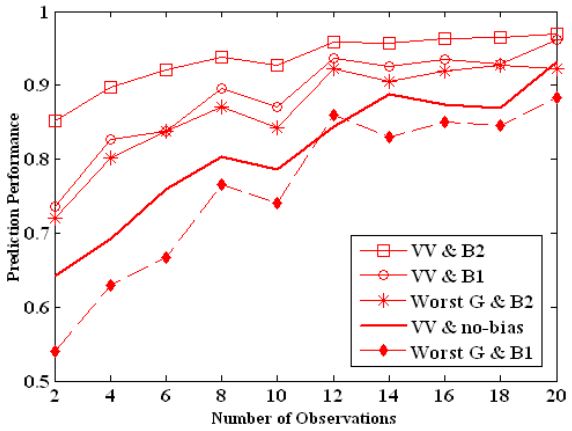

Figure 2. The effect of bias on VV and G.

The future directions of this work are twofold. First, we plan to generalize our algorithms to learn the preferred values of a variable as well as the total order on the variables. Second, we intend to develop democratic approximation techniques for other kinds of preference models.

Abstract

This paper extends many of the recent popular policy evaluation algorithms to a generalized framework that includes least-squares temporal difference (LSTD) learning, least-squares policy evaluation (LSPE) and a variant of incremental LSTD (iLSTD). The basis of this extension is a preconditioning technique that solves a stochastic model equation. This paper also studies three significant issues of the new framework: it presents a new rule of step-size that can be computed online, provides an iterative way to apply preconditioning, and reduces the complexity of related algorithms to near that of temporal difference (TD) learning.

1. Introduction

In Reinforcement Learning (RL), a primary concern is how to reuse experience in an intelligent and fast way. To achieve this we must consider two major issues, namely, the data efficiency and the computational efficiency. Recently these two issues were widely studied by the research on temporal difference (TD) leaning. TD is a classical algorithm well suited for policy evaluation (Sutton, 1988), and achieves great success for its wide applications in control and AI games (Sutton & Barto, 1998). One of its significant advantages is its superior computational efficiency. If the feature vector has K components, TD requires $O(K)$ complexity. However, previous research shows that TD uses experience inefficiently (Lin & Mitchell, 1992)(Geramifard et al., 2006a). The reason is that TD throws the transition information away after using it for one update of weights. One way to reuse this information is to accumulate it into a data set once it has been experienced. Then TD methods are repeatedly applied to the data set. This pattern is known as experience replay (Lin & Mitchell, 1992), and has a high efficiency in using experience because each transition is exploited to the maximum extent. However, this method may be inefficient to perform online because the data set is possible to grow extremely large if the exploration process runs for a long time[1]. Another way is to extract some data structure from the sequence of experience and update the weights with the help of this structure. This way is more desirable because the data structure requires much smaller size of memory than the data set, and leads to recent popular algorithms such as least-squares temporal difference (LSTD) (Boyan, 1999) and least-squares policy evaluation (LSPE) (Nedić & Bertsekas, 2003). Compared to TD, the two algorithms are more data efficient, but similar to the experience replay, are still computationally expensive.

LSTD inverts some accumulated matrix per time step, and generally requires $O(K^3)$. Recursive LSTD (RLSTD) computes the inversion of LSTD's matrix iteratively using Sherman-Morison formula and reduces the complexity to $O(K^2)$ (Bradtke & Barto, 1996)(Xu et al., 2002). LSPE is similar to LSTD and will be examined later. Recently incremental LSTD (iLSTD) was proposed to strike a balance between LSTD and TD (Geramifard et al., 2006a)(Geramifard et al., 2006b): its data efficiency is almost as good as LSTD, but its computational cost is very near to that of TD. However, iLSTD still requires tuning the step-size manually as TD. In contrast, LSTD has no parameter to tune.

The aim of this paper is to explore the relations among recent popular policy evaluation algorithms. A framework of policy evaluation algorithms called the *preconditioned temporal difference* (PTD) learning is introduced, which includes LSTD, LSPE and a variant of iLSTD, *etc.* Furthermore, we maintain LSTD's prop-

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] Lin avoided this problem by using only a window of most recent experience (Lin & Mitchell, 1992). This, however, results in loss of information and it is in general difficult to prespecify the window size.

erty of ease of tuning. This paper proposes an adaptive step-size that can be computed online by all PTD algorithms.

To reduce computational complexity $O(K^2)$ of the PTD algorithms due to the inversion of the preconditioner matrix, we develop an efficient incremental process to apply preconditioning, which leads to a set of incremental PTD algorithms. Incremental PTD algorithms take advantage of the sparse nature of RL tasks, storing and manipulating only the valid experience by a *condensed* structure every time step. We also present an efficient adaptive step-size for incremental PTD algorithms. Results on Boyan chain example show that PTD algorithms using the adaptive step-size gives much faster convergence than using previous rule of step-size; incremental PTD algorithms via condensed implementation have a high efficiency in using data while a low complexity similar to iLSTD.

1.1. Stationary Model Equation

Given a state space $\mathcal{S} = \{1, 2, \ldots, N\}$, the problem of *policy evaluation* is to predict the long-term optimal reward of a policy for each state s:

$$J(s) = \sum_{t=0}^{\infty} \gamma^t r(s_t, s_{t+1}), \quad s_0 = s, \quad 0 < \gamma \leq 1,$$

where γ is the discount factor, and $r(s_t, s_{t+1})$ is the reward received by the agent at time t. Given $K (K \leq N)$ feature functions $\varphi_k(\cdot) : \mathcal{S} \mapsto \mathcal{R}$, $k = 1, \ldots, K$, the feature of state s_t is $\phi_t = [\varphi_1(s_t), \varphi_2(s_t), \ldots, \varphi_K(s_t)]'$. The optimal reward vector J can now be approximated by $\hat{J} = \Phi w$, where w is the weight vector, and Φ is the feature matrix whose entries are $\Phi(j, k) = \varphi_k(j)$, $k = 1, \ldots, K$; $j = 1, \ldots, N$.

For an ergodic Markov chain that has steady-state probabilities $\pi(1), \pi(2), \ldots, \pi(N)$, (Tsitsiklis & Van Roy, 1997) proved that TD(λ) eventually finds a weight vector w^* that satisfies a linear system

$$Aw^* = -b, \tag{1}$$

where A and b are defined by

$$A = \Phi' D(\gamma P - I) \sum_{k=0}^{\infty} (\lambda\gamma P)^k \Phi, \quad b = \Phi' D \sum_{k=0}^{\infty} (\lambda\gamma P)^k \bar{r},$$

D is the diagonal matrix with diagonal entries $\pi(i)$, $i = 1, \ldots, N$; $\lambda \in [0, 1]$ is the eligibility trace factor; P is the transition probability matrix; I is the identity matrix; and $\bar{r}$ is the vector with components $\bar{r}_i = \sum_{j=1}^{N} P_{i,j} r(i, j)$, $i = 1, \ldots, N$. For each $\lambda \in [0, 1]$, w^* is also the limit point of LSTD(λ), LSPE(λ) and iLSTD(λ). Equation (1) is only useful for analysis but not applicable in practice and will be called the stationary model equation.

1.2. Law of Large Numbers

A common structure grown by LSTD(λ), LSPE(λ) and iLSTD(λ) is updated incrementally. If the current transition from s_t to s_{t+1} incurs a reward r_t, then a matrix and a vector are updated by

$$\tilde{A}_{t+1} = \tilde{A}_t + z_t(\gamma\phi_{t+1} - \phi_t)'; \quad \tilde{b}_{t+1} = \tilde{b}_t + z_t r_t,$$

where z_t is the eligibility trace, computed recursively by $z_{t+1} = \lambda\gamma z_t + \phi_{t+1}$. Because the components of $\tilde{A}_{t+1}$ and $\tilde{b}_{t+1}$ can get to infinity it is better to use some well-defined term. For infinite-horizon problems, (Tadić, 2001)(Nedić & Bertsekas, 2003) used the following structure

$$A_{t+1} = \frac{1}{t+1}\tilde{A}_{t+1}; \quad b_{t+1} = \frac{1}{t+1}\tilde{b}_{t+1}, \tag{2}$$

which satisfies the law of large numbers. However, (2) are no longer consistent estimations of A and b for absorbing Markov chains such as Boyan chain example. In Section 2.1, such an extension is proposed.

1.3. Related Algorithms

At time t, the rule of LSTD(λ) for updating weights can be specified as $w_{t+1} = -\tilde{A}_{t+1}^{-1}\tilde{b}_{t+1}$. In practice, $\tilde{A}_t$ can be singular and a perturbation which sets $\tilde{A}_0$ to $\delta_0^- I$ ($\delta_0^- < 0$) should be used.

LSPE(λ) was proposed for infinite-horizon problem (Nedić & Bertsekas, 2003). If the current step-size is α_t, LSPE updates w by

$$w_{t+1} = w_t + \alpha_t (D_{t+1})^{-1} (A_{t+1} w_t + b_{t+1}), \tag{3}$$

where

$$D_{t+1} = \frac{1}{t+1}\left(\delta_0^+ I + \sum_{k=0}^{t} \phi_k \phi_k'\right), \quad \delta_0^+ > 0.$$

In the long run, D_{t+1} converges to $\Phi' D \Phi$.

1.4. Preconditioning

Generally, solutions to a linear system like (1) can be categorized into two classes. The first is the direct methods (Saad, 2003), which factorize A into easily invertible matrices, including Gaussian elimination and LU/QR factorization, *etc.* However, the complexity involved in factorizing A is not practical for large scale systems. The second class, known as the iterative solutions, scales well with the problem size and is very efficient for large and sparse linear systems.

According to the literature of iterative solutions, preconditioning is especially effective for symmetric system (Saad, 2003), but usually for RL tasks, matrix A is not symmetric. Therefore, the original stationary model equation is first transformed into the following symmetric form

$$A'Aw^* = -A'b, \tag{4}$$

which can be solved by Richardson's iteration (Saad, 2003)

$$w_{\tau+1} = w_\tau - \alpha A' \left(Aw_\tau + b\right), \tag{5}$$

where α is some positive scalar that should satisfy

$$\rho(I - \alpha A'A) < 1.$$

The technique of preconditioning refers to a general technique which preconditions a system before solving it. For example, preconditioning (4) gives us the preconditioned symmetric model equation

$$C^{-1}A'Aw^* = -C^{-1}A'b,$$

where C is an invertible matrix, usually called the *preconditioner*. Then the model equation is solved by the iteration

$$w_{\tau+1} = w_\tau - C^{-1}A' \left(Aw_\tau + b\right). \tag{6}$$

Convergence rate of (6) is governed by the spectral radius of $I - C^{-1}A'A$: the smaller the radius is, the faster the solution will be (Saad, 2003). Therefore a good preconditioner should make the preconditioned radius smaller than the original radius, *i.e.*, $\rho(I - C^{-1}A'A) < \rho(I - \alpha A'A)$.

2. The Generalized Framework

We first give consistent estimations of A and b for absorbing Markov chains, and then we show how to apply them together with preconditioning to policy evaluation.

2.1. Robbins-Monro for Absorbing Chains

A trajectory of an absorbing Markov chain is a finite sequence $s_0, \ldots, s_q$, where s_q is the absorbing state. Given trajectories $1, \ldots, M$, where the mth trajectory has length L_m, the consistent estimations of A and b are

$$A_M = \frac{1}{T}\sum_{m=1}^{M}\sum_{t=0}^{L_m} z_t(\gamma\phi_{t+1} - \phi_t)', \tag{7}$$

and

$$b_M = \frac{1}{T}\sum_{m=1}^{M}\sum_{t=0}^{L_m} z_t r_t, \tag{8}$$

where T is the number of all observed state visits in M trajectories, and z_t is the eligibility trace. Similarly, for absorbing Markov chain, LSPE should use the following structure to estimate $\Phi' D \Phi$:

$$D_M = \frac{1}{T}\sum_{m=1}^{M}\sum_{t=0}^{L_m} \phi_t\phi_t'. \tag{9}$$

On a transition from s_t to s_{t+1}, estimations (7), (8) and (9) can be updated incrementally, which is achieved by a Robbins-Monro (RM) procedure:

$$A_{t+1} = A_t + \frac{1}{T}(z_t(\gamma\phi_{t+1} - \phi_t)' - A_t), \tag{10}$$

$$b_{t+1} = b_t + \frac{1}{T}(z_t r_t - b_t), \tag{11}$$

and

$$D_{t+1} = D_t + \frac{1}{T}(\phi_t\phi_t' - D_t), \tag{12}$$

where T is updated by $T = T + 1$ after the three estimations. The convergence of RM procedure can be proved in similar manner to the case of infinite-horizon problems (Tadić, 2001)(Nedić & Bertsekas, 2003).

2.2. The Framework

Given A_{t+1} and b_{t+1} estimated by RM, we can define a *stochastic model equation*

$$A_{t+1}w = -b_{t+1}.$$

Because RM estimations have some error, the stochastic model equation is not satisfied, and there exists a nonzero residual vector

$$e_{t+1}(w) = A_{t+1}w + b_{t+1}. \tag{13}$$

A natural idea is that the current weights can be improved by minimizing the residual error $||e_{t+1}(w)||^2$, which produces a gradient descent algorithm

$$w_{t+1} = w_t - \alpha_t A'_{t+1}(A_{t+1}w_t + b_{t+1}),$$

where α_t is a positive step-size. Gradient descent algorithm is a stochastic form of the iteration (5).

The general preconditioned temporal difference (PTD) learning applies the technique of preconditioning to improve the convergence rate of gradient descent. Assume C_{t+1} is a chosen preconditioner, the rule of PTD can be cast as

$$w_{t+1} = w_t - \alpha_t C_{t+1}^{-1} A'_{t+1}(A_{t+1}w_t + b_{t+1}), \tag{14}$$

where α_t is some scalar but not necessarily positive. With the rule proposed in Section 3, the step-size guarantees the convergence of PTD algorithms and makes

them more flexible in stochastic environments than (6).

The choice of preconditioner is a key issue. Generally, preconditioner should decrease the spectral radius of gradient descent:

$$\rho(I - \alpha_t C_{t+1}^{-1} A'_{t+1} A_{t+1}) < \rho(I - \alpha_t A'_{t+1} A_{t+1}).$$

Gradient descent makes no preconditioning because it chooses the identity matrix as preconditioner. Good examples of preconditioner can be found in recent popular policy evaluation algorithms.

2.3. Relations to Previous Algorithms

LSTD, LSPE and iLSTD are all special forms of applying preconditioner to gradient descent algorithm:

$C_{t+1} = -A'_{t+1} D_{t+1}$, where D_{t+1} is defined in (12). One can easily verify that this is a variant of LSPE(λ).

$C_{t+1} = A'_{t+1} A_{t+1}$. This is an extended form of LSTD: $w_{t+1} = (1 - \alpha_t) w_t + \alpha_t(-A_{t+1}^{-1} b_{t+1})$. Using 1 as the step-size, we get exactly LSTD(λ). Later we will see that LSTD is optimal in choosing its step-size because certain residual error is minimized.

$C_{t+1} = -A'_{t+1}$. This approach is a variant of iLSTD(λ) (Yao & Liu, 2008).

3. The Rule of Step-size

This section presents an adaptive process to compute the step-size online for gradient descent algorithm, LSTD, iLSTD and LSPE. The four algorithms all use a preconditioner in the form of $A'_{t+1} B_{t+1}$, which is assumed to be used by general PTD algorithms.

The update direction of PTD is provided by a *preconditioned residual* (p-residual) vector

$$\delta_t = B_{t+1}^{-1} e_{t+1}(w_t), \tag{15}$$

where e_{t+1} is the residual vector defined in (13). This p-residual is an "old" one, because it is obtained before the weight update. After the weight update, the p-residual vector changes to

$$\theta_{t+1} = B_{t+1}^{-1} e_{t+1}(w_{t+1}).$$

From (14) and (15), θ_{t+1} can be rewritten as

$$\begin{aligned} \theta_{t+1} &= B_{t+1}^{-1}(A_{t+1}(w_t - \alpha_t \delta_t) + b_{t+1}) \\ &= \delta_t - \alpha_t B_{t+1}^{-1} A_{t+1} \delta_t. \end{aligned}$$

Because θ_{t+1} stands for an improved difference between the two sides of the preconditioned stochastic model equation, naturally we hope that the new p-residual error is smaller than the old one: $||\theta_{t+1}||^2 < ||\delta_t||^2$. This can be guaranteed by requiring that θ_{t+1} be orthogonal to $\theta_{t+1} - \delta_t$. Accordingly, we obtain a new rule of step-size

$$\alpha_t = \frac{\delta'_t B_{t+1}^{-1} A_{t+1} \delta_t}{(B_{t+1}^{-1} A_{t+1} \delta_t)'(B_{t+1}^{-1} A_{t+1} \delta_t)}. \tag{16}$$

This step-size is the optimal value that minimizes the new p-residual error over $\alpha \in \mathcal{R}$, *i.e.*, $\alpha_t = \arg\min ||\theta_{t+1}||^2$. Obviously the step-size is positive when $B_{t+1}^{-1} A_{t+1}$ is positive definite, which is true for gradient descent algorithm, iLSTD, and LSTD.

It is interesting that in (16), if $B_{t+1} = A_{t+1}$, then the step-size is equal to 1. This indicates that LSTD's choice of step-size is optimal in the sense that the p-residual error $||(1 - \alpha_t)(w_t + A_{t+1}^{-1} b_{t+1})||^2$ is minimized. When $B_{t+1} = -I$, the residual error $||(I + \alpha_t A_{t+1}) e_{t+1}(w_t)||^2$ is minimized; for ease of later comparisons with previous step-size of iLSTD, this variant will be called the Minimal Residual (MR) algorithm.

To compute p-residual vector and step-size, PTD algorithms have to carry out matrix inversion, which requires $O(K^3)$. Sherman-Morison formula is a solution to reduce this complexity to $O(K^2)$. Another efficient solution is to apply preconditioning incrementally and take advantage of the sparse nature of RL tasks.

4. Incremental PTD

The key of incremental preconditioning is to approximate the p-residual and the adaptive step-size in an iterative way.

4.1. Iterative P-residual and Approximated Step-size

Let κ_t be the error caused by the residual and the current iterative p-residual, defined by

$$\kappa_t = e_{t+1}(w_t) - B_{t+1} \hat{\delta}_t. \tag{17}$$

The new estimation of δ_t can be improved by

$$\hat{\delta}_{t+1} = \hat{\delta}_t - \beta_t \kappa_t, \tag{18}$$

where β_t is computed by

$$\beta_t = -\frac{\kappa'_t (B_{t+1} \kappa_t)}{(B_{t+1} \kappa_t)'(B_{t+1} \kappa_t)}. \tag{19}$$

Substituting the p-residual δ_t in (14) with the iterative p-residual $\hat{\delta}_t$, we get the general form of incremental PTD algorithms

$$w_{t+1} = w_t - \hat{\alpha}_t \hat{\delta}_t, \tag{20}$$

Algorithm 1 Efficient matrix-vector multiplication using CSR.

Input: $Z_Q^{t+1}(a, c, d)$ and a vector β_t
Output: A vector $o_t = Q_{t+1}\beta_t$
for $k = 1$ **to** K **do**
  $k_1 = d_{t+1}(k)$
  $k_2 = d_{t+1}(k+1) - 1$
  $o_t(k) = a_{t+1}(k_1 : k_2)'\beta_t(c_{t+1}(k_1 : k_2))$
end for

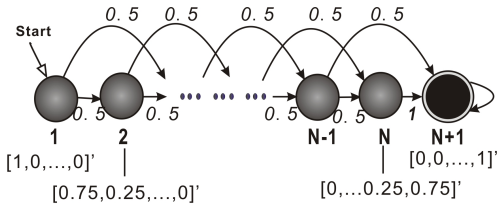

Figure 1. Boyan chain example with $N + 1$ states. The transition probabilities are marked on the arch.

where $\hat{\alpha}_t$ is computed by the following steps.

Given the iterative p-residual $\hat{\delta}_t$, steps (21a)–(21d) compute a vector v, which is an approximation of $B_{t+1}^{-1}A_{t+1}\delta_t$; then the approximated step-size is computed by (21e):

$$\xi_t = A_{t+1}\hat{\delta}_t, \tag{21a}$$

$$\chi_t = \xi_t - B_{t+1}v_t, \tag{21b}$$

$$\eta_t = -\frac{\chi_t'(B_{t+1}\chi_t)}{(B_{t+1}\chi_t)'(B_{t+1}\chi_t)}, \tag{21c}$$

$$v_{t+1} = v_t - \eta_t\chi_t, \tag{21d}$$

$$\hat{\alpha}_t = \frac{\hat{\delta}_t'v_{t+1}}{v_{t+1}'v_{t+1}}. \tag{21e}$$

If $B_{t+1} = -I$, iterative p-residual reproduces p-residual exactly and we get MR(λ); If $B_{t+1} = -D_{t+1}$, we get an incremental form of LSPE(λ) (iLSPE(λ)) that applies preconditioning via iterative p-residual.

4.2. Incremental PTD Using CSR

If the function approximation used is sparse, then matrix Φ is sparse. While this seems a restrictive condition, several popular linear function approximation schemes such as lookup table, Boyan's linear interpolation approximation and tile coding (Sutton & Barto, 1998), are indeed sparse. If the transition matrix is also sparse, matrices A_{t+1} and B_{t+1} will both have many zero entries, implying that "no experience is available for the states related to these entries". Therefore, it is better to remove the void experience and store only the valid experience by a *condensed* structure. Here the Compressed Sparse Row (CSR) format (Saad, 2003) is used. Let Q_t stand for A_t or B_t. The CSR format is a triplet $Z_Q^t(a_t, c_t, d_t)$, where a_t is a real array containing all the real values of the nonzero elements of Q_t; c_t is an integer array containing the column indices of the elements stored in a_t; and d_t is an integer array containing the pointers to the beginning of each row in a_t and c_t.

When Q_{t+1} is sparse, the need for fast matrix-vector multiplication offers a place where CSR fits in. The details are shown by Algorithm 1, whose complexity is $O(l_{t+1})$, where l_{t+1} is the number of nonzero entries in Q_{t+1}. Now (17), (19), (21a), (21b) and (21c) can make a call to Algorithm 1, and the complexity of incremental PTD is given by the following theorem which is proved in (Yao & Liu, 2008).

Theorem 4.2.1 (Complexity of incremental PTD)**.** *The per-time-step complexity of incremental PTD using CSR is $O(qK)$, where q is a small positive real related to the sparsity of matrix A.*

5. Boyan Chain Example

Boyan chain and the features are shown in Figure 1. Transition from N to $N + 1$ incurs a reward -2; transition from $N + 1$ incurs 0; the other transitions incur -3. The discount factor γ is set to 1.

The first experiment is another implementation of experience replay. As RM procedure is able to extract compressed experience information by estimations of A and b, it is natural to ask whether experience can be well replayed by repeatedly presenting RM's estimations to PTD algorithms. Two questions arise for this approach. Will it lead to convergence? What is the role of λ for PTD(λ)?

RM(λ) were first run and averaged over 10 sets of 10000 trajectories, and then their estimated structures were repeatedly presented to Gradient descent(GRAD(λ)), iLSTD(λ), LSPE(λ) and LSTD(λ). All compared algorithms used the adaptive step-size derived in Section 3, and converged to satisfactory solutions for a variety of problem sizes with all $\lambda \in [0, 1]$. The case of $N = 12$ is shown in Figure 2. It is very interesting that for all PTD algorithms smaller λ gives better performance; $\lambda = 0$ performs best and $\lambda = 1$ performs worst, —exactly the same role with that for TD(λ) under repeated presentation training paradigm (Sutton, 1988). Explanation can be given if we view TD as a model exploration process: although TD does not use the model A and b explicitly, its learn-

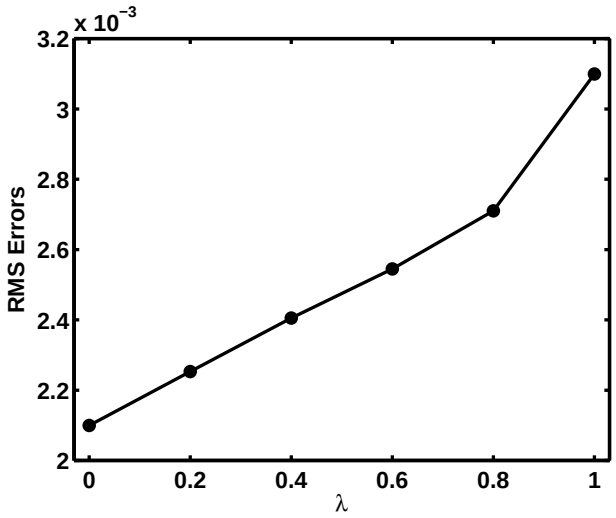

Figure 2. Effects of λ: the (same) RMS errors by GRAD(λ), MR(λ), LSPE(λ) and LSTD(λ).

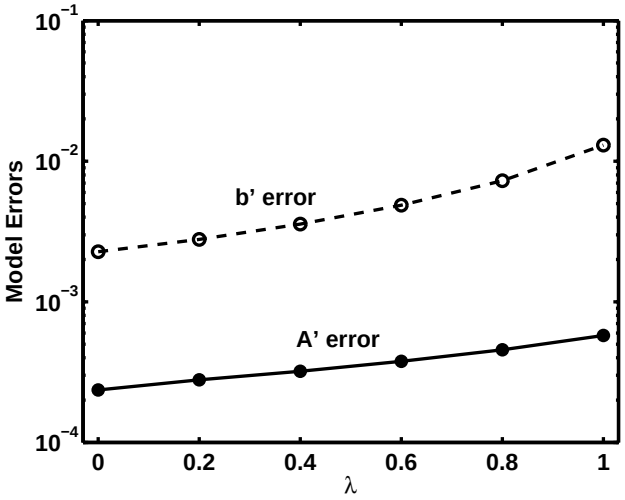

Figure 3. Model errors by RM(λ) procedures.

ing requires exploring and sampling temporal values of the model. It appears that both TD and PTD algorithms rely on the model data reflected by the sets of trajectories.

To explore λ's effect for algorithms, we only have to study its role for the model data, which is extracted by RM procedure. Results are shown in Figure 3, where the model errors are measured by $||A_T - A||_2$ and $||b_T - b||_2$, averaged over 10 sets of 10000 trajectories. It can be observed that smaller λ has smaller modeling errors for A and b, —the role of λ for RM(λ) is just what should be consistent with that for TD(λ) and PTD(λ).

Although all PTD algorithms converge to the same solution, their rates of convergence are quite different. The case of $\lambda = 1$ is shown in Figure 4. MR, LSPE and LSTD are faster than Gradient descent because they make use of preconditioning and their spectral radii are smaller than that of Gradient descent. Figure 5 compares the spectral radii $\rho(I - \alpha_t C_t^{-1} A_t' A_t)$ of different algorithms.

Algorithms were also compared under the same learning paradigm as Boyan (Boyan, 1999), where weights were updated immediately after RM estimations at each time step. All compared algorithms used the adaptive rule except that iLSPE used the approximate step-size developed in Section 4.1. For both adaptive step-size and approximated step-size, a satisfactory convergence was obtained. Results are shown in Figure 6 and Figure 7, where each point was the averaged RMS error over 10 sets of data. It is clear that some intermediate value of λ performs best in both learning error and convergence rate for all algorithms. Generally, four preconditioned algorithms learns faster than Gradient descent algorithm. However, the convergence rate advantages of MR(λ), iLSPE(λ), LSPE(λ) and LSTD(λ) over Gradient descent are becoming smaller as λ increases. The reason may be that larger λ causes larger model error and deteriorates the effects of preconditioning.

Experiment was also run to compare the adaptive step-size with the rule used by (Geramifard et al., 2006a), which takes $\alpha_t = \frac{c_0(c_1+1)}{traj\#+c_1}$, where c_0 was chosen from $\{0.01, 0.1, 1\}$, and c_1 was chosen from $\{100, 1000, 10^6\}$. The best performance of all the nine combinations of the two constants was experimentally chosen for iLSTD. Figure 8 shows that RMS error of MR (adaptive step-size) is faster to decrease than that of iLSTD. From Figure 8, we can also observe that PTD's predictions (such as those given by LSTD and LSPE) have larger variations than incremental PTD's (such as those given by MR and iLSPE). The reason is that PTD algorithms are based on the inversion of preconditioner, which is not well conditioned at the beginning stage of learning; while incremental PTD algorithms avoid numerical instability via iterative p-residual.

Table 1 compares the complexity of PTD and incremental PTD algorithms, where CSR are used for MR (one CSR for A_t) and iLSPE (one CSR for A_t and one CSR for D_t). We can see that incremental PTD algorithms have a clear computational advantage over

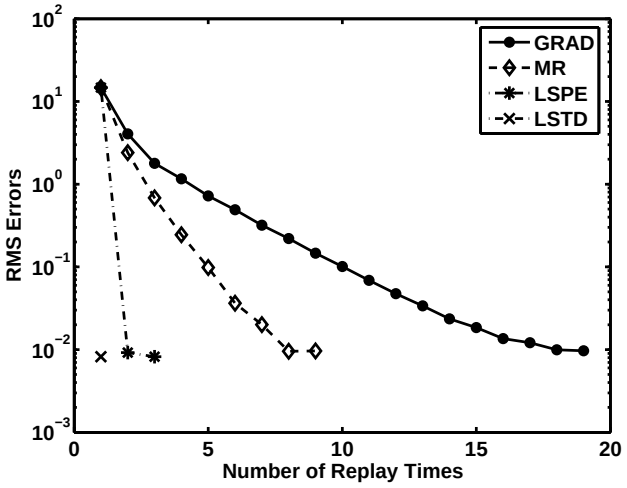

Figure 4. The role of preconditioner ($\lambda = 1$). Algorithms are stopped if RMS error is smaller than 0.01.

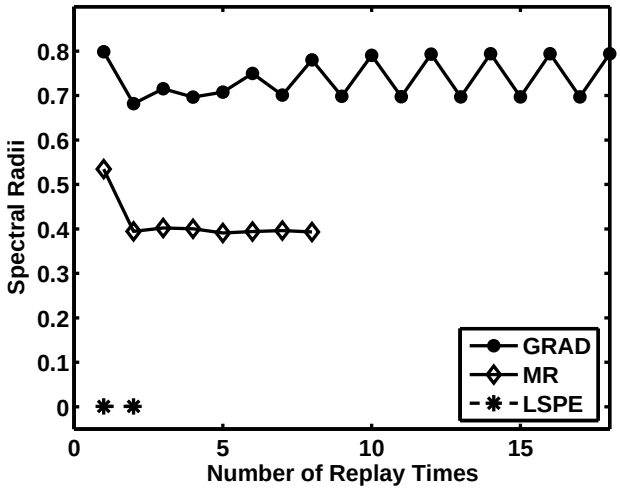

Figure 5. Spectral radius comparisons ($\lambda = 1$). LSTD's spectral radius is 0 permanently, thus not shown.

Table 1. Comparison of per-time-step running time (ms) of PTD and incremental PTD algorithms on $K = 401$ ($\lambda = 0$). The machine used is Pentium(R) 4 PC (CPU 3.00GHZ; RAM 1.00GB).

LSTD	LSPE	iLSTD	MR	iLSPE
72.3	120.3	5.9	10.6	21.9

Table 2. Comparison of memory requirements for A using CSR and full matrix for a variety of problem sizes ($\lambda = 0$).

N	12	100	400	800	1200	1600
$\frac{l}{K^2}$	0.75	0.1479	0.04	0.0198	0.0132	0.01

PTD algorithms. Reason lies in that CSR enables incremental PTD to manipulate much smaller size of data than PTD. Table 2 shows the relative memory requirements of CSR and full matrix for a variety of problem sizes by the ratio l/K^2, where l is the nonzero entries of A. We can observe that the larger the size of state space is, the more advantages will be gained by using CSR.

6. Conclusion

In this paper we proposed two general frameworks, PTD and incremental PTD, which are more data efficient than TD. Generally PTD approaches such as LSTD and LSPE are computationally expensive, whereas incremental PTD algorithms such as MR and iLSPE can take advantage of sparse nature of RL tasks, and have complexity near to that of iLSTD and TD. We also develop an adaptive process for computing the step-size online for PTD algorithms, and an approximated process for computing the step-size for incremental PTD algorithms.

Abstract

We extend the well-known BFGS quasi-Newton method and its limited-memory variant LBFGS to the optimization of nonsmooth convex objectives. This is done in a rigorous fashion by generalizing three components of BFGS to subdifferentials: The local quadratic model, the identification of a descent direction, and the Wolfe line search conditions. We apply the resulting subLBFGS algorithm to L_2-regularized risk minimization with binary hinge loss, and its direction-finding component to L_1-regularized risk minimization with logistic loss. In both settings our generic algorithms perform comparable to or better than their counterparts in specialized state-of-the-art solvers.

1. Introduction

The (L)BFGS quasi-Newton method (Nocedal and Wright, 1999) is widely regarded as the workhorse of smooth nonlinear optimization due to its combination of computational efficiency with good asymptotic convergence. Given a smooth objective function $J : \mathbb{R}^d \to \mathbb{R}$ and a current iterate $\boldsymbol{w}_t \in \mathbb{R}^d$, BFGS forms a local quadratic model of J:

$$Q_t(\boldsymbol{p}) \;:=\; J(\boldsymbol{w}_t) + \tfrac{1}{2}\,\boldsymbol{p}^\top \boldsymbol{B}_t^{-1}\boldsymbol{p} + \nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}, \quad (1)$$

where $\boldsymbol{B}_t \succ 0$ is a positive-definite estimate of the inverse Hessian of J. Minimizing $Q_t(\boldsymbol{p})$ gives the quasi-Newton direction

$$\boldsymbol{p}_t := -\boldsymbol{B}_t \nabla J(\boldsymbol{w}_t), \quad (2)$$

which is used for the parameter update:

$$\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + \eta_t \boldsymbol{p}_t. \quad (3)$$

The step size $\eta_t \in \mathbb{R}_+$ is normally determined by a line search obeying the Wolfe conditions:

$$\begin{aligned} J(\boldsymbol{w}_{t+1}) \;&\leq\; J(\boldsymbol{w}_t) + c_1 \eta_t \nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}_t \\ \text{and} \quad \nabla J(\boldsymbol{w}_{t+1})^\top \boldsymbol{p}_t \;&\geq\; c_2 \nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}_t, \end{aligned} \quad (4)$$

with $0 < c_1 < c_2 < 1$. The matrix $\boldsymbol{B}_t$ is then modified via the incremental rank-two update

$$\boldsymbol{B}_{t+1} = (\boldsymbol{I} - \varrho_t \boldsymbol{s}_t \boldsymbol{y}_t^\top)\boldsymbol{B}_t(\boldsymbol{I} - \varrho_t \boldsymbol{y}_t \boldsymbol{s}_t^\top) + \varrho_t \boldsymbol{s}_t \boldsymbol{s}_t^\top, \quad (5)$$

where $\boldsymbol{s}_t := \boldsymbol{w}_{t+1} - \boldsymbol{w}_t$ and $\boldsymbol{y}_t := \nabla J(\boldsymbol{w}_{t+1}) - \nabla J(\boldsymbol{w}_t)$ denote the most recent step along the optimization trajectory in parameter and gradient space, respectively, and $\varrho_t := (\boldsymbol{y}_t^\top \boldsymbol{s}_t)^{-1}$. Given a descent direction $\boldsymbol{p}_t$, the Wolfe conditions ensure that $(\forall t)\ \boldsymbol{s}_t^\top \boldsymbol{y}_t > 0$ and hence $\boldsymbol{B}_0 \succ 0 \implies (\forall t)\ \boldsymbol{B}_t \succ 0$.

Limited-memory BFGS (LBFGS) is a variant of BFGS designed for solving large-scale optimization problems where the $O(d^2)$ cost of storing and updating $\boldsymbol{B}_t$ would be prohibitively expensive. LBFGS approximates the quasi-Newton direction directly from the last m pairs of $\boldsymbol{s}_t$ and $\boldsymbol{y}_t$ via a matrix-free approach. This reduces the cost to $O(md)$ space and time per iteration, with m freely chosen (Nocedal and Wright, 1999).

Smoothness of the objective function is essential for standard (L)BFGS because both the local quadratic model (1) and the Wolfe conditions (4) require the existence of the gradient ∇J at every point. Even though nonsmooth convex functions are differentiable everywhere except on a set of Lebesgue measure zero (Hiriart-Urruty and Lemaréchal, 1993), in practice (L)BFGS often fails to converge on such problems (Lukšan and Vlček, 1999; Haarala, 2004). Various subgradient-based approaches, such as subgradient descent (Nedich and Bertsekas, 2000) or bundle methods (Teo et al., 2007), are therefore preferred.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

Although a convex function might not be differentiable everywhere, a subgradient always exists. Let $\boldsymbol{w}$ be a point where a convex function J is finite. Then a subgradient is the normal vector of any tangential supporting hyperplane of J at $\boldsymbol{w}$. Formally, $\boldsymbol{g}$ is called a subgradient of J at $\boldsymbol{w}$ if and only if

$$J(\boldsymbol{w}') \;\geq\; J(\boldsymbol{w}) + (\boldsymbol{w}' - \boldsymbol{w})^\top \boldsymbol{g} \quad \forall \boldsymbol{w}'. \tag{6}$$

The set of all subgradients at a point is called the subdifferential, and is denoted by $\partial J(\boldsymbol{w})$. If this set is not empty then J is said to be *subdifferentiable at* $\boldsymbol{w}$. If it contains exactly one element, *i.e.,* $\partial J(\boldsymbol{w}) = \{\nabla J(\boldsymbol{w})\}$, then J is *differentiable* at $\boldsymbol{w}$.

In this paper we systematically modify the standard (L)BFGS algorithm so as to make it amenable to subgradients. This results in sub(L)BFGS, a new subgradient quasi-Newton method which is applicable to a wide variety of nonsmooth convex optimization problems encountered in machine learning.

In the next section we describe our new algorithm generically, before we discuss its application to L_2-regularized risk minimization with hinge loss in Section 3. Section 4 compares and contrasts our work with other recent efforts in this area. Encouraging experimental results are reported in Section 5. We conclude with an outlook and discussion in Section 6.

2. Subgradient BFGS Method

We modify the standard BFGS algorithm to derive our new algorithm (subBFGS, Algorithm 1) for nonsmooth convex optimization. These modifications can be grouped into three areas, which we elaborate on in turn: generalizing the local quadratic model, finding a descent direction, and finding a step size that obeys a subgradient reformulation of the Wolfe conditions.

2.1. Generalizing the Local Quadratic Model

Recall that BFGS assumes the objective function J is differentiable everywhere, so that at the current iterate $\boldsymbol{w}_t$ we can construct a local quadratic model (1) of $J(\boldsymbol{w}_t)$. For a nonsmooth objective function, such a model becomes ambiguous at non-differentiable points (Figure 1). To resolve the ambiguity, we could simply replace the gradient $\nabla J(\boldsymbol{w}_t)$ in (1) with some subgradient $\boldsymbol{g}_t \in \partial J(\boldsymbol{w}_t)$. However, as will be discussed later, the resulting quasi-Newton direction $\boldsymbol{p}_t := -\boldsymbol{B}_t \boldsymbol{g}_t$ is not necessarily a descent direction. To address this fundamental modeling problem, we first generalize the

Algorithm 1 SUBGRADIENT BFGS (SUBBFGS)

Initialize: $t := 0, \boldsymbol{w}_0 = \boldsymbol{0}, \boldsymbol{B}_0 = \boldsymbol{I}$;
Set direction-finding stopping tolerances $\epsilon, k_{\max} \in \mathbb{R}_+$;
Compute subgradient $\boldsymbol{g}_0 \in \partial J(\boldsymbol{w}_0)$;
while not converged **do**
  $\boldsymbol{p}_t = \texttt{descentDirection}(\boldsymbol{g}_t, \epsilon, k_{\max})$; (Algorithm 2)
  if $\boldsymbol{p}_t =$ failure **then**
    Return $\boldsymbol{w}_t$;
  end if
  Find η_t that obeys (14); (*e.g.*, Algorithm 3)
  $\boldsymbol{s}_t = \eta_t \boldsymbol{p}_t$;
  $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + \boldsymbol{s}_t$;
  Compute subgradient $\boldsymbol{g}_{t+1} \in \partial J(\boldsymbol{w}_{t+1})$;
  $\boldsymbol{y}_t = \boldsymbol{g}_{t+1} - \boldsymbol{g}_t$;
  Update $\boldsymbol{B}_{t+1}$ via (5);
  $t := t + 1$;
end while

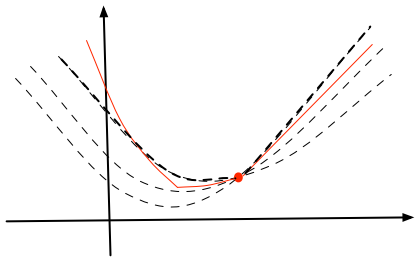

Figure 1. Quadratic models (dashed) *vs.* tightest pseudo-quadratic fit (7) (bold dashes) to the objective function (solid line) at a subdifferentiable point (solid disk).

local quadratic model as follows:

$$\begin{aligned} Q_t(\boldsymbol{p}) \;&:=\; J(\boldsymbol{w}_t) + M_t(\boldsymbol{p}), \quad \text{where} \\ M_t(\boldsymbol{p}) \;&:=\; \tfrac{1}{2}\boldsymbol{p}^\top \boldsymbol{B}_t^{-1} \boldsymbol{p} \;+\; \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}. \end{aligned} \tag{7}$$

Note that where J is differentiable, (7) reduces to the familiar BFGS quadratic model (1). At non-differentiable points, however, the model is no longer quadratic, as the supremum may be attained at different elements of $\partial J(\boldsymbol{w}_t)$ for different directions $\boldsymbol{p}$. Instead it can be viewed as the tightest pseudo-quadratic fit to J at $\boldsymbol{w}_t$ (Figure 1).

Ideally, we would like to minimize $Q_t(\boldsymbol{p})$, or equivalently $M_t(\boldsymbol{p})$, in (7) to obtain the best search direction,

$$\boldsymbol{p}^* := \operatorname*{arginf}_{\boldsymbol{p} \in \mathbb{R}^d} M_t(\boldsymbol{p}). \tag{8}$$

This is generally intractable due to the presence of a supremum over the entire subdifferential set $\partial J(\boldsymbol{w}_t)$. In many machine learning problems, however, the set $\partial J(\boldsymbol{w}_t)$ has some special structure that simplifies calculation of the supremum in (7). In what follows, we develop an iteration that is guaranteed to find a quasi-Newton descent direction, assuming an oracle that supplies $\operatorname{argsup}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$ for a given direction

Algorithm 2 $\boldsymbol{p}_t = \texttt{descentDirection}(\boldsymbol{g}^{(1)}, \epsilon, k_{\max})$

input subgradient $\boldsymbol{g}^{(1)} \in \partial J(\boldsymbol{w}_t)$,
tolerance $\epsilon \in \mathbb{R}_+$, iteration limit $k_{\max}$;
output descent direction $\boldsymbol{p}_t$;

1: Initialize: $i := 1$, $\bar{\boldsymbol{g}}^{(1)} = \boldsymbol{g}^{(1)}$, $\boldsymbol{p}^{(1)} = -\boldsymbol{B}_t \boldsymbol{g}^{(1)}$;
2: $\boldsymbol{g}^{(2)} = \operatorname{argsup}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}^{(1)}$;
3: Calculate $\epsilon^{(1)}$ via (13);
4: **while** $(\boldsymbol{g}^{(i+1)\top} \boldsymbol{p}^{(i)} > 0$ or $\epsilon^{(i)} > \epsilon)$ and $i < k_{\max}$ **do**
5: $\quad \mu^* := \min\left[1, \frac{(\boldsymbol{g}^{(i+1)} - \bar{\boldsymbol{g}}^{(i)})^\top \boldsymbol{p}^{(i)}}{(\boldsymbol{g}^{(i+1)} - \bar{\boldsymbol{g}}^{(i)})^\top \boldsymbol{B}_t (\boldsymbol{g}^{(i+1)} - \bar{\boldsymbol{g}}^{(i)})}\right]$;
6: $\quad \bar{\boldsymbol{g}}^{(i+1)} = (1-\mu^*)\bar{\boldsymbol{g}}^{(i)} + \mu^* \boldsymbol{g}^{(i+1)}$;
7: $\quad \boldsymbol{p}^{(i+1)} = (1-\mu^*)\boldsymbol{p}^{(i)} - \mu^* \boldsymbol{B}_t \boldsymbol{g}^{(i+1)}$;
8: $\quad \boldsymbol{g}^{(i+2)} = \operatorname{argsup}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}^{(i+1)}$;
9: $\quad$ Calculate $\epsilon^{(i+1)}$ via (13);
10: $\quad i := i + 1$;
11: **end while**
12: **if** $\boldsymbol{g}^{(i+1)\top} \boldsymbol{p}^{(i)} > 0$ **then**
13: $\quad$ **return** failure;
14: **else**
15: $\quad$ **return** $\operatorname{argmin}_{j \le i} M_t(\boldsymbol{p}^{(j)})$.
16: **end if**

$\boldsymbol{p} \in \mathbb{R}^d$. In Section 3.1 we provide an efficient implementation of such an oracle for L_2-regularized risk minimization with the hinge loss.

2.2. Finding a Descent Direction

A direction $\boldsymbol{p}_t$ is a descent direction if and only if $\boldsymbol{g}^\top \boldsymbol{p}_t < 0 \; \forall \boldsymbol{g} \in \partial J(\boldsymbol{w}_t)$ (Belloni, 2005), or equivalently

$$\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t \; < \; 0. \tag{9}$$

In particular, for a smooth convex function the quasi-Newton direction (2) is always a descent direction because $\nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}_t = -\nabla J(\boldsymbol{w}_t)^\top \boldsymbol{B}_t \nabla J(\boldsymbol{w}_t) < 0$ holds due to the positivity of $\boldsymbol{B}_t$.

For nonsmooth functions, however, the quasi-Newton direction $\boldsymbol{p}_t := -\boldsymbol{B}_t \boldsymbol{g}_t$ for a given $\boldsymbol{g}_t \in \partial J(\boldsymbol{w}_t)$ may not fulfill the descent condition (9), making it impossible to find a step that obeys (4), thus causing a failure of the line search. We now present an iterative approach to finding a quasi-Newton *descent* direction.

Inspired by bundle methods (Teo et al., 2007), we build the following convex lower bound on $M_t(\boldsymbol{p})$:

$$M_t^{(i)}(\boldsymbol{p}) \; := \; \tfrac{1}{2} \boldsymbol{p}^\top \boldsymbol{B}_t^{-1} \boldsymbol{p} + \sup_{j \le i} \boldsymbol{g}^{(j)\top} \boldsymbol{p}, \tag{10}$$

where $i, j \in \mathbb{N}$. Given a $\boldsymbol{p}^{(i)} \in \mathbb{R}^d$ the lower bound (10) is successively tightened by computing

$$\boldsymbol{g}^{(i+1)} := \operatorname*{argsup}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}^{(i)}, \tag{11}$$

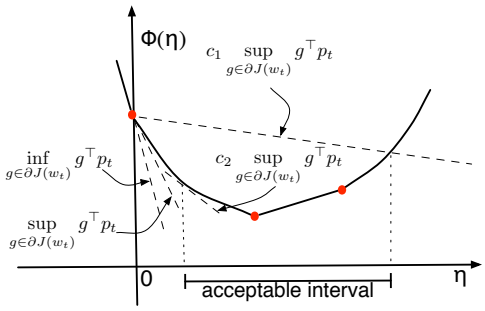

Figure 2. Geometric interpretation of the subgradient Wolfe conditions (14). Solid disks are subdifferentiable points; the slopes of dashed lines are indicated.

such that $M_t^{(i)}(\boldsymbol{p}) \le M_t^{(i+1)}(\boldsymbol{p}) \le M_t(\boldsymbol{p}) \; \forall \boldsymbol{p} \in \mathbb{R}^d$. Here we set $\boldsymbol{g}^{(1)} \in \partial J(\boldsymbol{w}_t)$, and assume that $\boldsymbol{g}^{(i+1)}$ is provided by an oracle. To solve $\inf_{\boldsymbol{p} \in \mathbb{R}^d} M_t^{(i)}(\boldsymbol{p})$, we rewrite it as a constrained optimization problem:

$$\inf_{\boldsymbol{p}, \xi} \left(\tfrac{1}{2} \boldsymbol{p}^\top \boldsymbol{B}_t^{-1} \boldsymbol{p} + \xi\right) \text{ s.t. } \boldsymbol{g}^{(j)\top} \boldsymbol{p} \le \xi \;\; \forall j \le i. \tag{12}$$

This problem can be solved exactly via quadratic programming, but doing so may incur substantial computational expense. Instead we adopt an alternative approach (Algorithm 2) which does not solve $\inf_{\boldsymbol{p} \in \mathbb{R}^d} M_t^{(i)}(\boldsymbol{p})$ to optimality. The key idea is to write the proposed descent direction at iteration $i+1$ as a convex combination of $\boldsymbol{p}^{(i)}$ and $-\boldsymbol{B}_t \boldsymbol{g}^{(i+1)}$. The optimal combination coefficient μ^* can be computed exactly (Step 5 of Algorithm 2) using an argument based on maximizing dual progress. Finally, to derive an implementable stopping criterion, we define $\epsilon^{(i)}$ to be

$$\min_{j \le i} \left[\boldsymbol{p}^{(j)\top} \boldsymbol{g}^{(j+1)} - \tfrac{1}{2}(\boldsymbol{p}^{(j)\top} \bar{\boldsymbol{g}}^{(j)} + \boldsymbol{p}^{(i)\top} \bar{\boldsymbol{g}}^{(i)})\right], \tag{13}$$

where $\bar{\boldsymbol{g}}^{(i)}$ is an aggregated subgradient (Step 6 of Algorithm 2) which lies in the convex hull of $\boldsymbol{g}^{(j)} \in \partial J(\boldsymbol{w}_t) \; \forall j \le i$. $\epsilon^{(i)}$ is monotonically decreasing, and upper bounds the distance from the optimal value of the dual of $M_t(\boldsymbol{p})$, leading us to a practical stopping criterion (Step 4 of Algorithm 2) for our direction-finding procedure. Yu et al. (2008) provide details, and prove that Algorithm 2 converges to the optimal dual objective value with precision ϵ at an $O(1/\epsilon)$ rate.

2.3. Subgradient Line Search

Given the current iterate $\boldsymbol{w}_t$ and a search direction $\boldsymbol{p}_t$, the task of a line search is to find a step size $\eta \in \mathbb{R}_+$ which decreases the objective function along the line $\boldsymbol{w}_t + \eta \boldsymbol{p}_t$, *i.e.*, $J(\boldsymbol{w}_t + \eta \boldsymbol{p}_t) =: \Phi(\eta)$. The Wolfe conditions (4) are used in line search routines to enforce a sufficient decrease in the objective value, and

to exclude unnecessarily small step sizes (Nocedal and Wright, 1999). However, the original Wolfe conditions require the objective function to be smooth. To extend them to nonsmooth convex problems, we propose the following subgradient reformulation:

$$J(\boldsymbol{w}_{t+1}) \;\leq\; J(\boldsymbol{w}_t) \;+\; c_1\eta_t \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t$$
$$\text{and} \sup_{\boldsymbol{g}'\in\partial J(\boldsymbol{w}_{t+1})} \boldsymbol{g}'^\top \boldsymbol{p}_t \;\geq\; c_2 \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t, \qquad (14)$$

where $0 < c_1 < c_2 < 1$. Figure 2 illustrates how these conditions enforce acceptance of non-trivial step sizes that decrease the objective value. Yu et al. (2008) formally show that for any given descent direction we can always find a positive step size that satisfies (14).

2.4. Limited-Memory Subgradient BFGS

It is straightforward to implement an LBFGS variant of our subBFGS algorithm: We simply modify Algorithms 1 and 2 to compute all products of $\boldsymbol{B}_t$ with a vector by means of the standard LBFGS matrix-free scheme (Nocedal and Wright, 1999).

3. sub(L)BFGS Implementation for L_2-Regularized Risk Minimization

Many machine learning algorithms can be viewed as minimizing the L_2-regularized risk

$$J(\boldsymbol{w}) \;:=\; \frac{c}{2}\|\boldsymbol{w}\|^2 \;+\; \frac{1}{n}\sum_{i=1}^{n} l(\boldsymbol{w}^\top \boldsymbol{x}_i, z_i), \qquad (15)$$

where $\boldsymbol{x}_i \in \mathcal{X} \subseteq \mathbb{R}^d$ are the training instances, $z_i \in \mathcal{Z} \subseteq \mathbb{R}$ the corresponding labels, and the loss l is a non-negative convex function of $\boldsymbol{w}$ which measures the discrepancy between z_i and the predictions arising from $\boldsymbol{w}$ via $\boldsymbol{w}^\top \boldsymbol{x}_i$. A loss function commonly used for binary classification is the hinge loss

$$l(\boldsymbol{w}^\top \boldsymbol{x}, z) \;:=\; \max(0, 1 - z\,\boldsymbol{w}^\top \boldsymbol{x}), \qquad (16)$$

where $z \in \{\pm 1\}$. L_2-regularized risk minimization with binary hinge loss is a convex but nonsmooth optimization problem; in this section we show how sub(L)BFGS (Algorithm 1) can be applied to it.

Differentiating (15) after plugging in (16) yields

$$\partial J(\boldsymbol{w}) = c\,\boldsymbol{w} - \frac{1}{n}\sum_{i=1}^{n} \beta_i z_i \boldsymbol{x}_i = \bar{\boldsymbol{w}} - \frac{1}{n}\sum_{i\in\mathcal{M}} \beta_i z_i \boldsymbol{x}_i, \qquad (17)$$

where $\bar{\boldsymbol{w}} := c\,\boldsymbol{w} - \frac{1}{n}\sum_{i\in\mathcal{E}} z_i \boldsymbol{x}_i$ and

$$\beta_i := \begin{cases} 1 & \text{if } i \in \mathcal{E}, \quad \mathcal{E} := \{i : 1 - z_i \boldsymbol{w}^\top \boldsymbol{x}_i > 0\}, \\ [0,1] & \text{if } i \in \mathcal{M}, \quad \mathcal{M} := \{i : 1 - z_i \boldsymbol{w}^\top \boldsymbol{x}_i = 0\}, \\ 0 & \text{if } i \in \mathcal{W}, \quad \mathcal{W} := \{i : 1 - z_i \boldsymbol{w}^\top \boldsymbol{x}_i < 0\}. \end{cases}$$

$\mathcal{E}$, $\mathcal{M}$, and $\mathcal{W}$ index the set of points which are in error, on the margin, and well-classified, respectively.

3.1. Realizing the Direction-Finding Method

Recall that our sub(L)BFGS algorithm requires an oracle that provides $\operatorname{argsup}_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$ for a given direction $\boldsymbol{p}$. For L_2-regularized risk minimization with binary hinge loss we can implement such an oracle at computational cost linear in the number $|\,\mathcal{M}_t\,|$ of current marginal points. (Normally $|\,\mathcal{M}_t\,| \ll n$.) Towards this end we use (17) to obtain

$$\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p} \;=\; \sup_{\beta_i, i\in\mathcal{M}_t} \left(\bar{\boldsymbol{w}}_t - \frac{1}{n}\sum_{i\in\mathcal{M}_t} \beta_i z_i \boldsymbol{x}_i\right)^\top \boldsymbol{p}$$
$$= \;\bar{\boldsymbol{w}}_t^\top \boldsymbol{p} - \frac{1}{n}\sum_{i\in\mathcal{M}_t} \inf_{\beta_i\in[0,1]} \beta_i z_i \boldsymbol{x}_i^\top \boldsymbol{p}. \qquad (18)$$

Since for a given $\boldsymbol{p}$ the first term of the right-hand side of (18) is a constant, the supremum is attained when we set $\beta_i\ \forall i \in \mathcal{M}_t$ via the following strategy:

$$\beta_i := \begin{cases} 0 & \text{if } z_i \boldsymbol{x}_i^\top \boldsymbol{p}_t \geq 0, \\ 1 & \text{if } z_i \boldsymbol{x}_i^\top \boldsymbol{p}_t < 0. \end{cases} \qquad (19)$$

3.2. Implementing the Line Search

The one-dimensional convex function Φ obtained by restricting (15) to a line can be evaluated efficiently. To see this, rewrite the objective as

$$J(\boldsymbol{w}) \;:=\; \frac{c}{2}\|\boldsymbol{w}\|^2 + \frac{1}{n}\mathbf{1}^\top \max(\mathbf{0}, \mathbf{1} - \boldsymbol{z}\cdot\boldsymbol{X}\boldsymbol{w}), \qquad (20)$$

where $\mathbf{0}$ and $\mathbf{1}$ are column vectors of zeros and ones, respectively, $\cdot$ denotes the Hadamard (componentwise) product, and $\boldsymbol{z} \in \mathbb{R}^n$ collects correct labels corresponding to each row of data in $\boldsymbol{X} := [\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_n]^\top \in \mathbb{R}^{n\times d}$. Given a search direction $\boldsymbol{p}_t$ at an iterate $\boldsymbol{w}_t$, this allows us to write

$$\Phi(\eta) := J(\boldsymbol{w}_t + \eta\boldsymbol{p}_t) = \frac{1}{n}\boldsymbol{\delta}(\eta)^\top[\mathbf{1} - (\boldsymbol{f} + \eta\Delta\boldsymbol{f})] \qquad (21)$$
$$+ \frac{c}{2}\|\boldsymbol{w}_t\|^2 + c\eta\boldsymbol{w}_t^\top \boldsymbol{p}_t + \frac{c\eta^2}{2}\|\boldsymbol{p}_t\|^2$$

where $\boldsymbol{f} := \boldsymbol{z}\cdot\boldsymbol{X}\boldsymbol{w}_t$, $\Delta\boldsymbol{f} := \boldsymbol{z}\cdot\boldsymbol{X}\boldsymbol{p}_t$, and

$$\delta_i(\eta) := \begin{cases} 1 & \text{if } f_i + \eta\,\Delta f_i < 1, \\ [0,1] & \text{if } f_i + \eta\,\Delta f_i = 1, \\ 0 & \text{if } f_i + \eta\,\Delta f_i > 1 \end{cases} \qquad (22)$$

for $1 \leq i \leq n$. We cache $\boldsymbol{f}$ and $\Delta\boldsymbol{f}$, expending $O(nd)$ computational effort. We also cache $\frac{c}{2}\|\boldsymbol{w}_t\|^2$, $c\boldsymbol{w}_t^\top \boldsymbol{p}_t$, and $\frac{c}{2}\|\boldsymbol{p}_t\|^2$, each of which requires $O(n)$ work. The

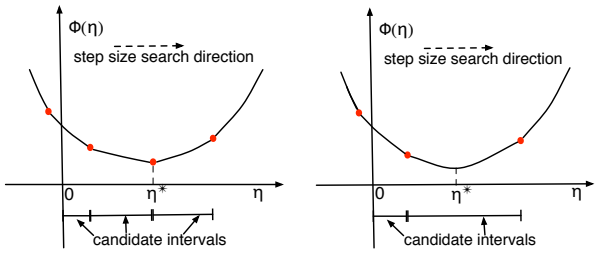

Figure 3. Nonsmooth convex function Φ of step size η. Solid disks are subdifferentiable points; the optimal η^* falls on such a point (left), or between two such points (right).

evaluation of $\boldsymbol{\delta}(\eta)$ and its inner product with $\mathbf{1} - (\boldsymbol{f} + \eta\,\Delta\boldsymbol{f})$ both take $O(n)$ effort. All other terms in (21) can be computed in constant time, thus reducing the amortized cost of evaluating $\Phi(\eta)$ to $O(n)$. We are now in a position to introduce an exact line search which takes advantage of this scheme.

3.2.1. Exact Line Search

Differentiating (21) with respect to η and setting the gradient to zero shows that $\eta^* := \operatorname{argmin}_\eta \Phi(\eta)$ satisfies $\eta^* = (\boldsymbol{\delta}(\eta^*)^\top \Delta\boldsymbol{f}/n - c\,\boldsymbol{w}_t^\top \boldsymbol{p}_t)/(c\,\|\boldsymbol{p}_t\|^2)$. It is easy to verify that $\Phi(\eta)$ is piecewise quadratic, and differentiable everywhere except at $\eta_i := (1-f_i)/\Delta f_i$, where it becomes subdifferentiable. At these points an element of the indicator function $\boldsymbol{\delta}(\eta)$ (22) changes from 0 to 1 or vice versa; otherwise $\boldsymbol{\delta}(\eta)$ remains constant. Thus for a smooth interval (η_a, η_b) between subdifferentiable points η_a and η_b (*cf.* Figure 3), if the candidate step

$$\eta^*_{a,b} = \frac{\boldsymbol{\delta}(\eta')^\top \Delta\boldsymbol{f}/n - c\,\boldsymbol{w}_t^\top \boldsymbol{p}_t}{c\,\|\boldsymbol{p}_t\|^2}, \quad \eta' \in (\eta_a, \eta_b) \qquad (23)$$

lies in the interval, it is optimal: $\eta^*_{a,b} \in [\eta_a, \eta_b] \Rightarrow \eta^* = \eta^*_{a,b}$. Otherwise, the interval boundary is optimal if its subdifferential contains zero: $0 \in \partial\,\Phi(\eta_a) \Rightarrow \eta^* = \eta_a$. Sorting the subdifferentiable points η_i facilitates efficient search over intervals; see Algorithm 3 for details.

Algorithm 3 $\eta = \texttt{linesearch}(\boldsymbol{w}_t, \boldsymbol{p}_t, c, \boldsymbol{f}, \Delta\boldsymbol{f})$

input $\boldsymbol{w}_t, \boldsymbol{p}_t, c, \boldsymbol{f}$, and $\Delta\boldsymbol{f}$ as in (21);

  $\delta_i := \begin{cases} 1 & \text{if } f_i + \eta\,\Delta f_i < 1; \\ 0 & \text{otherwise;} \end{cases}$
end for
$\varrho := \boldsymbol{\delta}^\top \Delta\boldsymbol{f}/n$;
while $j \le \texttt{length}(\boldsymbol{\pi})$ **do**
  $\eta := (\varrho - b)/h$; (candidate step)
  if $\eta \in [\alpha_{\pi_{j-1}}, \alpha_{\pi_j}]$ **then**
    return η;
  else if $\eta < \alpha_{\pi_{j-1}}$ **then**
    return $\eta := \alpha_{\pi_{j-1}}$;
  else
    repeat
      $\varrho := \begin{cases} \varrho - \Delta f_{\pi_j}/n & \text{if } \delta_{\pi_j} = 1, \\ \varrho + \Delta f_{\pi_j}/n & \text{otherwise;} \end{cases}$
      $j := j + 1$;
    until $\alpha_{\pi_j} \ne \alpha_{\pi_{j-1}}$
  end if
end while

4. Related Work

Lukšan and Vlček (1999) propose an extension of BFGS to nonsmooth convex problems. Their algorithm samples gradients around non-differentiable points in order to obtain a descent direction. In many machine learning problems evaluating the objective function and its gradient is very expensive. Therefore, our direction-finding algorithm (Algorithm 2) repeatedly samples subgradients from the set $\partial J(\boldsymbol{w})$ via the oracle, which is computationally more efficient.

Recently, Andrew and Gao (2007) introduced a variant of nonsmooth BFGS, the Orthant-Wise Limited-memory Quasi-Newton (OWL-QN) algorithm, suitable for optimizing L_1-regularized log-linear models:

$$J(\boldsymbol{w}) := c\|\boldsymbol{w}\|_1 + \frac{1}{n}\sum_{i=1}^{n} \ln(1 + e^{-z_i \boldsymbol{w}^\top \boldsymbol{x}_i}), \qquad (24)$$

where the logistic loss is smooth, but the regularizer is only subdifferentiable at points where $\boldsymbol{w}$ has zero elements. From the optimization viewpoint this objective is very similar to the L_2-regularized hinge loss; the direction finding and line search methods that we discussed in Sections 3.1 and 3.2, respectively, can be applied to this problem with slight modifications.

OWL-QN is based on the observation that the L_1 regularizer is linear within any given orthant. Therefore, it maintains an approximation $\boldsymbol{B}^{\text{ow}}$ to the inverse Hessian of the logistic loss, and uses an efficient scheme to select orthants for optimization. In fact, its success greatly depends on its direction-finding subroutine, which demands a specially chosen subgradient $\boldsymbol{g}^{\text{ow}}$ (Andrew and Gao, 2007, Equation 4) to produce the quasi-Newton direction, $\boldsymbol{p}^{\text{ow}} = \pi(\boldsymbol{p}, \boldsymbol{g}^{\text{ow}})$, where $\boldsymbol{p} := -\boldsymbol{B}^{\text{ow}}\boldsymbol{g}^{\text{ow}}$ and the projection π returns a search direction by setting the i^{th} element of $\boldsymbol{p}$ to zero whenever $p_i g_i^{\text{ow}} > 0$. As shown in Section 5, the direction-

finding subroutine of OWL-QN can be replaced by Algorithm 2, which in turn makes the algorithm more robust to the choice of subgradients.

Many optimization techniques use past gradients to build a model of the objective function. Bundle method solvers like SVMStruct (Joachims, 2006) and BMRM (Teo et al., 2007) use them to lower-bound the objective by a piecewise linear function which is minimized to obtain the next iterate. This fundamentally differs from the BFGS approach of using past gradients to approximate the (inverse) Hessian, hence building a quadratic model of the objective function.

Vojtěch and Sonnenburg (2007) speed up the convergence of a bundle method solver for the L_2-regularized binary hinge loss. Their main idea is to perform a line search along the line connecting two successive iterates of a bundle method solver. Although developed independently, their line search algorithm is very reminiscent of the method we describe in Section 3.2.1.

5. Experiments

We now evaluate the performance of our subLBFGS algorithm, and compare it to other state-of-the-art nonsmooth optimization methods on L_2-regularized hinge loss minimization. We also compare a variant of OWL-QN that uses our direction-finding routine to the original on L_1-regularized logistic loss minimization.

Our experiments used four datasets: the Covertype dataset of Blackard, Jock & Dean, CCAT from the Reuters RCV1 collection, the Astro-physics dataset of abstracts of scientific papers from the Physics ArXiv (Joachims, 2006), and the MNIST dataset of handwritten digits with two classes: even and odd digits. We used subLBFGS with a buffer of size $m = 15$ throughout. Table 1 summarizes our parameter settings, and reports the overall number of direction-finding iterations for all experiments. We followed the choices of Vojtěch and Sonnenburg (2007) for the L_2 regularization constants; for L_1 they were chosen from the set $10^{\{-6,-5,\cdots,-1\}}$ to achieve the lowest test error.

On convex problems such as these every convergent optimizer will reach the same solution; comparing generalisation performance is therefore pointless. We combined training and test datasets to evaluate the convergence of each algorithm in terms of the objective function value *vs.* CPU seconds. All experiments were carried out on a Linux machine with dual 2.8 GHz Xeon processors with 4GB RAM.

5.1. L_2-Regularized Hinge Loss

For our first set of experiments, we applied subLBFGS together with our exact line search (Algorithm 3) to the task of L_2-regularized hinge loss minimization. Our control methods are the bundle method solver BMRM (Teo et al., 2007) and an optimized cutting plane algorithm, OCAS version 0.6.0 (Vojtěch and Sonnenburg, 2007), both of which demonstrated strong results on the L_2-regularized hinge loss minimization in their corresponding papers.

Figure 4 shows that subLBFGS (solid) reaches the neighbourhood of the optimum (less than 10^{-3} away) noticeably (up to 7 times) faster than BMRM (dashed). As BMRM's approximation to the objective function improves over the course of optimization, it gradually catches up with subLBFGS, though ultimately subLBFGS still converges faster on 3 out of 4 datasets. The performance of subLBFGS and OCAS (dash-dotted) are very similar: OCAS converges slightly faster than subLBFGS on the Astrophysics dataset but is outperformed by subLBFGS on the MNIST dataset.

5.2. L_1-Regularized Logistic Loss

To demonstrate the utility of our direction-finding routine (Algorithm 2) in its own right, we plugged it into the OWL-QN algorithm (Andrew and Gao, 2007) as an alternative direction-finding method, such that $\boldsymbol{p}^{\text{ow}} = \texttt{descentDirection}(\boldsymbol{g}^{\text{ow}}, \epsilon, k_{\max})$,[1] and compared this variant (denoted by OWL-QN*) with the original on L_1-regularized logistic loss minimization.

Using the stopping criterion suggested by Andrew and Gao (2007), we run experiments until the averaged rel-

[1] Note for the objective (24) it is trivial to construct an oracle that supplies $\text{argsup}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$.

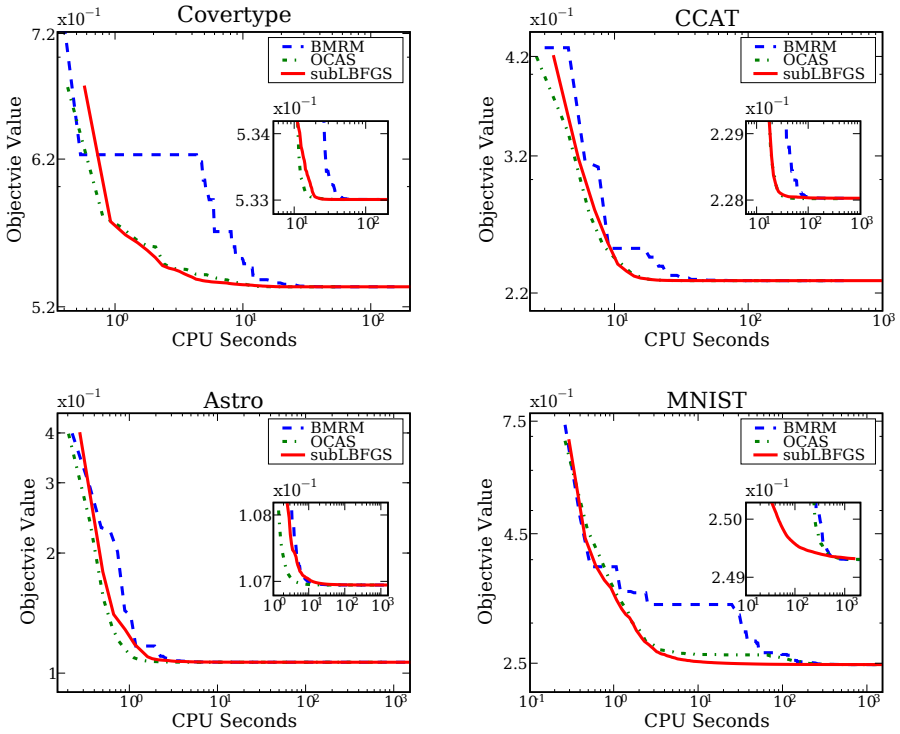

Figure 4. Objective function value *vs.* CPU seconds on L_2-regularized hinge loss minimization tasks.

ative change in the objective value over the previous 5 iterations falls below 10^{-5}. Figure 5 shows only minor differences in convergence between the two algorithms.

To examine the algorithms' sensitivity to the choice of subgradients, we also ran them with random subgradients (as opposed to the specially chosen $\boldsymbol{g}^{\text{ow}}$ used before) fed to their corresponding direction-finding routines. OWL-QN relies heavily on its particular choice of subgradients, hence breaks down completely under these conditions: The only dataset where we could even plot its (poor) performance was Covertype (dotted OWL-QN(2) line in Figure 5). Our direction-finding routine, by contrast, is self-correcting and thus not affected by this manipulation: The curves for OWL-QN*(2) (plotted for Covertype in Figure 5) lie virtually on top of those for OWL-QN*. Table 1 shows that in this case more direction-finding iterations are needed, *i.e.*, $k_{L_1\text{rand}} \geq k_{L_1}$. This empirically confirms that as long as $\operatorname{argsup}_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$ is given, Algorithm 2 can indeed be used as a canned quasi-Newton direction-finding routine.

6. Outlook and Discussion

We proposed an extension of BFGS suitable for handling nonsmooth problems often encountered in the machine learning context. As our experiments show, our algorithms are versatile and applicable to many problems, while their performance is comparable to if not better than that of their counterparts in custom-built solvers.

In some experiments we observe that subLBFGS initially makes rapid progress towards the solution but slows down closer to the optimum. We hypothesize that initially its quadratic model allows subLBFGS to make rapid progress, but closer to the optimum it is no longer an accurate model of an objective function dominated by the nonsmooth hinges. We are therefore contemplating hybrid solvers which seamlessly switch between sub(L)BFGS and bundle solvers.

In this paper we applied subLBFGS to L_2-regularized risk minimization with binary hinge loss. It can also be extended to deal with generalizations of the hinge loss, such as multi-class, multi-category, and ordinal regression problems; this is part of our ongoing research.

Finally, to put our contributions in perspective, recall that we modified three aspects of the standard BFGS algorithm, namely the quadratic model (Section 2.1), the descent direction finding (Section 2.2), and the line search (Section 2.3). Each of these modifications is versatile enough to be used as a component in other nonsmooth optimization algorithms. This not only offers the promise of improving existing algorithms, but

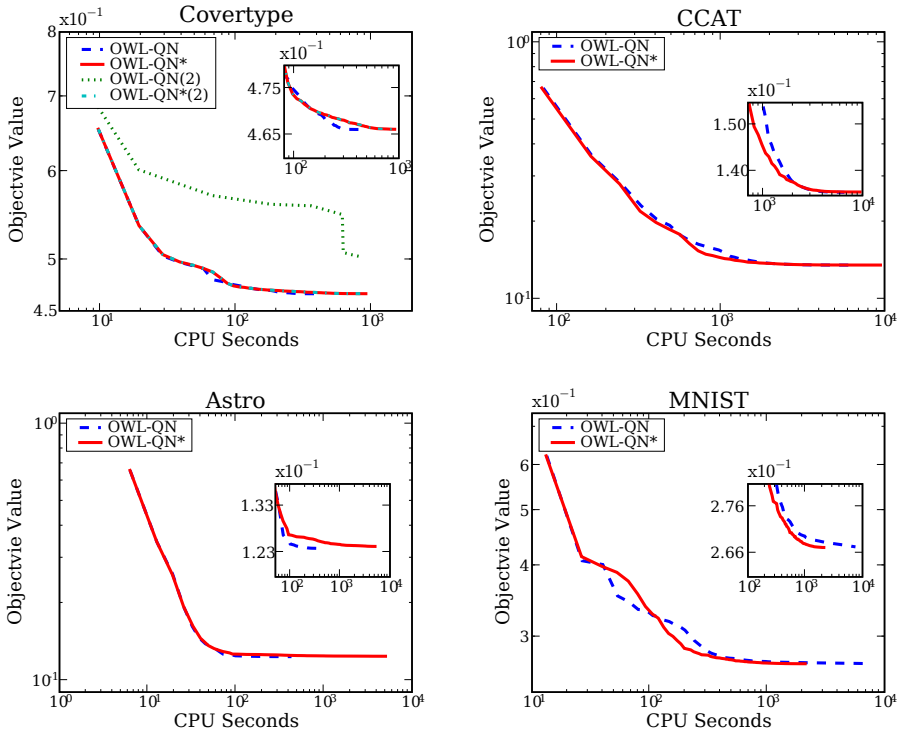

Figure 5. Objective function value *vs.* CPU seconds on L_1-regularized logistic loss minimization tasks.

may also help clarify connections between them. We hope that this will focus attention on those core subroutines that need to be made more efficient in order to handle larger and larger datasets.

Predicting Diverse Subsets Using Structural SVMs

Yisong Yue YYUE@CS.CORNELL.EDU
Thorsten Joachims TJ@CS.CORNELL.EDU
Department of Computer Science, Cornell University, Ithaca, NY 14853 USA

Abstract

In many retrieval tasks, one important goal involves retrieving a diverse set of results (e.g., documents covering a wide range of topics for a search query). First of all, this reduces redundancy, effectively showing more information with the presented results. Secondly, queries are often ambiguous at some level. For example, the query "Jaguar" can refer to many different topics (such as the car or feline). A set of documents with high topic diversity ensures that fewer users abandon the query because no results are relevant to them. Unlike existing approaches to learning retrieval functions, we present a method that explicitly trains to diversify results. In particular, we formulate the learning problem of predicting diverse subsets and derive a training method based on structural SVMs.

1. Introduction

State of the art information retrieval systems commonly use machine learning techniques to learn ranking functions (Burges et al., 2006; Chapelle et al., 2007). Existing machine learning approaches typically optimize for ranking performance measures such as mean average precision or normalized discounted cumulative gain. Unfortunately, these approaches do not consider diversity, and also (often implicitly) assume that a document's relevance can be evaluated independently from other documents.

Indeed, several recent studies in information retrieval have emphasized the need to optimize for diversity (Zhai et al., 2003; Carbonell & Goldstein, 1998; Chen & Karger, 2006; Zhang et al., 2005; Swaminathan et al., 2008). In particular, they stressed the need to model inter-document dependencies. However, none of these approaches addressed the learning problem, and thus either use a limited feature space or require extensive tuning for different retrieval settings. In contrast, we present a method which can automatically learn a good retrieval function using a rich feature space.

In this paper we formulate the task of diversified retrieval as the problem of predicting diverse subsets. Specifically, we formulate a discriminant based on maximizing word coverage, and perform training using the structural SVM framework (Tsochantaridis et al., 2005). For our experiments, diversity is measured using subtopic coverage on manually labeled data. However, our approach can incorporate other forms of training data such as clickthrough results. To the best of our knowledge, our method is the first approach that can directly train for subtopic diversity. We have also made available a publicly downloadable implementation of our algorithm[1].

For the rest of this paper, we first provide a brief survey of recent related work. We then present our model and describe the prediction and training algorithms. We finish by presenting experiments on labeled query data from the TREC 6-8 Interactive Track as well as a synthetic dataset. Our method compares favorably to conventional methods which do not perform learning.

2. Related Work

Our prediction method is most closely related to the Essential Pages method (Swaminathan et al., 2008), since both methods select documents to maximize weighted word coverage. Documents are iteratively selected to maximize the marginal gain, which is also similar to approaches considered by (Zhai et al., 2003; Carbonell & Goldstein, 1998; Chen & Karger, 2006; Zhang et al., 2005). However, none of these previous approaches addressed the learning problem.

Learning to rank is a well-studied problem in machine learning. Existing approaches typically consider the one-dimensional ranking problem, e.g., (Burges et al.,

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

[1] `http://projects.yisongyue.com/svmdiv/`

2006; Yue et al., 2007; Chapelle et al., 2007; Zheng et al., 2007; Li et al., 2007). These approaches maximize commonly used measures such as mean average precision and normalized discounted cumulative gain, and generalize well to new queries. However, diversity is not considered. These approaches also evaluate each document independently of other documents.

From an online learning approach, Kleinberg et al. (2008) used a multi-armed bandit method to minimize abandonment (maximizing clickthrough) for a single query. While abandonment is provably minimized, their approach cannot generalize to new queries.

The diversity problem can also be treated as learning preferences for sets, which is the approach taken by the DD-PREF modeling language (desJardins et al., 2006; Wagstaff et al., 2007). In their case, diversity is measured on a per feature basis. Since subtopics cannot be treated as features (it is only given in the training data), their method cannot be directly applied to maximizing subtopic diversity. Our model does not need to derive diversity directly from individual features, but does require richer forms of training data (i.e., subtopics explicitly labeled).

Another approach uses a global class hierarchy over queries and/or documents, which can be leveraged to classify new documents and queries (Cai & Hofmann, 2004; Broder et al., 2007). While previous studies on hierarchical classification did not focus on diversity, one might consider diversity by mapping subtopics onto the class hierarchy. However, it is difficult for such hierarchies to achieve the granularity required to measure diversity for individual queries (see beginning of Section 6 for a description of subtopics used in our experiments). Using a large global hierarchy also introduces other complications such as how to generate a comprehensive set of topics and how to assign documents to topics. It seems more efficient to collect labeled training data containing query-specific subtopics (e.g., TREC Interactive Track).

3. The Learning Problem

For each query, we assume that we are given a set of candidate documents $\mathbf{x} = \{x_1, \ldots, x_n\}$. In order to measure diversity, we assume that each query spans a set of topics (which may be distinct to that query). We define $\mathbb{T} = \{T_1, \ldots, T_n\}$, where topic set T_i contains the subtopics covered by document $x_i \in \mathbf{x}$. Topic sets may overlap. Our goal is to select a subset $\mathbf{y}$ of K documents from $\mathbf{x}$ which maximizes topic coverage.

If the topic sets $\mathbb{T}$ were known, a good solution could be computed via straightforward greedy subset selection, which has a $(1 - 1/e)$-approximation bound (Khuller et al., 1997). Finding the globally optimal subset takes n choose K time, which we consider intractable for even reasonably small values of K. However, the topic sets of a candidate set are not known, nor is the set of all possible topics known. We merely assume to have a set of training examples of the form $(\mathbf{x}^{(i)}, \mathbb{T}^{(i)})$, and must find a good function for predicting $\mathbf{y}$ in the absence of $\mathbb{T}$. This in essence is the learning problem.

Let $\mathcal{X}$ denote the space of possible candidate sets $\mathbf{x}$, $\mathcal{T}$ the space of topic sets $\mathbb{T}$, and $\mathcal{Y}$ the space of predicted subsets $\mathbf{y}$. Following the standard machine learning setup, we formulate our task as learning a hypothesis function $h : \mathcal{X} \rightarrow \mathcal{Y}$ to predict a $\mathbf{y}$ when given $\mathbf{x}$. We quantify the quality of a prediction by considering a loss function $\Delta : \mathcal{T} \times \mathcal{Y} \rightarrow \Re$ which measures the penalty of choosing $\mathbf{y}$ when the topics to be covered are those in $\mathbb{T}$.

We restrict ourselves to the supervised learning scenario, where training examples $(\mathbf{x}, \mathbb{T})$ consist of both the candidate set of documents and the subtopics. Given a set of training examples, $S = \{(\mathbf{x}^{(i)}, \mathbb{T}^{(i)}) \in \mathcal{X} \times \mathcal{T} : i = 1, \ldots, N\}$, the strategy is to find a function h which minimizes the empirical risk,

$$R_S^{\Delta}(h) = \frac{1}{N} \sum_{i=1}^{N} \Delta(\mathbb{T}^{(i)}, h(\mathbf{x}^{(i)})).$$

We encourage diversity by defining our loss function $\Delta(\mathbb{T}, \mathbf{y})$ to be the weighted percentage of distinct subtopics in $\mathbb{T}$ not covered by $\mathbf{y}$, although other formulations are possible, which we discuss in Section 8.

We focus on hypothesis functions which are parameterized by a weight vector $\mathbf{w}$, and thus wish to find $\mathbf{w}$ to minimize the empirical risk, $R_S^{\Delta}(\mathbf{w}) \equiv R_S^{\Delta}(h(\cdot; \mathbf{w}))$. We use a discriminant $\mathcal{F} : \mathcal{X} \times \mathcal{Y} \rightarrow \Re$ to compute how well predicting $\mathbf{y}$ fits for $\mathbf{x}$. The hypothesis then predicts the $\mathbf{y}$ which maximizes $\mathcal{F}$:

$$h(\mathbf{x}; \mathbf{w}) = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}} \mathcal{F}(\mathbf{x}, \mathbf{y}; \mathbf{w}). \quad (1)$$

We assume our discriminant to be linear in a joint feature space $\Psi : \mathcal{X} \times \mathcal{Y} \rightarrow \Re^m$, which we can write as

$$\mathcal{F}(\mathbf{x}, \mathbf{y}; \mathbf{w}) = \mathbf{w}^T \Psi(\mathbf{x}, \mathbf{y}). \quad (2)$$

The feature representation Ψ must enable meaningful discrimination between high quality and low quality predictions. As such, different feature representations may be appropriate for different retrieval settings. We discuss some possible extensions in Section 8.

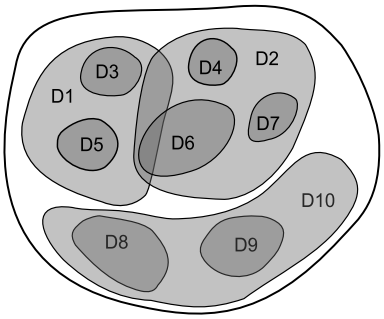

Figure 1. Visualization of Documents Covering Subtopics

This word appears ...
... in a document in $\mathbf{y}$.
... at least 5 times in a document in $\mathbf{y}$.
... with frequency at least 5% in a document in $\mathbf{y}$.
... in the title of a document in $\mathbf{y}$.
... within the top 5 TFIDF of a document in $\mathbf{y}$.

Table 1. Examples of Importance Criteria

The word v has ...
... a $\lvert D_1(v)\rvert/n$ ratio of at least 40%
... a $\lvert D_2(v)\rvert/n$ ratio of at least 50%
... a $\lvert D_\ell(v)\rvert/n$ ratio of at least 25%

Table 2. Examples of Document Frequency Features

4. Maximizing Word Coverage

Figure 1 depicts an abstract visualization of our prediction problem. The sets represent candidate documents $\mathbf{x}$ of a query, and the area covered by each set is the "information" (represented as subtopics $\mathbb{T}$) covered by that document. If $\mathbb{T}$ were known, we could use a greedy method to find a solution with high subtopic diversity. For $K = 3$, the optimal solution in Figure 1 is $\mathbf{y} = \{D1, D2, D10\}$. In general however, the subtopics are unknown. We instead assume that the candidate set contains discriminating features which separates subtopics from each other, and these are primarily based on word frequencies.

As a proxy for explicitly covering subtopics, we formulate our discriminant Ψ based on weighted word coverage. Intuitively, covering more (distinct) words should result in covering more subtopics. The relative importance of covering any word can be modeled using features describing various aspects of word frequencies within documents in $\mathbf{x}$. We make no claims regarding any generative models relating topics to words, but rather simply assume that word frequency features are highly discriminative of subtopics within $\mathbf{x}$.

We now present a simple example of Ψ from (2). Let $V(\mathbf{y})$ denote the union of words contained in the documents of the predicted subset $\mathbf{y}$, and let $\phi(v, \mathbf{x})$ denote the feature vector describing the frequency of word v amongst documents in $\mathbf{x}$. We then write Ψ as

$$\Psi(\mathbf{x}, \mathbf{y}) = \sum_{v \in V(\mathbf{y})} \phi(v, \mathbf{x}). \tag{3}$$

Given a model vector $\mathbf{w}$, the benefit of covering word v in candidate set x is $\mathbf{w}^T \phi(v, \mathbf{x})$. This benefit is realized when a document in $\mathbf{y}$ contains v, i.e., $v \in V(\mathbf{y})$. We use the same model weights for all words. A prediction is made by choosing $\mathbf{y}$ to maximize (2).

This formulation yields two properties which enable optimizing for diversity. First, covering a word twice provides no additional benefit. Second, the feature vector $\phi(v, \mathbf{x})$ is computed using other documents in the candidate set. Thus, diversity is measured locally rather than relative to the whole corpus. Both properties are absent from conventional ranking methods which evaluate each document individually.

In practical applications, a more sophisticated Ψ may be more appropriate. We develop our discriminant by addressing two criteria: how well a document covers a word, and how important it is to cover a word in $\mathbf{x}$.

4.1. How well a document covers a word

In our simple example (3), a single word set $V(\mathbf{y})$ is used, and all words that appear at least once in $\mathbf{y}$ are included. However, documents do not cover all words equally well, which is something not captured in (3). For example, a document which contains 5 instances of the word "lion" might cover the word better than another document which only contains 2 instances.

Instead of using only one $V(\mathbf{y})$, we can use L such word sets $V_1(\mathbf{y}), \ldots, V_L(\mathbf{y})$. Each word set $V_\ell(\mathbf{y})$ contains only words satisfying certain importance criteria. These importance criteria can be based on properties such as appearance in the title, the term frequency in the document, and having a high TFIDF value in the document (Salton & Buckley, 1988). Table 1 contains examples of importance criteria that we considered. For example, if importance criterion ℓ requires appearing at least 5 times in a document, then $V_\ell(\mathbf{y})$ will be the set of words which appear at least 5 times in some document in $\mathbf{y}$. The most basic criterion simply requires appearance in a document, and using only this criterion will result in (3).

We use a separate feature vector $\phi_\ell(v, \mathbf{x})$ for each importance level. We will describe ϕ_ℓ in greater detail in Section 4.2. We define Ψ from (2) to be the vector

Algorithm 1 Greedy subset selection by maximizing weighted word coverage

Input: $\mathbf{w}$, $\mathbf{x}$
Initialize solution $\hat{\mathbf{y}} \leftarrow \emptyset$
for $k = 1, \ldots, K$ **do**
  $\hat{x} \leftarrow \text{argmax}_{x:x \notin \hat{\mathbf{y}}} \mathbf{w}^T \Psi(\mathbf{x}, \hat{\mathbf{y}} \cup \{d\})$
  $\hat{\mathbf{y}} \leftarrow \hat{\mathbf{y}} \cup \{\hat{x}\}$
end for
return $\hat{\mathbf{y}}$

composition of all the ϕ_ℓ vectors,

$$\Psi(\mathbf{x}, \mathbf{y}) = \begin{bmatrix} \sum_{v \in V_1(\mathbf{y})} \phi_1(v, \mathbf{x}) \\ \vdots \\ \sum_{v \in V_L(\mathbf{y})} \phi_L(v, \mathbf{x}) \\ \sum_{i=1}^{n} y_i \psi(x_i, \mathbf{x}) \end{bmatrix}. \quad (4)$$

We can also include a feature vector $\psi(x, \mathbf{x})$ to encode any salient document properties which are not captured at the word level (e.g., "this document received a high score with an existing ranking function").

4.2. The importance of covering a word

In this section, we describe our formulation for the feature vectors $\phi_1(v, \mathbf{x}), \ldots, \phi_L(v, \mathbf{x})$. These features encode the benefit of covering a word, and are based primarily on document frequency in $\mathbf{x}$.

Using the importance criteria defined in Section 4.1, let $D_\ell(v)$ denote the set of documents in $\mathbf{x}$ which cover word v at importance level ℓ. For example, if the importance criterion is "appears at least 5 times in the document", then $D_\ell(v)$ is the set of documents that have at least 5 copies of v. This is, in a sense, a complementary definition to $V_\ell(\mathbf{y})$.

We use thresholds on the ratio $|D_\ell(v)|/n$ to define feature values of $\phi_\ell(v, \mathbf{x})$ that describe word v at different importance levels. Table 2 describes examples of features that we considered.

4.3. Making Predictions

Putting the formulation together, $\mathbf{w}_\ell^T \phi_\ell(v, \mathbf{x})$ denotes the benefit of covering word v at importance level ℓ, where $\mathbf{w}_\ell$ is the sub-vector of $\mathbf{w}$ which corresponds to ϕ_ℓ in (4). A word is only covered at importance level ℓ if it appears in $V_\ell(\mathbf{y})$. The goal then is to select K documents which maximize the aggregate benefit.

Selecting the K documents which maximizes (2) takes n choose K time, which quickly becomes intractable for even small values of K. Algorithm 1 describes a greedy algorithm which iteratively selects the document with highest marginal gain. Our prediction problem is a special case of the Budgeted Max Coverage problem (Khuller et al., 1997), and the greedy algorithm is known to have a $(1 - 1/e)$-approximation bound. During prediction, the weight vector $\mathbf{w}$ is assumed to be already learned.

5. Training with Structural SVMs

SVMs have been shown to be a robust and effective approach to complex learning problems in information retrieval (Yue et al., 2007; Chapelle et al., 2007). For a given training set $S = \{(\mathbb{T}^{(i)}, \mathbf{x}^{(i)})\}_{i=1}^N$, we use the structural SVM formulation, presented in Optimization Problem 1, to learn a weight vector $\mathbf{w}$.

Optimization Problem 1. (STRUCTURAL SVM)

$$\min_{\mathbf{w}, \xi \geq 0} \frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{N}\sum_{i=1}^{N} \xi_i \quad (5)$$

s.t. $\forall i, \forall \mathbf{y} \in \mathcal{Y} \setminus \mathbf{y}^{(i)}$:

$$\mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}) \geq \mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}) + \Delta(\mathbb{T}^{(i)}, \mathbf{y}) - \xi_i \quad (6)$$

The objective function (5) is a tradeoff between model complexity, $\|\mathbf{w}\|^2$, and a hinge loss relaxation of the training loss for each training example, $\sum \xi_i$, and the tradeoff is controlled by the parameter C. The $\mathbf{y}^{(i)}$ in the constraints (6) is the prediction which minimizes $\Delta(\mathbb{T}^{(i)}, \mathbf{y}^{(i)})$, and can be chosen via greedy selection.

The formulation of Ψ in (4) is very similar to learning a straightforward linear model. The key difference is that each training example is now a set of documents $\mathbf{x}$ as opposed to a single document. For each training example, each "suboptimal" labeling is associated with a constraint (6). There are now an immense number of constraints to define for SVM training.

Despite the large number of constraints, we can use Algorithm 2 to solve OP 1 efficiently. Algorithm 2 is a cutting plane algorithm, iteratively adding constraints until we have solved the original problem within a desired tolerance ϵ (Tsochantaridis et al., 2005). The algorithm starts with no constraints, and iteratively finds for each example $(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$ the $\hat{\mathbf{y}}$ which encodes the most violated constraint. If the corresponding constraint is violated by more than ϵ we add $\hat{\mathbf{y}}$ into the working set $\mathcal{W}_i$ of active constraints for example i, and re-solve (5) using the updated $\mathcal{W}$. Algorithm 2's outer loop is guaranteed to halt within a polynomial number of iterations for any desired precision ϵ.

Theorem 1. *Let* $\bar{R} = \max_i \max_{\mathbf{y}} \|\Psi(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}) - \Psi(\mathbf{x}^{(i)}, \mathbf{y})\|$, $\bar{\Delta} = \max_i \max_{\mathbf{y}} \Delta(\mathbb{T}^{(i)}, \mathbf{y})$, *and for any*

Algorithm 2 Cutting plane algorithm for solving OP 1 within tolerance ϵ.

Input: $(\mathbf{x}^{(1)}, \mathbb{T}^{(1)}), \ldots, (\mathbf{x}^{(N)}, \mathbb{T}^{(N)})$, C, ϵ
$\mathcal{W}_i \leftarrow \emptyset$ for all $i = 1, \ldots, n$
repeat
  for $i = 1, \ldots, n$ **do**
    $H(\mathbf{y}; \mathbf{w}) \equiv \Delta(\mathbb{T}^{(i)}, \mathbf{y}) + \mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}) - \mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}_i)$
    compute $\hat{\mathbf{y}} = \text{argmax}_{\mathbf{y} \in \mathcal{Y}} H(\mathbf{y}; \mathbf{w})$
    compute $\xi_i = \max\{0, \max_{\mathbf{y} \in \mathcal{W}_i} H(\mathbf{y}; \mathbf{w})\}$
    if $H(\hat{\mathbf{y}}; \mathbf{w}) > \xi_i + \epsilon$ **then**
      $\mathcal{W}_i \leftarrow \mathcal{W}_i \cup \{\hat{\mathbf{y}}\}$
      $\mathbf{w} \leftarrow$ optimize (5) over $\mathcal{W} = \bigcup_i \mathcal{W}_i$
    end if
  end for
until no $\mathcal{W}_i$ has changed during iteration

$\epsilon > 0$, Algorithm 2 terminates after adding at most

$$\max\left\{\frac{2n\bar{\Delta}}{\epsilon}, \frac{8C\bar{\Delta}\bar{R}^2}{\epsilon^2}\right\}$$

constraints to the working set $\mathcal{W}$. See (Tsochantaridis et al., 2005) for proof.

However, each iteration of the inner loop of Algorithm 2 must compute $\text{argmax}_{\mathbf{y} \in \mathcal{Y}} H(\mathbf{y}; \mathbf{w})$, or equivalently,

$$\underset{\mathbf{y} \in \mathcal{Y}}{\text{argmax}}\, \Delta(\mathbb{T}^{(i)}, \mathbf{y}) + \mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}), \tag{7}$$

since $\mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$ is constant with respect to $\mathbf{y}$. Though closely related to prediction, this has an additional complication with the $\Delta(\mathbb{T}^{(i)}, \mathbf{y})$ term. As such, a constraint generation oracle is required.

5.1. Finding Most Violated Constraint

The constraint generation oracle must efficiently solve (7). Unfortunately, solving (7) exactly is intractable since exactly solving the prediction task,

$$\underset{\mathbf{y} \in \mathcal{Y}}{\text{argmax}}\, \mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}),$$

is intractable. An approximate method must be used. The greedy inference method in Algorithm 1 can be easily modified for this purpose. Since constraint generation is also a special case of the Budgeted Max Coverage Problem, the $(1-1/e)$-approximation bound still holds. Despite using an approximate constraint generation oracle, SVM training is still known to terminate in a polynomial number of iterations (Finley & Joachims, 2008). Furthermore in practice, training typically converges much faster than the worst case considered by the theoretical bounds.

Intuitively, a small set of the constraints can approximate to ϵ precision the feasible space defined by the intractably many constraints. When constraint generation is approximate however, the ϵ precision guarantee no longer holds. Nonetheless, using approximate constraint generation can still offer good performance, which we will evaluate empirically.

6. Experiment Setup

We tested the effectiveness of our method using the TREC 6-8 Interactive Track Queries[2]. Relevant documents are labeled using subtopics. For example, query 392 asked human judges to identify different applications of robotics in the world today, and they identified 36 subtopics among the results such as nanorobots and using robots for space missions.

The 17 queries we used are 307, 322, 326, 347, 352, 353, 357, 362, 366, 387, 392, 408, 414, 428, 431, 438, and 446. Three of the original 20 queries were discarded due to having small candidate sets, making them uninteresting for our experiments. Following the setup in (Zhai et al., 2003), candidate sets only include documents which are relevant to at least one subtopic. This decouples the diversity problem, which is the focus of our study, from the relevance problem. In practice, approaches like ours might be used to post-process the results of a commercial search engine. We also performed Porter stemming and stop-word removal.

We used a 12/4/1 split for our training, validation and test sets, respectively. We trained our SVM using C values varying from 1e-5 to 1e3. The best C value is then chosen on the validation set, and evaluated on the test query. We permuted our train/validation/test splits until all 17 queries were chosen once for the test set. Candidate sets contain on average 45 documents, 20 subtopics, and 300 words per document. We set the retrieval size to $K = 5$ since some candidate sets contained as few as 16 documents.

We compared our method against Okapi (Robertson et al., 1994), and Essential Pages (Swaminathan et al., 2008). Okapi is a conventional retrieval function which evaluates the relevance of each document individually and does not optimize for diversity. Like our method, Essential Pages also optimizes for diversity by selecting documents to maximize weighted word coverage (but based on a fixed, rather than a learned, model). In their model, the benefit of document x_i covering a word v is defined to be

$$TF(v, x_i) \log\left(\frac{1}{DF(v, \mathbf{x})}\right),$$

[2] `http://trec.nist.gov/`

Method	Loss
Random	0.469
Okapi	0.472
Unweighted Model	0.471
Essential Pages	0.434
$\text{SVM}^{\Delta}_{div}$	0.349
$\text{SVM}^{\Delta}_{div2}$	0.382

Table 3. Performance on TREC ($K = 5$)

where $TF(v, x_i)$ is the term frequency of v in x_i and $DF(v, \mathbf{x})$ is the document frequency of v in $\mathbf{x}$.

We define our loss function to be the weighted percentage of subtopics not covered. For a given candidate set, each subtopic's weight is proportional to the number of documents that cover that subtopic. This is attractive since it assigns a high penalty to not covering a popular subtopic. It is also compatible with our discriminant since frequencies of important words will vary based on the distribution of subtopics.

The small quantity of TREC queries makes some evaluations difficult, so we also generated a larger synthetic dataset of 100 candidate sets. Each candidate set has 100 documents covering up to 25 subtopics. Each document samples 300 words independently from a multinomial distribution over 5000 words. Each document's word distribution is a mixture of its subtopics' distributions. We used this dataset to evaluate how performance changes with retrieval size K. We used a 15/10/75 split for training, validation, and test sets.

7. Experiment Results

Let $\text{SVM}^{\Delta}_{div}$ denote our method which uses term frequencies and title words to define importance criteria (how well a document covers a word), and let $\text{SVM}^{\Delta}_{div2}$ denote our method which in addition also uses TFIDF. $\text{SVM}^{\Delta}_{div}$ and $\text{SVM}^{\Delta}_{div2}$ use roughly 200 and 300 features, respectively. Table 1 contains examples of importance criteria that could be used.

Table 3 shows the performance results on TREC queries. We also included the performance of randomly selecting 5 documents as well as an unweighted word coverage model (all words give equal benefit when covered). Only Essential Pages, $\text{SVM}^{\Delta}_{div}$ and $\text{SVM}^{\Delta}_{div2}$ performed better than random.

Table 4 shows the per query comparisons between $\text{SVM}^{\Delta}_{div}$, $\text{SVM}^{\Delta}_{div2}$ and Essential Pages. Two stars indicate 95% significance using the Wilcoxon signed rank test. While the comparison is not completely fair since Essential Pages was designed for a slightly different setting, it demonstrates the benefit of automatically fitting a retrieval function to the specific task at hand.

Method Comparison	Win / Tie / Lose
$\text{SVM}^{\Delta}_{div}$ vs Essential Pages	14 / 0 / 3 **
$\text{SVM}^{\Delta}_{div2}$ vs Essential Pages	13 / 0 / 4
$\text{SVM}^{\Delta}_{div}$ vs $\text{SVM}^{\Delta}_{div2}$	9 / 6 / 2

Table 4. Per Query Comparison on TREC ($K = 5$)

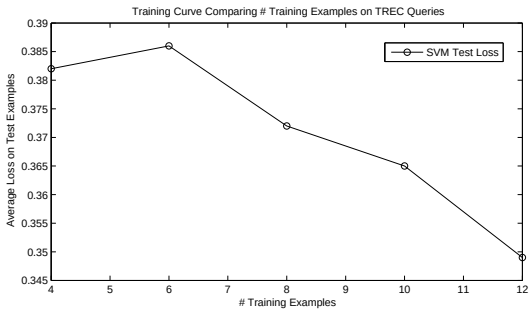

Figure 2. Comparing Training Size on TREC ($K = 5$)

Despite having a richer feature space, $\text{SVM}^{\Delta}_{div2}$ performs worse than $\text{SVM}^{\Delta}_{div}$. We conjecture that the top TFIDF words do not discriminate between subtopics. These words are usually very descriptive of the query as a whole, and thus will appear in all subtopics.

Figure 2 shows the average test performance of $\text{SVM}^{\Delta}_{div}$ as the number of training examples is varied. We see a substantial improvement in performance as training set size increases. It appears that more training data would further improve performance.

7.1. Approximate Constraint Generation

Using appoximate constraint generation might compromise our model's ability to (over-)fit the data. We addressed this concern by examining the training loss as the C parameter is varied. The training curve of $\text{SVM}^{\Delta}_{div}$ is shown in Figure 3. Greedy optimal refers to the loss incurred by a greedy method with knowledge of subtopics. As we increase C (favoring low training loss over low model complexity), our model is able to fit the training data almost perfectly. This indicates that approximate constraint generation is acceptable for our training purposes.

7.2. Varying Predicted Subset Size

We used the synthetic dataset to evaluate the behavior of our method as we vary the retrieval size K. It is difficult to perform this evaluation on the TREC queries – since some candidate sets have very few documents

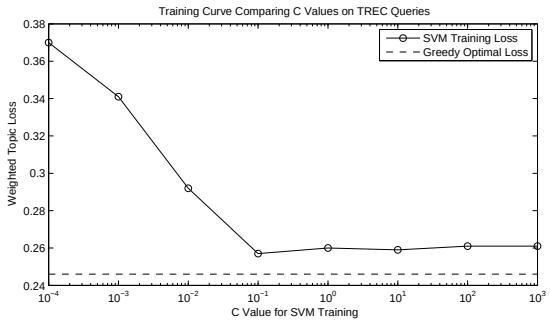

Figure 3. Comparing C Values on TREC ($K = 5$)

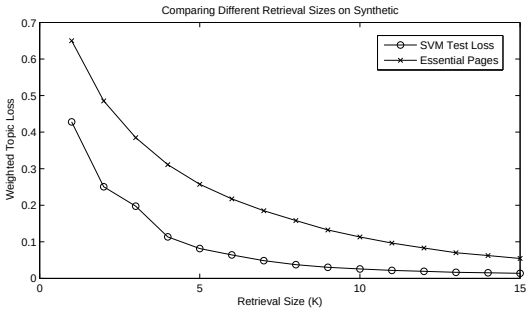

Figure 4. Varying Retrieval Size on Synthetic

or subtopics, using higher K would force us to discard more queries. Figure 4 shows that the test performance of $\text{SVM}^{\Delta}_{div}$ consistently outperforms Essential Pages at all levels of K.

7.3. Running Time

Predicting takes linear time. During training, Algorithm 2 loops for 10 to 100 iterations. For ease of development, we used a Python interface[3] to SVM^{struct}. Even with our unoptimized code, most models trained within an hour, with the slowest finishing in only a few hours. We expect our method to easily accomodate much more data since training scales linearly with dataset size (Joachims et al., to appear).

8. Extensions

8.1. Alternative Discriminants

Maximizing word coverage might not be suitable for other types of retrieval tasks. Our method is a general framework which can incorporate other discriminant formulations. One possible alternative is to maximize the pairwise distance of items in the predicted subset. Learning a weight vector for (2) would then amount to finding a distance function for a specific retrieval task.

[3] `http://www.cs.cornell.edu/~tomf/svmpython2/`

Any discriminant can be used so long as it captures the salient properties of the retrieval task, is linear in a joint feature space (2), and has effective inference and constraint generation methods.

8.2. Alternative Loss Functions

Our method is not restricted to using subtopics to measure diversity. Only our loss function $\Delta(\mathbb{T}, \mathbf{y})$ makes use of subtopics during SVM training. We can also incorporate loss functions which can penalize other types of diversity criteria and also use other forms of training data, such as clickthrough logs. The only requirement is that it must be computationally compatible with the constraint generation oracle (7).

8.3. Additional Word Features

Our choice of features is based almost exclusively on word frequencies. The sole exception is using title words as an importance criterion. The goal of these features is to describe how well a document covers a word and the importance of covering a word in a candidate set. Other types of word features might prove useful, such as anchor text, URL, and any meta information contained in the documents.

9. Conclusion

In this paper we have presented a general machine learning approach to predicting diverse subsets. Our method compares favorably to methods which do not perform learning, demonstrating the usefulness of training feature rich models for specific retrieval tasks. To the best of our knowledge, our method is the first approach which directly trains for subtopic diversity. Our method is also efficient since it makes predictions in linear time and has training time that scales linearly in the number of queries.

In this paper we separated the diversity problem from the relevance problem. An interesting direction for future work would be to jointly model both relevance and diversity. This is a more challenging problem since it requires balancing a tradeoff for presenting both novel and relevant information.

The non-synthetic TREC dataset is also admittedly small. Generating larger (and publicly available) labeled datasets which encode diversity information is another important direction for future work.

Department of Computer Science and Engineering, Hong Kong University of Science and Technology, Hong Kong

Abstract

Low-rank matrix approximation is an effective tool in alleviating the memory and computational burdens of kernel methods and sampling, as the mainstream of such algorithms, has drawn considerable attention in both theory and practice. This paper presents detailed studies on the Nyström sampling scheme and in particular, an error analysis that directly relates the Nyström approximation quality with the encoding powers of the landmark points in summarizing the data. The resultant error bound suggests a simple and efficient sampling scheme, the k-means clustering algorithm, for Nyström low-rank approximation. We compare it with state-of-the-art approaches that range from greedy schemes to probabilistic sampling. Our algorithm achieves significant performance gains in a number of supervised/unsupervised learning tasks including kernel PCA and least squares SVM.

1. Introduction

Kernel methods play a central role in machine learning and have demonstrated huge success in modelling real-world data with highly complex, nonlinear structures. Examples include the support vector machine, kernel Fisher discriminant analysis and kernel principal component analysis. The key element of kernel methods is to map the data into a kernel-induced Hilbert space $\varphi(\cdot)$ where dot product between points can be computed equivalently through the kernel evaluation $\langle \varphi(x_i), \varphi(x_j) \rangle = K(x_i, x_j)$. Given n sample points, this necessitates the calculation of an $n \times n$ symmetric, positive (semi-)definite kernel matrix. The resultant complexities in terms of both space (quadratic) and time (usually cubic) can be quite demanding for large problems, posing a big challenge on practical applications.

Appearing in *Proceedings of the 25^{th} International Conference on Machine Learning*, Helsinki, Finland, 2008.

A useful way to alleviate the memory and computational burdens of kernel methods is to utilize the rapid decaying spectra of the kernel matrices (Williams & Seeger, 2000) and perform low-rank approximation in the form of $K = GG'$, where $G \in \mathbb{R}^{n \times m}$ with $m \ll n$. However, the optimal (eigenvalue) decomposition takes $O(n^3)$ time and efficient alternatives have to be sought. In the following, we give a brief review on efficient techniques for low-rank decompositions of symmetric, positive (semi-)definite kernel matrices.

Greedy approaches have been applied in several fast algorithms for approximating the kernel matrix. In (Smola & Schölkopf, 2000), the kernel matrix K is approximated by the subspace spanned by a subset of its columns. The basis vectors are chosen incrementally to minimize an upper bound of the approximation error. The algorithm takes $O(m^2nl)$ time using a probabilistic heuristic, where l is the random subset size. In (Ouimet & Bengio, 2005), a greedy sampling scheme is proposed based on how well a sample point can be represented by a (constrained) linear combination of the current subspace basis in the feature space. Their algorithm scales as $O(m^2n)$. Another well-known greedy approach for low-rank approximation of positive semi-definite matrices is the incomplete Cholesky decomposition (Fine & Scheinberg, 2001; Bach & Jordan, 2005; Bach & Jordan, 2002). It is a variant of the Cholesky decomposition that skip pivots below a certain threshold, and factorizes the kernel matrix K as $K = GG'$ where $G \in \mathbb{R}^{n \times m}$ is a lower triangular matrix.

Another class of low-rank approximation algorithms stem from the Nyström method. The Nyström method was originally designed to solve integral equations (Baker, 1977). Given a kernel matrix K, the Nyström method can be deemed as choosing a subset of m columns (hence rows) $E \in \mathbb{R}^{n \times m}$, and reconstructing the complete kernel matrix by $K \simeq EW^{-1}E'$, where W is the intersection of the selected rows and columns of K. The most popular sampling scheme for Nyström method is random sampling, which leads to fast versions of kernel machines (Williams & Seeger, 2001; Lawrence & Herbrich, 2003) and spectral

clustering (Fowlkes et al., 2004). In (Platt, 2005), several variants of multidimensional scaling are all shown to be related to the Nyström approximation.

There are also a large body of randomized algorithms for low-rank decomposition of arbitrary matrices (Frieze et al., 1998; Achlioptas & McSherry, 2001; Drineas et al., 2003), where the goal is to design column/row sampling probabilities that achieve provable probabilistic bounds. These algorithms are designed for a more general purpose and will not be the focus of this paper. However, we note that one of these randomized algorithms has been recently revised for efficient low-rank approximation of the symmetric Gram matrix (Drineas & Mahoney, 2005). Therefore we will use it as a representative of randomized algorithms in our empirical evaluations. The basic idea of (Drineas & Mahoney, 2005) is to sample the columns of the kernel matrix based on a pre-computed distribution using the norms of the columns. The reconstruction of the kernel matrix is also normalized by the sampling distribution.

In terms of efficiency, greedy approaches usually take $O(m^2n)$ time for sampling, while the random scheme only needs $O(n)$ and is much more efficient. Probabilistic approaches, or randomized algorithms in general, are usually more expensive in that the sampling distributions have to be computed based on the original matrix, which require at least $O(n^2)$. In terms of memory, note that the matrices (E and W) needed in the Nyström method with random sampling can be simply computed on demand. This greatly reduces the memory requirement for very large-scale problems. In contrast, the intermediate matrices for greedy approaches have to be incrementally updated and stored.

Although the Nyström method possesses desirable scaling properties and has been applied with success in various machine learning problems, analysis on its key step of choosing the landmark set is relatively limited. In (Drineas & Mahoney, 2005), a probabilistic error bound is provided on the Nyström low-rank approximation. However, the error bound only applies to the specially designed sampling scheme, which needs to compute the norms of all the rows/columns of the kernel matrix and is hence quite expensive. In (Zhang & Kwok, 2006), a block quantization scheme is proposed for fast spectral embedding. The kernel eigen-system is approximated by first computing a block-wise constant kernel matrix and then extrapolating its eigenvectors through the weighted Nyström extension. However, the error analysis is only on the block-quantization step, and how the Nyström method affects the approximation quality in general remains unclear. Thus, the motivation of this paper is to provide a more concrete analysis on how the sampling scheme (or the choice of the landmark points) in general influences the Nyström low-rank approximation, and to improve the sampling strategy while still preserving its computational efficiency.

Our key finding is that the Nyström low-rank approximation depends crucially on the quantization error induced by encoding the sample set with the landmark points. This suggests that, instead of applying the greedy or probabilistic sampling, the landmark points can be simply chosen as the k-means cluster centers, which finds a local minimum of the quantization error. To the best of our knowledge, the k-means has not been applied in the Nyström low-rank approximation. The complexity of k-means is only linear in the sample size and dimension and, as our analysis expected, it demonstrates very encouraging performance that is consistently better than all known variants of Nyström. We also compare it with the greedy approach of incomplete Cholesky decomposition and again obtain positive results.

The rest of the paper is organized as follows. In Section 2, we give a brief introduction of the Nyström method. In Section 3, we present an error analysis on how the Nyström low-rank approximation is affected by the chosen landmark points, and propose the k-means algorithm for the sampling step. In Section 4, we compare our approach with a number of state-of-the-art low-rank decomposition techniques (including both greedy and probabilistic sampling approaches). The last section gives concluding remarks.

2. Nyström Method

The Nyström method is originated from the numerical treatment of integral equations of the form

$$\int p(y)k(x,y)\phi_i(y)dy = \lambda_i\phi_i(x), \tag{1}$$

where $p(\cdot)$ is the probability density function, k is a positive definite kernel function, and $\lambda_1 \geq \lambda_2 \geq \cdots \geq 0$ and $\phi_1, \phi_2, \ldots$ are the eigenvalues and eigenfunctions of the integral equation, respectively. Given a set of i.i.d. samples $\{x_1, x_2, \ldots, x_q\}$ drawn from $p(\cdot)$, the basic idea is to approximate the integral in (1) by the empirical average:

$$\frac{1}{q}\sum_{j=1}^{q} k(x,x_j)\phi_i(x_j) \simeq \lambda_i\phi_i(x). \tag{2}$$

Choosing x in (2) from $\{x_1, x_2, \ldots, x_q\}$ leads to a standard eigenvalue decomposition $K^{(q)}U^{(q)} = U^{(q)}\Lambda^{(q)}$, where $K^{(q)}_{ij} = k(x_i, x_j)$ for $i, j = 1, 2, \ldots, q$, $U^{(q)} \in \mathbb{R}^{q\times q}$ has orthonormal columns and $\Lambda^{(q)} \in \mathbb{R}^{q\times q}$ is a diagonal matrix. The eigenfunctions ϕ_i's and eigenvalues λ_i's in (1) can be approximated by $U^{(q)}$ and $\Lambda^{(q)}$, as (Williams & Seeger, 2001):

$$\phi_i(x_j) \simeq \sqrt{q}U^{(q)}_{ji}, \quad \lambda_i \simeq \lambda^{(q)}_i/q. \tag{3}$$

This means, the Nyström method using different subset sizes q's are all approximations to λ_i and ϕ_i in the inte-

gral equation (1). As a result, the Nyström method using a small q can also be deemed as approximating the Nyström method using a large q. Suppose the sample set $\mathcal{X} = \{x_i\}_{i=1}^n$, with the corresponding $n \times n$ kernel matrix K. Then the Nyström method that randomly chooses a subset $\mathcal{Z} = \{z_i\}_{i=1}^m$ of m landmark points will approximate the eigen-system of the full kernel matrix $K\Phi_K = \Phi_K\Lambda_K$ by (Williams & Seeger, 2001)

$$\Phi_K \simeq \sqrt{\frac{m}{n}} E\Phi_{\mathcal{Z}}\Lambda_{\mathcal{Z}}^{-1}, \;\; \Lambda_K \simeq \frac{n}{m}\Lambda_{\mathcal{Z}}. \tag{4}$$

Here, $E \in \mathbb{R}^{n\times m}$ with $E_{ij} = k(x_i, z_j)$, and $\Phi_{\mathcal{Z}}, \Lambda_{\mathcal{Z}} \in \mathbb{R}^{m\times m}$ contain the eigenvectors and eigenvalues of $W \in \mathbb{R}^{m\times m}$ where $W_{ij} = k(z_i, z_j)$. Using the approximations in (4), K can be reconstructed as

$$\begin{aligned} K &\simeq \left(\sqrt{\frac{m}{n}} E\Phi_{\mathcal{Z}}\Lambda_{\mathcal{Z}}^{-1}\right)\left(\frac{n}{m}\Lambda_{\mathcal{Z}}\right)\left(\sqrt{\frac{m}{n}} E\Phi_{\mathcal{Z}}\Lambda_{\mathcal{Z}}^{-1}\right)' \\ &= EW^{-1}E'. \end{aligned} \tag{5}$$

Equation (5) is the basis for Nyström low-rank approximation of the kernel matrix (Williams & Seeger, 2001; Fowlkes et al., 2004).

3. Error Analysis of the Nyström Method

In this section we analyze how the Nyström approximation error depends on the choice of landmark points. We first provide an important observation (Section 3.1), and then derive the error bound in more general settings based on a "clustered" data model (Section 3.2-3.4). The error bound gives important insights on the design of efficient sampling schemes for accurate low-rank approximation (Section 3.5).

3.1. Observation

Proposition 1. *Given the data set $\mathcal{X} = \{x_i\}_{i=1}^n$, and the landmark point set $\mathcal{Z} = \{z_j\}_{j=1}^m$. Then the Nyström reconstruction of the kernel entry $K(x_i, x_j)$ will be exact if there exist two landmark points such that $z_p = x_i$, and $z_q = x_j$.*

Proof. Let $K_{x_k,\mathcal{Z}} \in \mathbb{R}^{1\times m}$ be the similarity between x_k and the landmark points $\mathcal{Z}$. Then the Nyström reconstruction of the kernel entry will be $K_{x_i,\mathcal{Z}}W^{-1}K'_{x_j,\mathcal{Z}}$, where $W \in R^{m\times m}$ is the kernel matrix defined on the landmark set $\mathcal{Z}$. Let $W^{(k)}$ be the kth row of W, then we have $K_{x_i,\mathcal{Z}} = W^{(p)}$ and $K_{x_j,\mathcal{Z}} = W^{(q)}$ since $x_i = z_p$, and $x_j = z_q$. As a result, the reconstructed entry will be $W^{(p)}W^{-1}(W^{(q)})' = W_{pq} = K(z_p, z_q) = K(x_i, x_j)$. □

Proposition 1 indicates that the landmark points should be chosen to overlap sufficiently with the original data. However, it is often impossible to use a small landmark set to represent every sample point accurately.

3.2. Approximation Error of Sub-Kernel Matrix

In this section we apply a "clustered" data model to analyze the quality of Nyström low rank approximation. Here, the data clusters can be naturally obtained by assigning each sample to the closest landmark point. As will be seen, this model allows us to derive an explicit error bound for the Nyström approximation.

Again, suppose that the landmark set is $\mathcal{Z} = \{z_i\}_{i=1}^m$, and the whole sample set $\mathcal{X}$ is partitioned into m disjoint clusters $\mathcal{S}_k$'s. Let $c(i)$ be the function that maps each sample $x_i \in \mathcal{X}$ to the closest landmark point $z_{c(i)} \in \mathcal{Z}$, i.e., $c(i) = \arg\min_{j=1,2,\cdots,m} \|x_i - z_j\|$. Our goal is to study the approximation error in (5):

$$\mathcal{E} = \left\|K - EW^{-1}E'\right\|_F, \tag{6}$$

where $\|\cdot\|_F$ denotes the matrix Frobenious norm.

First, we consider the simpler notion of *partial approximation error* defined as follows.

Definition 1. *Suppose each cluster has T samples*[1]*. Repeat the following sampling process T times: at each time t, pick one sample from each cluster, and denote the set of samples chosen at time t as $\mathcal{X}_{\mathcal{I}_t}$. Then $\mathcal{X} = \{\mathcal{X}_{\mathcal{I}_1} \cup \mathcal{X}_{\mathcal{I}_1} \cup ... \cup \mathcal{X}_{\mathcal{I}_T}\}$, and the whole kernel matrix will be correspondingly decomposed into T^2 blocks, each of size $m \times m$. Let $K_{\mathcal{I}_i,\mathcal{I}_j}$, and $E_{\mathcal{I}_i,\mathcal{Z}}$ be the $m\times m$ similarity matrices defined on $(\mathcal{X}_{\mathcal{I}_i}, \mathcal{X}_{\mathcal{I}_i})$ and $(\mathcal{X}_{\mathcal{I}_i}, \mathcal{Z})$, respectively, and $W \in \mathbb{R}^{m\times m}$ the kernel matrix defined on $\mathcal{Z}$. The* partial approximation error *is the difference between $K_{\mathcal{I}_i,\mathcal{I}_j}$ and its Nyström approximation under the Frobenius norm*

$$\mathcal{E}_{\mathcal{I}_i,\mathcal{I}_j} = \|K_{\mathcal{I}_i,\mathcal{I}_j} - E_{\mathcal{I}_i,\mathcal{Z}}W^{-1}E'_{\mathcal{I}_j,\mathcal{Z}}\|_F. \tag{7}$$

We assume the kernel k satisfies the following property:

$$(k(a,b) - k(c,d))^2 \le C_{\mathcal{X}}^k\left(\|a-c\|^2 + \|b-d\|^2\right), \forall a,b,c,d \tag{8}$$

where $C_{\mathcal{X}}^k$ is a constant depending on k and the sample set $\mathcal{X}$. The validity of this assumption on a number of commonly used kernels will be proved in Section 3.4.

Proposition 2. *For kernel k satisfying property (8), the partial approximation error $\mathcal{E}_{\mathcal{I}_i,\mathcal{I}_j}$ is bounded by*

$$\begin{aligned} \mathcal{E}_{\mathcal{I}_i,\mathcal{I}_j} \le\; & \sqrt{2mC_{\mathcal{X}}^k(e_{\mathcal{I}_i} + e_{\mathcal{I}_j})} + \sqrt{mC_{\mathcal{X}}^k e_{\mathcal{I}_i}} \\ & + \sqrt{mC_{\mathcal{X}}^k e_{\mathcal{I}_j}} + mC_{\mathcal{X}}^k\sqrt{e_{\mathcal{I}_i}e_{\mathcal{I}_j}}\|W^{-1}\|_F. \end{aligned} \tag{9}$$

where $e_{\mathcal{I}_i}$ is the quantization error induced by coding each sample in $\mathcal{X}_{\mathcal{I}_i}$ by the closest landmark point in $\mathcal{Z}$, i.e.,

$$e_{\mathcal{I}_i} = \textstyle\sum_{x_i\in\mathcal{X}_{\mathcal{I}_i}} \left\|x_i - z_{c(i)}\right\|^2. \tag{10}$$

[1] If cluster sizes differ, add "virtual samples" to each cluster such that all the clusters have the same size (which is equal to $T = \max_k |\mathcal{S}_k|$). The virtual samples added to cluster $\mathcal{S}_k$ are chosen as the landmark point z_k for that cluster, so they will not induce extra quantization errors but will loosen the bound.

Proof. We will first define the following matrices

$$A_{\mathcal{I}_i,\mathcal{I}_j} = K_{\mathcal{I}_i,\mathcal{I}_j} - W; B_{\mathcal{I}_i,\mathcal{Z}} = E_{\mathcal{I}_i,\mathcal{Z}} - W; \\ C_{\mathcal{I}_j,\mathcal{Z}} = E_{\mathcal{I}_j,\mathcal{Z}} - W, \tag{11}$$

and then show that they have bounded Frobenius norms. Without loss of generality, we specify the indices as follows: $K_{\mathcal{I}_i,\mathcal{I}_j}(p,q) = k(x_{\mathcal{I}_i(p)}, x_{\mathcal{I}_j(q)})$; $E_{\mathcal{I}_i,\mathcal{Z}}(p,q) = k(x_{\mathcal{I}_i(p)}, z_q)$; $E_{\mathcal{I}_j,\mathcal{Z}}(p,q) = k(x_{\mathcal{I}_j(p)}, z_q)$; and $W(p,q) = k(z_p, z_q)$. With property (8), we have

$$\begin{aligned} \| A_{\mathcal{I}_i,\mathcal{I}_j} \|_F^2 &= \sum_{p,q=1}^{m} \left(k(x_{\mathcal{I}_i(p)}, x_{\mathcal{I}_j(q)}) - k(z_p, z_q) \right)^2 \\ &\leq C_{\mathcal{X}}^k \sum_{p,q=1}^{m} \left(\left\| x_{\mathcal{I}_i(p)} - z_p \right\|^2 + \left\| x_{\mathcal{I}_i(q)} - z_q \right\|^2 \right) \\ &= mC_{\mathcal{X}}^k \left(\sum_{p=1}^{m} \left\| x_{\mathcal{I}_i(p)} - z_p \right\|^2 + \sum_{q=1}^{m} \left\| x_{\mathcal{I}_j(q)} - z_q \right\|^2 \right) \\ &= 2mC_{\mathcal{X}}^k \left(e_{\mathcal{I}_i} + e_{\mathcal{I}_j} \right), \end{aligned}$$

where $e_{\mathcal{I}_i}$ is the same as that in (10) since $c(\mathcal{I}(q)) = q$.

For matrix $B_{\mathcal{I}_i,\mathcal{Z}}$, we have

$$\begin{aligned} \|B_{\mathcal{I}_i,\mathcal{Z}}\|_F^2 &= \sum_{p,q} \left(k(x_{\mathcal{I}_i(p)}, z_q) - k(z_p, z_q) \right)^2 \\ &\leq mC_{\mathcal{X}}^k \sum_{p=1}^{m} \left\| x_{\mathcal{I}_i(p)} - z_p \right\|^2 = mC_{\mathcal{X}}^k e_{\mathcal{I}_i}, \end{aligned}$$

and similarly for matrix $C_{\mathcal{I}_j,\mathcal{Z}}$ $\|C_{\mathcal{I}_j,\mathcal{Z}}\|_F^2 \leq mC_{\mathcal{X}}^k e_{\mathcal{I}_j}$.

Note that the partial approximation error $\mathcal{E}_{\mathcal{I}_i,\mathcal{I}_j}$ (7) can be re-written as follows using (11).

$$\begin{aligned} &\| \mathcal{E}_{\mathcal{I}_i,\mathcal{I}_j} \|_F = \left\| W + A_{\mathcal{I}_i,\mathcal{I}_j} - (W + B_{\mathcal{I}_i,\mathcal{Z}}) W^{-1} (W + C_{\mathcal{I}_j,\mathcal{Z}})' \right\|_F \\ &= \left\| W + A_{\mathcal{I}_i,\mathcal{I}_j} - W' - C'_{\mathcal{I}_j,\mathcal{Z}} - B_{\mathcal{I}_i,\mathcal{Z}} - B_{\mathcal{I}_i,\mathcal{Z}} W^{-1} C'_{\mathcal{I}_j,\mathcal{Z}} \right\|_F \\ &\leq \|A_{\mathcal{I}_i,\mathcal{I}_j}\|_F + \|B_{\mathcal{I}_i,\mathcal{Z}}\|_F + \|C_{\mathcal{I}_j,\mathcal{Z}}\|_F + \|B_{\mathcal{I}_i,\mathcal{Z}}\|_F \|C_{\mathcal{I}_j,\mathcal{Z}}\|_F \|W^{-1}\|_F \end{aligned}$$

Using the bounds on $\|A_{\mathcal{I}_i,\mathcal{I}_j}\|$, $\|B_{\mathcal{I}_i,\mathcal{Z}}\|$, $\|C_{\mathcal{I}_j,\mathcal{Z}}\|$ together with the definition in (11), we have Proposition 2 □

3.3. Approximation Error of Complete Kernel Matrix

With the estimated partial approximation error, we can now obtain a bound on the complete error for Nyström approximation (6). The basic idea is to sum up the partial errors $\mathcal{E}_{\mathcal{I}_i,\mathcal{I}_j}$ over all $i, j = 1, 2, ..., T$.

Proposition 3. *The error of the Nyström approximation (6) is bounded by*

$$\mathcal{E} \leq 4T\sqrt{mC_{\mathcal{X}}^k eT} + mC_{\mathcal{X}}^k Te \|W^{-1}\|_F \tag{12}$$

where $T = \max_k |\mathcal{S}_k|$*, and* $e = \sum_{i=1}^{n} \left\| x_i - z_{c(i)} \right\|^2$ *is the total quantization error of coding each sample* $x_i \in \mathcal{X}$ *with the closest landmark point* $z_j \in \mathcal{Z}$*.*

Proof. Here we sum up the terms in (9) separately.

$$\begin{aligned} &\sum_{i,j=1}^{T} \sqrt{2mC_{\mathcal{X}}^k (e_{\mathcal{I}_i} + e_{\mathcal{I}_j})} = \sqrt{2mC_{\mathcal{X}}^k} \sum_{i=1}^{T} \left(\sum_{j=1}^{T} \sqrt{e_{\mathcal{I}_i} + e_{\mathcal{I}_j}} \right) \\ &\leq \sqrt{2mC_{\mathcal{X}}^k} \sum_{i=1}^{T} \left(\sqrt{T} \sqrt{Te_{\mathcal{I}_i} + \sum_{j=1}^{T} e_{\mathcal{I}_j}} \right) \leq 2T\sqrt{mC_{\mathcal{X}}^k Te} \end{aligned}$$

where $e = \sum_{j=1}^{T} e_{\mathcal{I}_j} = \sum_{x_i \in \mathcal{X}} \|x_i - z_{c(i)}\|^2$ is the same as defined in proposition 3. Similarly, the second term (and the third term) in (9) can be summarized as

$$\sum_{i,j=1}^{T} \sqrt{mC_{\mathcal{X}}^k e_{\mathcal{I}_i}} = \sqrt{mC_{\mathcal{X}}^k} \sum_{j=1}^{T} \left(\sum_{i=1}^{T} \sqrt{e_{\mathcal{I}_i}} \right) \leq T\sqrt{mC_{\mathcal{X}}^k eT}$$

The last term in (9) can be summarized as

$$\begin{aligned} \sum_{i,j=1}^{T} mC_{\mathcal{X}}^k \sqrt{e_{\mathcal{I}_i} e_{\mathcal{I}_j}} \|W^{-1}\|_F &= mC_{\mathcal{X}}^k \|W^{-1}\|_F \left(\sum_{i=1}^{T} \sqrt{e_{\mathcal{I}_i}} \right)^2 \\ &\leq mC_{\mathcal{X}}^k \|W^{-1}\|_F Te \end{aligned}$$

By combining all these terms, we arrive at Proposition 3. □

3.4. $C_{\mathcal{X}}^k$ Under Different Kernels

In this section, we show that many commonly used kernel functions satisfy the property in (8). Consider the stationary kernel $k(x,y) = \kappa\left(\left\|\frac{x-y}{\sigma}\right\|\right)$, including the Gaussian kernel $\kappa(\alpha) = \exp(-\alpha^2)$, Laplacian kernel $\kappa(\alpha) = \exp(-\alpha)$, and inverse distance kernel $\kappa(\alpha) = (\alpha + \epsilon)^{-1}$. By using the mean value theorem and triangular inequality, we have, for any $a, b, c, d \in R^d$,

$$\begin{aligned} (k(a,b) - k(c,d))^2 &= \left(\kappa\left(\|a-b\|/\sigma \right) - \kappa\left(\|c-d\|/\sigma \right) \right)^2 \\ &= \left[\kappa'(\xi)/\sigma \right]^2 \left(\|a-b\| - \|c-d\| \right)^2. \end{aligned}$$

Let $v_1 = a - c$ and $v_2 = b - d$. Note that we have $\|c-d\| \leq \|a-b\| + \|v_1\| + \|v_2\|$ and similarly $\|a-b\| \leq \|c-d\| + \|v_1\| + \|v_2\|$. So $\|a-b\| - \|c-d\|$ is always bounded by

$$\begin{aligned} \left(\|a-b\| - \|c-d\| \right)^2 &\leq \left(\|a-c\| + \|b-d\| \right)^2 \\ &\leq 2\left(\|a-c\|^2 + \|b-d\|^2 \right). \end{aligned}$$

So $C_{\mathcal{X}}^k$ can be chosen as $\max[2\kappa'(\xi)/\sigma]^2$ which is often bounded ($C_{\mathcal{X}}^k$ is $\frac{1}{2\sigma^2}$ for the Gaussian, $\frac{1}{\sigma^2}$ for the Laplacian, and $\frac{1}{\sigma^2\epsilon^4}$ for the inverse distance). Similarly, for polynomial kernels of the form $k(x,y) = (\langle x, y \rangle + \epsilon)^d$,

$$\begin{aligned} &(k(a,b) - k(c,d))^2 = \left((a'b + \epsilon)^d - (c'd + \epsilon)^d \right)^2 \\ &= \left(p'(\xi)(a'b - c'd) \right)^2 = \left(p'(\xi) \left((a-c)'b + (b-d)'c \right) \right)^2 \\ &\leq \left[2p'(\xi) \right]^2 \left(\|(a-c)'b\|^2 + \|(b-d)'c\|^2 \right) \\ &\leq \left[2p'(\xi) R \right]^2 \left(\|a-c\|^2 + \|b-d\|^2 \right), \end{aligned}$$

where R is the larger one of the two quantities: the maximum pairwise distance between samples, and maximum distance between samples and the origin point; and $p(z) = z^d$. So $C_{\mathcal{X}}^k$ can be chosen as $\max[\kappa'(\xi)R]^2 = d^2R^d$.

3.5. Sampling Procedure

The error bound in Proposition 3 provides important insights on how to choose the landmark points in the Nyström method. As can be seen, consistently, that for a number of commonly used kernels, the most important factor that influences the approximation quality is e, the error of quantizing each of the samples in $\mathcal{X}$ with the closest landmark in $\mathcal{Z}$. If this quantization error is zero, the Nyström low-rank approximation of the kernel matrix will also be exact. This agrees well with the ideal case discussed in Section 3.1.

Motivated by this observation and the fact that k-means clustering can find a local minimum of the quantization error (Gersho & Gray, 1992), we propose to use the centers obtained from the k-means as the landmark points. Here, k is the desired number of landmark points in $\mathcal{Z}$. The larger the k, the more accurate the approximation though at the cost of higher computations. Despite its simplicity, the k-means procedure can greatly improve the approximation quality compared to other sampling schemes, as will be demonstrated empirically in Section 4. Recent advances in speeding up the k-means algorithms (Elkan, 2003; Kanungo et al., 2001) also make this k-means-based sampling strategy particularly suitable for large-scale problems.

4. Experiments

This section presents empirical evaluations of the various low-rank approximation schemes. First, we discuss how the low rank approximation fits into different applications. One is to solve linear systems of the form $(K + \sigma I)x = a$, where K is the kernel matrix, $\sigma \geq 0$ is a regularization parameter and I is the $n \times n$ identity matrix. Given the low-rank approximation $K \simeq GG'$, the following holds (Williams & Seeger, 2001) by the Woodbury formula

$$(K + \sigma I)^{-1} \simeq \frac{1}{\sigma}\left(I - G(\sigma I + G'G)^{-1}G'\right), \qquad (13)$$

which only needs $O(m^2n)$ time and $O(mn)$ memory. Therefore, it can be used in speeding up the Gaussian processes (Williams & Seeger, 2001) and least-squares SVM (LS-SVM) (Suykens & Vandewalle, 1999).

The second application is to reconstruct the eigen-system of a matrix approximated by its low-rank decomposition.

Proposition 4. *Given the low-rank approximation $K \approx GG'$, where $G \in \mathbb{R}^{n\times m}$ and $m \ll n$, the top m eigenvectors U of K can be obtained as $U \approx GV\Lambda^{-1/2}$ in $O(m^2n)$ time, where $V, \Lambda \in \mathbb{R}^{m\times m}$ are from the eigenvalue decomposition of the $m \times m$ matrix $S = G'G = V\Lambda V'$.*

Proof can be found in (Fowlkes et al., 2004). Therefore low-rank approximation is useful for algorithms that rely on eigenvectors of the kernel matrix, such as kernel PCA (Schölkopf et al., 1998), Laplacian eigenmap (Belkin & Niyogi, 2002) and normalized cut.

Note that the Nyström method, when designed originally to solve integral equations, did not provide orthogonal approximations to the kernel eigenfunctions. Thanks to the matrix completion view (5) (Fowlkes et al., 2004; Williams & Seeger, 2001), the Nyström method can be utilized for obtaining orthogonal eigenvectors (Proposition 4), though the time complexity increases from the simple Nyström extension (4) of $O(mn)$ to $O(m^2n)$. In the experiments we focus on the orthogonalized eigenvector approximation.

Table 1. Complexities of basis selection for the different methods.

	Ours	Nyström	Drineas	ICD
time	$O(mn)$	$O(n)$	$O(n^2)$	$O(m^2n)$
space	$O(mn)$	$O(mn)$	$O(mn)$	$O(mn)$

We compare altogether five low-rank approximation algorithms, including: 1. incomplete Cholesky decomposition (ICD)[2]; 2. Nyström method (with random sampling); 3. the method in (Drineas & Mahoney, 2005); 4. our method (for simplicity, the maximum number of k-means iterations is restricted to 10); 5. SVD. Note that SVD (or eigenvalue decomposition in our context) provides the best low-rank approximation in terms of both the Frobenius norm and spectral norm (Golub & Van Loan, 1996). The complexities of basis selection (i.e., choosing E and W in Nyström, or sampling the columns in (Drineas & Mahoney, 2005) and ICD) in the different algorithms are listed in Table 1. Evaluations are performed in the contexts of kernel matrix approximation (Section 4.1), kernel PCA (Section 4.2), and LS-SVM classification (Section 4.3). We use core(TM)-dual PC with 2.13GHz CPU and the codes are in matlab.

4.1. Approximating the Kernel Matrix

We first examine the performance of the low-rank approximation schemes by measuring their approximation errors (in terms of the Frobenius norm) on the kernel matrix. We choose a number of benchmark data sets from the LIBSVM archive[3], summarized in Table 2. Note that our approximation error bound in Proposition 3 applies to most kernel functions (Section 3.4), and preliminary experimental results with these kernels have shown the superiority of our sampling scheme compared with other low-rank approximation methods. However, due to lack of space, we

[2] http://www.di.ens.fr/∼fbach/kernel-ica/index.htm

[3] http://www.csie.ntu.edu.tw/∼cjlin/libsvmtools/datasets/

Table 2. A summary of data sets.

data	german	splice	adult1a	dna
size	1000	1000	1605	2000
dimension	24	60	123	180
data	segment	w1a	svmgd1a	satimage
size	2310	2477	3089	4435
dimension	19	300	4	36

will only report results for the Gaussian kernel $K(x, y) = \exp(-\|x - y\|^2/\gamma)$. Here, γ is chosen as the average squared distance between data points and the mean of each data set. We gradually increase the subset size m from 1% to 10% of the data size. To reduce statistical variability, results of methods 2, 3, and 4 are based on averages over 20 repetitions.

The approximation errors are plotted in Figure 1. As can be seen, our algorithm is only inferior to SVD on most data sets. Moreover, though the method in (Drineas & Mahoney, 2005) involves a more complicated probabilistic sampling scheme, its performance is only comparable or sometimes even worse than the Nyström method with simple random sampling. Similar observations have also been reported in the context of SVD (Drineas et al., 2003). ICD seems to be inferior on several data sets. However, for data sets whose kernel spectra decay rapidly to zero[4] (such as the segment, svmguide1a and satimage), ICD can also quickly attain performance comparable to others.

We also examine empirically the relationship between $\mathcal{E}$ and e under different sampling schemes. Figure 2 reports the results on the german data, where $m = 100$ and each sampling scheme is repeated 100 times. As can be seen, there is a strong, positive correlation between $\mathcal{E}$ and e. This is observed on most data and agrees with our error analysis.

4.2. Kernel PCA

In kernel PCA, the key step is to obtain eigenvectors of the centered kernel matrix HKH, where $H = I - \frac{1}{n}11' \in \mathbb{R}^{n\times n}$. Following Proposition 2 of (Ouimet & Bengio, 2005), with the low-rank decomposition $K \simeq GG'$, the centered kernel matrix can be written as $(HG)(HG)'$ or $(G - \bar{G})(G - \bar{G})'$, where $\bar{G} \in R^{n\times m}$ and all its rows equal to the mean of rows in G. Hence the top m eigenvectors can be obtained in $O(m^2 n)$ time according to Proposition 4.

We evaluate the low rank approximation schemes by the embedding onto the top 3 principal directions. We align the approximate embeddings ($\tilde{U}$) with the standard KPCA embedding (U) through a linear transform, and report the minimum misalignment error: $\min_{A\in\mathbb{R}^{3\times 3}} \|U - \tilde{U}A\|_F$. The parameter setting is the same as in Section 4.1, except that we fix $m = 0.05n$ for all the low-rank decomposition algorithms. Again, results of methods 2, 3, 4 in Table 3 are averaged over 20 repetitions. As we can seen, our algorithm is the best on most data sets, next comes the standard Nyström and the method by (Drineas & Mahoney, 2005). The time consumptions of all low-rank approximation schemes are significantly lower than SVD.

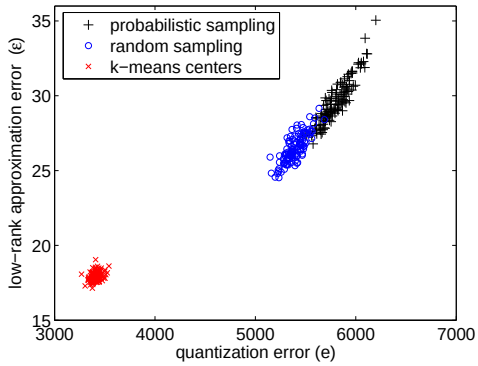

Figure 2. Low-rank approximation error versus quantization error for different sampling schemes.

4.3. Least Squares SVM

Given the kernel matrix K, the training labels $y \in \{\pm 1\}^{n\times 1}$, and the regularization parameter $C > 0$, the LS-SVM classifier $f(x) = \sum_{i=1}^n \alpha_i \phi(x, x_i) + b$ is solved by $b = y'M^{-1}1/y'M^{-1}y$, and $\alpha = M^{-1}(1 - by)$, where 1 is a vector of all ones, and $M = Y(K + I/C)Y$ and $Y = \text{diag}(y)$. Note that $M^{-1} = Y(K + I/C)^{-1}Y$ can be computed efficiently using (13).

We evaluate different low-rank approximation schemes in LS-SVM, using some difficult pairs of the USPS digits[5]. We use Gaussian kernel $\exp(-\|x - y\|^2/\gamma)$ and $C = 0.5$. Table 4 reports the classification performance of the standard LS-SVM, and those with different low-rank approximation schemes, at $m = 0.05n$ and $0.1n$. Again, methods 2, 3, 4 are repeated 20 times. For $m = 0.05n$, our approach is significantly better than methods 1,2,3 with a confidence level that is at least 99.5%. For $m = 0.1n$, ours is also better with a confidence level that is at least 97.5% on the first 7 pairs. For the last 4 pairs, the differences between our approach and methods 1,2,3 are not statistically significant. Note, however, that the testing errors obtained by the various approximation algorithms on these 4 pairs are all close to those of the exact LS-SVM, i.e., all approximation algorithms have reached their possibly best performance.

[4]Note that the (squared) rank-m approximation error of SVD is $\sum_{i=m+1}^n \sigma_i^2$, where σ_i's are the singular values of K sorted in descending order (Golub & Van Loan, 1996). Therefore, if SVD's error in Figure 1 drops rapidly, so does the spectrum of K.

5. Conclusion

The Nyström method is a useful technique for low-rank approximation. However, analysis on its key step of choosing the landmark points and especially that in terms of approximation quality is still limited. In this paper, we draw an intuitive but important connection between the Nyström approximation quality and the encoding capacities of landmark points. Our analysis suggests the k-means as a natural sampling scheme. Despite its simplicity, the k-means-based sampling gives encouraging performance when empirically compared with state-of-the-art low-rank approximation techniques. One future direction is to utilize label/side information for task-specific decomposition, where one excellent example is (Bach & Jordan, 2005) in the context of incomplete Cholesky decomposition.

Estimating Local Optimums in EM Algorithm over Gaussian Mixture Model

Abstract

EM algorithm is a very popular iteration-based method to estimate the parameters of Gaussian Mixture Model from a large observation set. However, in most cases, EM algorithm is not guaranteed to converge to the global optimum. Instead, it stops at some local optimums, which can be much worse than the global optimum. Therefore, it is usually required to run multiple procedures of EM algorithm with different initial configurations and return the best solution. To improve the efficiency of this scheme, we propose a new method which can estimate an upper bound on the logarithm likelihood of the local optimum, based on the current configuration after the latest EM iteration. This is accomplished by first deriving some region bounding the possible locations of local optimum, followed by some upper bound estimation on the maximum likelihood. With this estimation, we can terminate an EM algorithm procedure if the estimated local optimum is definitely worse than the best solution seen so far. Extensive experiments show that our method can effectively and efficiently accelerate conventional multiple restart EM algorithm.

1. Introduction

Gaussian Mixture Model (GMM) (McLachlan & Peel, 2000) is a powerful tool in unsupervised learning to model unlabelled data in a multi-dimensional space. However, given an observation data set, estimating the parameters of the underlying Gaussian Mixture Model of the data is not a trivial task, especially when the dimensionality or the number of components is large. Usually, this model estimation problem is transformed to a new problem, which try to find parameters maximizing the likelihood probability on the observations from the Gaussian distributions. In the past decades, EM algorithm (Dempster et al., 1977) has become the most widely method used in the problem of learning Gaussian Mixture Model (Ma et al., 2001; Jordan & Xu, 1995; McLachlan & Krishnan, 1996).

Although EM algorithm can converge in finite iterations, there is no guarantee on the convergence to global optimum. Instead, it usually stops at some local optimum, which can be arbitrarily worse than the global optimum. Although there have been extensive studies on how to avoid bad local optimums, it is still required to run EM algorithm with different random initial configurations and the best local optimum is returned as final result. This leads to a great waste of computation resource since most of the calculations do not have any contribution to the final result.

In this paper, we propose a fast stopping method to overcome the problem of trapping into bad local optimums. Given any current configuration after an EM iteration, our method can estimate an upper bound on the final likelihood of the local optimum current configuration is leading to. Therefore, if the estimated local optimum is definitely not better than the best local optimum achieved in previous runs, current procedure can be terminated immediately.

To facilitate such local optimum estimation, we first prove that a region in the parameter space can definitely cover the unknown local optimum. If a region covers the current configuration and any configuration on the boundary of the region gives lower likelihood than the current one does, we can show that the local optimum is "trapped" in the region; and we call such region as a maximal region. In this paper, we adopt a

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

special type of maximal region, which can be computed efficiently. Since the best likelihood of any configuration in a maximal region can be estimated in relatively short time, it can be decided immediately on whether current procedure still has potential to achieve a better local optimum. In our experiments, such method is shown to greatly improve the efficiency of original EM algorithm for GMM, on both synthetic and real data sets.

The rest of the paper is organized as follows. We first introduce the definitions and related works on Gaussian Mixture Model and EM algorithm in Section 2 . Section 3 proves the local trapping property of EM algorithm on GMM; and Section 4 presents our study on maximal region of local optimum. We propose our algorithm on estimating the likelihood of a local optimum in Section 5 . Section 6 shows some experimental result. Finally, section 7 concludes this paper.

2. Model and Related Works

In this section, we review the basic models of Gaussian Mixture Model, EM algorithm, and some acceleration method proposed for a special type of Gaussian Mixture Model (K-Means Algorithm).

2.1. Gaussian Mixture Model

In GMM model (McLachlan & Peel, 2000), there exist k underlying components $\{\omega_1, \omega_2, \ldots, \omega_k\}$ in a d-dimensional data set. Each component follows some Gaussian distribution in the space. The parameters of the component ω_j include $\mathbf{\Theta}_j = \{\boldsymbol{\mu}_j, \mathbf{\Sigma}_j, \pi_j\}$, in which $\boldsymbol{\mu}_j = (\boldsymbol{\mu}_j[1], \ldots, \boldsymbol{\mu}_j[d])$ is the center of the Gaussian distribution, $\mathbf{\Sigma}_j$ is the covariance matrix of the distribution and π_j is the probability of the component ω_j. Based on the parameters, the probability of a point coming from component ω_j appearing at $\boldsymbol{x} = (x[1], \ldots, x[d])$ can be represented by

$$\Pr(\boldsymbol{x}|\mathbf{\Theta}_j) = \frac{|\mathbf{\Sigma}_j^{-1}|^{1/2}}{(2\pi)^{d/2}} \exp\left\{-\frac{1}{2}(x-\boldsymbol{\mu}_j)^T \mathbf{\Sigma}_j^{-1}(x-\boldsymbol{\mu}_j)\right\}$$

Thus, given the component parameter set $\mathbf{\Theta} = \{\mathbf{\Theta}_1, \mathbf{\Theta}_2, \ldots, \mathbf{\Theta}_k\}$ but without any component information on an observation point $\boldsymbol{x}$, the probability of observing $\boldsymbol{x}$ is estimated by

$$\Pr(\boldsymbol{x}|\mathbf{\Theta}) = \sum_{j=1}^{k} \Pr(\boldsymbol{x}|\mathbf{\Theta}_j)\pi_j$$

The problem of learning GMM is estimating the parameter set $\mathbf{\Theta}$ of the k component to maximize the likelihood of a set of observations $D = \{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n\}$, which is represented by

$$\Pr(D|\mathbf{\Theta}) = \prod_{i=1}^{n} \Pr(\boldsymbol{x}_i|\mathbf{\Theta}) \tag{1}$$

Based on the parameters of the GMM model, the posterior probability of $\boldsymbol{x}_i$ from component ω_j (or the weight of $\boldsymbol{x}_i$ in component j), τ_{ij}, can be calculated as follows.

$$\tau_{ij} = \frac{\Pr(\boldsymbol{x}_i|\mathbf{\Theta}_j)\pi_j}{\sum_{l=1}^{k} \Pr(\boldsymbol{x}_i|\mathbf{\Theta}_l)\pi_l} \tag{2}$$

To simplify the notations, we use $\mathbf{\Phi}$ to denote the set of all τ_{ij} for any pair of i, j, and use $\Psi(\mathbf{\Theta})$ to denote the corresponding $\mathbf{\Phi}$ based on current configuration $\mathbf{\Theta}$. For ease of analysis, the original optimization problem on equation (1), is usually transformed to an equal maximization problem on the following variable, called log likelihood.

$$\begin{aligned} L(\mathbf{\Theta}, \mathbf{\Phi}) \quad = \quad & \sum_{i=1}^{n}\sum_{j=1}^{k} \tau_{ij}(\ln\frac{\pi_j}{\tau_{ij}} + \frac{\ln|\mathbf{\Sigma}_j^{-1}|}{2} - \\ & \frac{(\boldsymbol{x}_i-\boldsymbol{\mu}_j)^T\mathbf{\Sigma}_j^{-1}(\boldsymbol{x}_i-\boldsymbol{\mu}_j)}{2}) \end{aligned} \tag{3}$$

L is actually a function over $\mathbf{\Theta}$ and $\mathbf{\Phi}$, the latter of which is usually optimized according to $\mathbf{\Theta}$. Thus, the problem of learning GMM is finding an optimal parameter set $\mathbf{\Theta}^*$ which can maximize the function $L(\mathbf{\Theta}^*, \Psi(\mathbf{\Theta}^*))$.

2.2. EM Algorithm

EM algorithm (Dempster et al., 1977) is a widely used technique for probabilistic parameter estimation. To estimate $\mathbf{\Theta} = \{\mathbf{\Theta}_1, \ldots, \mathbf{\Theta}_k\}$, it starts with a randomly chosen initial parameter configuration $\mathbf{\Theta}^0$. Then, it keeps invoking iterations to recompute $\mathbf{\Theta}^{t+1}$ based on $\mathbf{\Theta}^t$. Every iteration consists of two steps, E-step and M-step. In E-step, the algorithm computes the expected value of τ_{ij} for each pair of i and j based on $\mathbf{\Theta}^t = \{\mathbf{\Theta}_1^t, \ldots, \mathbf{\Theta}_k^t\}$ and equation (2).

In M-step, the algorithm finds a new group of parameters $\mathbf{\Theta}^{t+1}$ to maximize L based on $\mathbf{\Phi}^t = \{\tau_{ij}^t\}$ and $\{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n\}$. The details of the update process for $\boldsymbol{\mu}_j$, $\mathbf{\Sigma}_j$ and π_j are listed below.

$$\boldsymbol{\mu}_j^{t+1}[l] = \frac{\sum_{i=1}^{n} \tau_{ij}^t \boldsymbol{x}_i[l]}{\sum_{i=1}^{n} \tau_{ij}^t} \tag{4}$$

$$\boldsymbol{\Sigma}_j^{t+1} = \frac{\sum_{i=1}^n \tau_{ij}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^{t+1})(\boldsymbol{x}_i - \boldsymbol{\mu}_j^{t+1})^T}{\sum_{i=1}^n \tau_{ij}^t} \quad (5)$$

$$\pi_j^{t+1} = \frac{\sum_{i=1}^n \tau_{ij}^t}{n} \quad (6)$$

The iteration process stops only when $\boldsymbol{\Theta}^N = \boldsymbol{\Theta}^{N-1}$ after N iterations. We note that both E-step and M-step always improve the objective function, i.e. $L(\boldsymbol{\Theta}^t, \boldsymbol{\Phi}^t) \geq L(\boldsymbol{\Theta}^t, \boldsymbol{\Phi}^{t-1}) \geq L(\boldsymbol{\Theta}^{t-1}, \boldsymbol{\Phi}^{t-1})$. Based on this property, EM-algorithm will definitely converge to some local optimum. The convergence properties of EM algorithm over GMM have been extensively studied in (Xu & Jordan, 1996; Ma et al., 2001).

2.3. K-Means Algorithm and Its Acceleration

K-Means algorithm can be considered as a special problem of GMM learning with several constraints. First, the covariance matrix for each component must be identity matrix. Second, the posterior probability τ_{ij} can only be 0 or 1. Therefore, in E-step of the algorithm, each point is assigned to the closest center under Euclidean distance; whereas in M-step, the set of geometric center of each cluster is used to replace the old set.

With the problem simplification from GMM to K-Means, there have been many methods proposed to accelerate the multiple restart EM algorithm for K-Means. In (Kanungo et al., 2002), for example, Kanungo et al. applied indexing technique to achieve a much more efficient implementation of E-step. In (Elkan, 2003), Elkan accelerated both E-step and M-step by employing triangle inequality of Euclidean distance to reduce the time for distance computations. In (Zhang et al., 2006), Zhang et al. introduced a lower bound estimation on the k-means local optimums to efficiently cut the procedures not leading to good solutions. However, all these methods proposed for k-means algorithm cannot be directly extended to the general GMM. As far as we know, our paper is the first study on acceleration of the multiple restart EM algorithm with robustness guarantee.

To improve the readability of the paper, we summarize all notations in Table 1.

Table 1: Table of Notations

Notation	Description
n	number of points in data
d	dimensionality of data space
k	number of components
ω_j	component j
$\boldsymbol{\Theta}_j$	parameter set of ω_j
$\boldsymbol{\mu}_j$	center of ω_j
$\boldsymbol{\Sigma}_j$	covariance matrix of ω_j
π_j	probability of ω_j
$\boldsymbol{\Theta}$	configuration of all components
$\boldsymbol{x}_i$	ith point in the data
τ_{ij}	posterior probability $\Pr(\omega_j \vert \boldsymbol{x}_i)$
$\boldsymbol{\Phi}$	the set of all τ_{ij}
$\Psi(\boldsymbol{\Theta})$	the optimal $\boldsymbol{\Phi}$ with $\boldsymbol{\Theta}$
$\mathcal{S}$	solutions space for configurations
$L(\boldsymbol{\Theta}, \boldsymbol{\Phi})$	objective log likelihood function
Δ	a parameter for a maximal region

3. Local Trapping Property

In this section, we prove the local trapping property of EM algorithm on GMM. To derive the analysis, we first define a solution space $\mathcal{S}$, containing $(d^2 + d + 1)k$ dimensions where d is the dimensionality of the original data space. Any configuration $\boldsymbol{\Theta}$, either valid or invalid, can be represented by a point in $\mathcal{S}$. Without loss of generality, we use $\boldsymbol{\Theta}$ to denote the configuration as well as the corresponding point in solution space $\mathcal{S}$. The rest of the section will be spent to prove the following theorem.

Theorem 1 *Given a closed region R in the solution space $\mathcal{S}$ covering current configuration $\boldsymbol{\Theta}^t$, EM algorithm converges to a local optimum in R if every configuration $\boldsymbol{\Theta}$ on the boundary of R has $L(\boldsymbol{\Theta}, \Psi(\boldsymbol{\Theta})) < L(\boldsymbol{\Theta}^t, \boldsymbol{\Phi}^t)$*

Given two configurations $\boldsymbol{\Theta}^t$ and $\boldsymbol{\Theta}^{t+1}$ across one EM iteration, we define a path between $\boldsymbol{\Theta}^t$ and $\boldsymbol{\Theta}^{t+1}$ in $\mathcal{S}$ as follows. This path consists of two parts, called P^1 and P^2 respectively. P^1 starts at $\boldsymbol{\Theta}^t$ and ends at $\boldsymbol{\Theta}^\#$, where $\boldsymbol{\Theta}^\# = \{\boldsymbol{\Theta}_j^\#\}$. Here $\boldsymbol{\Theta}_j^\# = \{\boldsymbol{\mu}_j^t, \boldsymbol{\Sigma}_j^\#, \pi_j^t\}$, and $\boldsymbol{\Sigma}_j^\# = \sum_i \tau_{ij}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^t)(\boldsymbol{x}_i - \boldsymbol{\mu}_j^t)^T / \sum_i \tau_{ij}^t$. An intermediate configuration between $\boldsymbol{\Theta}^t$ and $\boldsymbol{\Theta}^\#$ is defined as $\boldsymbol{\Theta}^\alpha$, in which $\boldsymbol{\mu}_j^t$ and π_j^t remain the same, while $\boldsymbol{\Sigma}_j^\alpha$ in $\boldsymbol{\Theta}^\alpha$ is $((1-\alpha)(\boldsymbol{\Sigma}^t)^{-1} + \alpha(\boldsymbol{\Sigma}^\#)^{-1})^{-1}$. When α increases from 0 to 1, we can move from $\boldsymbol{\Theta}^t$ to $\boldsymbol{\Theta}^\#$ in the solutions space $\mathcal{S}$. The second part of the path starts at $\boldsymbol{\Theta}^\#$ and ends at $\boldsymbol{\Theta}^{t+1}$. Any intermediate configuration $\boldsymbol{\Theta}^\beta = \{\boldsymbol{\Theta}_j^\beta\}$, where $\boldsymbol{\mu}_j^\beta = (1-\beta)\boldsymbol{\mu}_j^t + \beta\boldsymbol{\mu}_j^{t+1}$, $\boldsymbol{\Sigma}_j^\beta = \sum_i \tau_{ij}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta)(\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta)^T / \sum_i \tau_{ij}^t$, and $\pi_j^\beta = (\pi_j^t)^{1-\beta}(\pi_j^{t+1})^\beta$. Similarly, a continuous movement from $\boldsymbol{\Theta}^\#$ to $\boldsymbol{\Theta}^{t+1}$ can be made by increasing β from 0 to 1. The following lemmas prove that any intermediate configuration on the path is a better solution than $\boldsymbol{\Theta}^t$.

Lemma 1 *Given any intermediate configuration $\mathbf{\Theta}^\alpha$ between $\mathbf{\Theta}^t$ and $\mathbf{\Theta}^\#$, we have $L(\mathbf{\Theta}^\alpha, \Psi(\mathbf{\Theta}^\alpha)) \geq L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$.*

Proof: By the optimality property of $\Psi(\mathbf{\Theta}^\alpha)$, we have $L(\mathbf{\Theta}^\alpha, \Psi(\mathbf{\Theta}^\alpha)) \geq L(\mathbf{\Theta}^\alpha, \mathbf{\Phi}^t)$.

Since $\mathbf{\Sigma}_j^\# = \sum_i \tau_{ij}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^t)(\boldsymbol{x}_i - \boldsymbol{\mu}_j^t)^T / \sum_i \tau_{ij}^t$ is the optimal choice for $\mathbf{\Sigma}_j$ if τ_{ij}^t, $\boldsymbol{\mu}_j^t$ and π_j^t are fixed, we also have $L(\mathbf{\Theta}^\#, \mathbf{\Phi}^t) \geq L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$.

By the definition of $\mathbf{\Theta}^\alpha$ and the property of $\mathbf{\Theta}^\#$ above, the following equations can be easily derived.

$$\begin{aligned} & L(\mathbf{\Theta}^\alpha, \mathbf{\Phi}^t) \\ = \; & (1-\alpha) L(\mathbf{\Theta}^t, \mathbf{\Phi}^t) + \alpha L(\mathbf{\Theta}^\#, \mathbf{\Phi}^t) \\ \geq \; & L(\mathbf{\Theta}^t, \mathbf{\Phi}^t) \end{aligned}$$

Therefore, it is straightforward to reach the conclusion that $L(\mathbf{\Theta}^\alpha, \Psi(\mathbf{\Theta}^\alpha)) \geq L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$. □

Lemma 2 *Given any intermediate configuration $\mathbf{\Theta}^\beta$ between $\mathbf{\Theta}^\#$ and $\mathbf{\Theta}^{t+1}$, we have $L(\mathbf{\Theta}^\beta, \Psi(\mathbf{\Theta}^\alpha)) \geq L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$.*

Proof: Again, the basic inequality $L(\mathbf{\Theta}^\beta, \Psi(\mathbf{\Theta}^\beta)) \geq L(\mathbf{\Theta}^\beta, \mathbf{\Theta}^t)$ holds. Based on this, we can prove the lemma by showing $L(\mathbf{\Theta}^\beta, \mathbf{\Phi}^t) \geq L(\mathbf{\Theta}^\#, \mathbf{\Phi}^t)$, since $L(\mathbf{\Theta}^\#, \mathbf{\Phi}^t) \geq L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$.

If $\mathbf{\Sigma}_j^\beta = \sum_i \tau_{ij}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta)(\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta)^T / \sum_i \tau_{ij}^t$, a very interesting result is that $\sum_j \sum_i \tau_{ij}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta)^T (\mathbf{\Sigma}_j^\beta)^{-1} (\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta)$ remains constant for any β, as is shown below.

$$\sum_j \sum_i \tau_{ij}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta)^T (\mathbf{\Sigma}_j^\beta)^{-1} (\boldsymbol{x}_i - \boldsymbol{\mu}_j^\beta) = nd$$

Therefore, for any $\mathbf{\Theta}^\beta$, we only need to consider the sum $\sum_i \sum_j \tau_{ij}^t \left(\ln(\pi_j^\beta / \tau_{ij}^t) - \ln(|\mathbf{\Sigma}_j^\beta|)/2 \right)$.

By the definition of π_j^β, since $\pi_j^\beta = (\pi_j^t)^{1-\beta} (\pi_j^{t+1})^\beta$, we have $\ln \pi_j^\beta = (1-\beta) \ln \pi_j^t + \beta \ln \pi_j^{t+1}$. Then,

$$\sum_{i=1}^n \tau_{ij}^t \ln \frac{\pi_j^\beta}{\tau_{ij}^t} = (1-\beta) \sum_{i=1}^n \tau_{ij}^t \ln \frac{\pi_j^t}{\tau_{ij}^t} + \beta \sum_{i=1}^n \tau_{ij}^t \ln \frac{\pi_j^{t+1}}{\tau_{ij}^t} \tag{7}$$

Therefore, $\sum_i \sum_j \tau_{ij}^t \ln \frac{\pi_j^\beta}{\tau_{ij}^t} \geq \sum_i \sum_j \tau_{ij}^t \ln \frac{\pi_j^t}{\tau_{ij}^t}$, since $\sum_{i=1}^n \tau_{ij}^t \ln \frac{\pi_j^{t+1}}{\tau_{ij}^t} \geq \sum_{i=1}^n \tau_{ij}^t \ln \frac{\pi_j^t}{\tau_{ij}^t}$.

On the other hand, based on the definition of $\mathbf{\Sigma}_j^\beta$, we can prove that

$$\begin{aligned} \mathbf{\Sigma}_j^\beta \; = \; & \sum_{i=1}^n \tau_{i,j}^t (\boldsymbol{x}_i - \boldsymbol{\mu}_j^t)(\boldsymbol{x}_i - \boldsymbol{\mu}_j^t)^T + \\ & (\beta^2 - 2\beta) (\sum_{i=1}^n \tau_{i,j}^t) (\boldsymbol{\mu}_j^{t+1} - \boldsymbol{\mu}_j^t)(\boldsymbol{\mu}_j^{t+1} - \boldsymbol{\mu}_j^t)^T \end{aligned}$$

Since $\beta^2 - 2\beta \leq 0$ for any β between 0 and 1, $\ln |\mathbf{\Sigma}_j^\beta| \leq \ln |\mathbf{\Sigma}_j^\#|$. And thus, we have $-\ln |\mathbf{\Sigma}_j^\beta|/2 \geq -\ln |\mathbf{\Sigma}_j^\#|/2$.

Combing the results above, we reach the conclusion that $L(\mathbf{\Theta}^\beta, \mathbf{\Phi}^t) \geq L(\mathbf{\Theta}^\#, \mathbf{\Phi}^t)$, leading to the correctness of the lemma. □

Proof for Theorem 1

Proof: We prove the theorem by contradiction. If R satisfies the boundary condition but EM algorithm converges to some configuration out of R in $\mathcal{S}$, there is at least one pair of configurations $\{\mathbf{\Theta}^s, \mathbf{\Theta}^{s+1}\}$ that $\mathbf{\Theta}^s$ is in R but $\mathbf{\Theta}^{s+1}$ is not. By setting up the path $\{\mathbf{\Theta}^\alpha\} \cap \{\mathbf{\Theta}^\beta\}$ between $\mathbf{\Theta}^s$ and $\mathbf{\Theta}^{s+1}$ as defined above, we know there is at least one $\mathbf{\Theta}^\alpha$ ($\mathbf{\Theta}^\beta$) that $\mathbf{\Theta}^\alpha$ ($\mathbf{\Theta}^\beta$) is exactly on the boundary of R. By Lemma 1 (Lemma 2), we know $L(\mathbf{\Theta}^\alpha, \Psi(\mathbf{\Theta}^\alpha)) \geq L(\mathbf{\Theta}^s, \mathbf{\Phi}^s)$ ($L(\mathbf{\Theta}^\beta, \Psi(\mathbf{\Theta}^\beta)) \geq L(\mathbf{\Theta}^s, \mathbf{\Phi}^s)$). On the other hand, any $\mathbf{\Theta}^\alpha$ or $\mathbf{\Theta}^\beta$ is better than $\mathbf{\Theta}^t$ by the definition of R. This leads to the contradiction, since $L(\mathbf{\Theta}^s, \mathbf{\Phi}^s) > L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$. □

4. Maximal Region

Based on Theorem 1, we define the concept of *Maximal Region* in GMM as follows. Given the current configuration $\mathbf{\Theta}^t$, a region R in S is the maximal region for $\mathbf{\Theta}^t$, if (1) R covers $\mathbf{\Theta}^t$, and (2) any boundary configuration $\mathbf{\Theta}$ of R has $L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) < L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$, by Theorem 1, EM algorithm converges to some local optimum in R.

Given the current configuration $\mathbf{\Theta}^t$, there are infinite number of valid maximal regions in the solution space, most of which are hard to verify and manipulate. To facilitate efficient computation, we further propose a special class of maximal regions. Given $\mathbf{\Theta}^t$ and a positive real value $\Delta < 1$, we define a closed region $R(\mathbf{\Theta}^t, \Delta) \subseteq S$ as the union of any configuration $\mathbf{\Theta}$, each $\theta_j = \{\boldsymbol{\mu}_j, \mathbf{\Sigma}_j, \pi_j\}$ of which satisfies all of the conditions below: (1) $(1-\Delta)\pi_j^t \leq \pi_j \leq (1+\Delta)\pi_j^t$; (2) $-\Delta \leq tr((\mathbf{\Sigma}_j^t)^{-1}(\mathbf{\Sigma}_j^t) - I) \leq \Delta$; and (3) $(\boldsymbol{\mu}_j - \boldsymbol{\mu}_j^t)^T (\mathbf{\Sigma}_j^t)^{-1} (\boldsymbol{\mu}_j - \boldsymbol{\mu}_j^t) \leq \Delta^2$; where $tr(M)$ denotes the trace of the matrix M and I is the identity matrix of dimension d.

Theorem 2 *Any configuration* $\mathbf{\Theta}$ *on the boundary of* $R(\mathbf{\Theta}^t, \Delta)$ *has* $L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1}) \leq L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) - n \min_j \pi_j^t \Delta^2/6$.

Proof: Given any $R(\mathbf{\Theta}^t, \Delta)$, any configuration on the boundary must satisfy one of the following conditions for at least one j $(1 \leq j \leq k)$: (1) $(1-\Delta)\pi_j^t = \pi_j$; (2) $\pi_j^t = (1+\Delta)\pi_j^t$; (3) $|tr(\mathbf{\Sigma}_j^{-1}(\mathbf{\Sigma}_j^t) - I)| = \Delta$; and (4) $(\boldsymbol{\mu}_j - \boldsymbol{\mu}_j^t)^T(\mathbf{\Sigma}_j^t)^{-1}(\boldsymbol{\mu}_j - \boldsymbol{\mu}_j^t) = \Delta^2$.

If $\mathbf{\Theta}$ satisfies condition (1) for some component l, $L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1})$ is maximized if $\boldsymbol{\mu}_j^t$ and $\mathbf{\Sigma}_j^t$ remain unchanged for all j, while $\pi_j = \frac{1-(1-\Delta)\pi_l^t}{1-\pi_l^t}\pi_j^t$ for all $j \neq l$. Therefore, we have the following upper bound.

$$\begin{aligned}
& L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1}) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) \\
\leq\ & n\pi_l^t \ln(1-\Delta) + n(1-\pi_l^t)\ln\frac{1-(1-\Delta)\pi_l^t}{1-\pi_l^t} \\
=\ & n\pi_l^t \ln(1-\Delta) + n(1-\pi_l^t)\ln\left(1+\frac{\Delta\pi_l^t}{1-\pi_l^t}\right) \\
\leq\ & n\pi_l^t\left(-\Delta - \frac{\Delta^2}{2}\right) + n(1-\pi_l^t)\frac{\Delta\pi_l^t}{1-\pi_l^t} \\
=\ & -\frac{n\pi_l^t\Delta^2}{2}
\end{aligned}$$

The second inequality from the bottom is achieved by applying Taylor expansion on $\ln(1-\Delta)$. By iterating l with all k components, we have $L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1}) \leq L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) - \min_j n\pi_l^t\Delta^2/2$.

If $\mathbf{\Theta}$ satisfies condition (2) for some component l, $L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1})$ can be maximized similarly. We have

$$\begin{aligned}
& L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1}) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) \\
\leq\ & n\pi_l^t \ln(1+\Delta) + n(1-\pi_l^t)\ln\frac{1-(1+\Delta)\pi_l^t}{1-\pi_l^t} \\
=\ & n\pi_l^t \ln(1+\Delta) + n(1-\pi_l^t)\ln\left(1-\frac{\Delta\pi_l^t}{1-\pi_l^t}\right) \\
\leq\ & n\pi_l^t\left(\Delta - \frac{\Delta^2}{2} + \frac{\Delta^3}{3}\right) + n(1-\pi_l^t)\frac{\Delta\pi_l^t}{1-\pi_l^t} \\
\leq\ & -\frac{n\pi_l^t\Delta^2}{6}
\end{aligned}$$

Again, the third inequality from the bottom is due to Taylor expansion of $\ln(1+\Delta)$. The last inequality is because $\Delta^3 \leq \Delta^2$ for any $0 \leq \Delta \leq 1$.

If $\mathbf{\Theta}$ satisfies condition (3) for some component l, L is maximized if all other parameters remain the same. Thus,

$$\begin{aligned}
& L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1}) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) \\
\leq\ & \frac{n\pi_l^t}{2}\left(\ln|\mathbf{\Sigma}_l^{-1}\mathbf{\Sigma}_l^t| - tr\left(\left(\mathbf{\Sigma}_l^{-1} - (\mathbf{\Sigma}_l^t)^{-1}\right)\mathbf{\Sigma}_l^t\right)\right) \\
=\ & \frac{n\pi_l^t}{2}\left(tr\left(\log\left(\mathbf{\Sigma}_l^{-1}\mathbf{\Sigma}_l^t\right)\right) - tr\left(\mathbf{\Sigma}_l^{-1}\mathbf{\Sigma}_l^t - I\right)\right) \\
\leq\ & \frac{n\pi_l^t}{2}\left(-\frac{tr(\mathbf{\Sigma}_l^{-1}\mathbf{\Sigma}_l^t - I)^2}{2}\right) \\
=\ & -\frac{n\pi_l^t\Delta^2}{4}
\end{aligned}$$

The fourth equality is derived by the definitions of $\mathbf{\Sigma}_l^t$ and π_l^t. And the second inequality from bottom is due to the taylor expansion on the logarithm matrix.

Finally, if $\mathbf{\Theta}$ satisfies condition (4) for some component l, L is maximized if $\mathbf{\Sigma}_l = \frac{\sum \tau_{il}(\boldsymbol{x}_i - \boldsymbol{\mu}_l)(\boldsymbol{x}_i - \boldsymbol{\mu}_l)^T}{\sum \tau_{il}}$. In this case, $\sum_i \tau_l^{t-1}(\boldsymbol{x}_i - \boldsymbol{\mu}_j)^T\mathbf{\Sigma}_j^{-1}(\boldsymbol{x}_i - \boldsymbol{\mu}_j) = \sum_i \tau_l^{t-1}(\boldsymbol{x}_i - \boldsymbol{\mu}_j^t)^T(\mathbf{\Sigma}_j^t)^{-1}(\boldsymbol{x}_i - \boldsymbol{\mu}_j^t) = n\pi_j d$. Thus, the only difference on the log likelihood function L stems from the change on the determinant of the covariance matrix.

$$\begin{aligned}
& L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1}) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) \\
\leq\ & \sum_{i=1}^n \frac{\tau_{il}}{2}\left(-\ln|\mathbf{\Sigma}_l| + \ln|\mathbf{\Sigma}_l^t|\right) \\
=\ & \sum_{i=1}^n \frac{\tau_{il}}{2}\left(-\ln|\mathbf{\Sigma}_l^t + (\boldsymbol{\mu}_l - \boldsymbol{\mu}_l^t)(\boldsymbol{\mu}_l - \boldsymbol{\mu}_l^t)^T)| + \ln|\mathbf{\Sigma}_l^t|\right) \\
\leq\ & \sum_{i=1}^n \frac{\tau_{il}}{2}\left(-\ln\left(|\mathbf{\Sigma}_l^t| + |(\boldsymbol{\mu}_l - \boldsymbol{\mu}_l^t)(\boldsymbol{\mu}_l - \boldsymbol{\mu}_l^t)^T|\right) + \ln|\mathbf{\Sigma}_l^t|\right) \\
\leq\ & \sum_{i=1}^n \frac{\tau_{il}}{2}\left(-\ln\left(|\mathbf{\Sigma}_l^t| + \Delta^2|\mathbf{\Sigma}_l^t|\right) + \ln|\mathbf{\Sigma}_l^t|\right) \\
=\ & -\sum_{i=1}^n \frac{\tau_{il}\ln(1+\Delta^2)}{2} \\
\leq\ & -\frac{n\pi_l^t\Delta^2}{2}
\end{aligned}$$

The fourth inequality applies the property of positive definite matrices that $|A+B| > |A| + |B|$ (Lutkepohl, 1996) .

In all of the four cases, the reduction on the likelihood function L is at least $-\frac{n\min_j \pi_j^t\Delta^2}{6}$. This completes the proof of the theorem. □

Last theorem implies that $\mathbf{\Theta}$ will reduce the log likelihood function by at least $n\min_j^t \pi_j\Delta^2/6$ if $\mathbf{\Phi}$ remains $\mathbf{\Phi}^{t-1}$. The following question is how much we can increase the likelihood if we use the optimal $\Psi(\mathbf{\Theta})$ instead of $\mathbf{\Phi}^{t-1}$.

Lemma 3 *Given* $\mathbf{\Theta} \in R(\mathbf{\Theta}^t, \Delta)$, $Pr(\boldsymbol{x}_i|\theta_j)\pi_j$ *is no larger than* $(1+\Delta)^{1.5}\frac{|(\mathbf{\Sigma}_j^t)^{-1}|^{1/2}}{(2\pi)^{d/2}}\exp\{-(1-\Delta)M(\boldsymbol{x},\mathbf{\Theta}_j)^2/2\}\pi_j^t$, *where* $M(\boldsymbol{x},\mathbf{\Theta}_j)$ *is*

$$\max\left\{\sqrt{((x-\boldsymbol{\mu}_j^t)^T(\mathbf{\Sigma}_j^t)^{-1}(x-\boldsymbol{\mu}_j^t))}-\Delta, 0\right\}$$

Lemma 4 *Given* $\mathbf{\Theta} \in R(\mathbf{\Theta}^t, \Delta)$, $Pr(\boldsymbol{x}_i|\theta_j)\pi_j$ *is no smaller than* $(1-\Delta)^{1.5}\frac{|(\mathbf{\Sigma}_j^t)^{-1}|^{1/2}}{(2\pi)^{d/2}}\exp\{-(1+\Delta)N(\boldsymbol{x},\mathbf{\Theta}_j)^2/2\}\pi_j^t$, *where* $N(\boldsymbol{x},\mathbf{\Theta}_j)$ *is*

$$\sqrt{((x-\boldsymbol{\mu}_j^t)^T(\mathbf{\Sigma}_j^t)^{-1}(x-\boldsymbol{\mu}_j^t))}+\Delta$$

.

The proofs of Lemma 3 and Lemma 4 are available in (Zhang et al., 2008).

Lemma 5 *Given a region* $R(\mathbf{\Theta}^t, \Delta)$ *as defined above, an upper bound,* U_{ij}, *on* $\tau_{ij} \in \Psi(\mathbf{\Theta})$ *for any* $\mathbf{\Theta} \in R(\mathbf{\Theta}^t, \Delta)$ *can be calculated in constant time.*

Proof: For any configuration $\mathbf{\Theta}$ on the boundary of $R(\mathbf{\Theta}^t, \Delta)$, the optimal value of τ_{ij} can be calculated by equation (2). By Lemma 3 and Lemma 4, we can compute $\max_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_j)\pi_j$ and $\min_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_j)\pi_j$. Therefore,

$$\tau_{ij} \le U_{ij} = \frac{\max_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_j)\pi_j}{\sum_l \min_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_l)\pi_j}$$

$$\tau_{ij} \ge L_{ij} = \frac{\min_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_j)\pi_j}{\sum_l \max_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_l)\pi_j}$$

The calculations can be finished in constant time with the two sums pre-computed. □

By Lemma 5, the increase upper bound from $L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1})$ to $L(\mathbf{\Theta}, \Psi(\mathbf{\Theta}))$ can be calculated by the following equation.

$$\begin{aligned} & L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) - L(\mathbf{\Theta}, \mathbf{\Phi}^{t-1}) \\ \le\ & \ln \sum\sum U_{ij} \max_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_j)\pi_j - \\ & \ln \sum\sum \tau_{ij} \max_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\omega_j)\pi_j \end{aligned} \quad (8)$$

The following theorem gives a sufficient condition on a maximal region $R(\mathbf{\Theta}^t, \Delta)$ for some positive value Δ.

Theorem 3 $R(\mathbf{\Theta}^t, \Delta)$ *is a maximal region for* $\mathbf{\Theta}^t$ *if* $\ln \frac{\sum_i\sum_j U_{ij}\max_{\mathbf{\Theta}}\Pr(\boldsymbol{x}_i|\omega_j)\pi_j}{\sum_i\sum_j \tau_{ij}\max_{\mathbf{\Theta}}\Pr(\boldsymbol{x}_i|\omega_j)\pi_j} - n\min\pi_j^t\Delta^2/6 < L(\mathbf{\Theta}^t, \mathbf{\Phi}^t) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1})$

Proof: By the definition of L, we have

$$L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) \le \ln \frac{\sum_i\sum_j U_{ij}\Pr(\boldsymbol{x}_i|\omega_j)\pi_j}{\sum_i\sum_j \tau_{ij}\Pr(\boldsymbol{x}_i|\omega_j)\pi_j}$$

It is not hard to verify that the derivative of $L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1})$ to $\Pr(\boldsymbol{x}_i|\omega_j)\pi_j$ is always positive. Therefore, the equation above can be maximized if we employ the maximum value of $\Pr(\boldsymbol{x}_i|\omega_j)\pi_j$. Based on the analysis above, we know that

$$\begin{aligned} & L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1}) \\ \le\ & \ln \frac{\sum_i\sum_j U_{ij}\max_{\mathbf{\Theta}}\Pr(\boldsymbol{x}_i|\omega_j)\pi_j}{\sum_i\sum_j \tau_{ij}\max_{\mathbf{\Theta}}\Pr(\boldsymbol{x}_i|\omega_j)\pi_j} \end{aligned}$$

By Theorem 2, $L(\mathbf{\Theta}, \Phi^{t-1}) - L(\mathbf{\Theta}^t, \Phi^{t-1}) \le n\min_j \pi_j^t\Delta^2/6$. Therefore, by Theorem 1, $L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) < L(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$ if the condition of the theorem is satisfied. □

For any local optimum $\mathbf{\Theta}^*$ in the maximal region $R(\mathbf{\Theta}^t, \Delta)$, the following theorem upper bound the likelihood function $L(\mathbf{\Theta}^*, \Psi(\mathbf{\Theta}^*))$.

Theorem 4 *Given a valid maximal region* $R(\mathbf{\Theta}^t, \Delta)$, *if EM algorithm converges to local optimum* $\mathbf{\Theta}^*$, $L(\mathbf{\Theta}^*, \Psi(\mathbf{\Theta}^*)) \le L(\mathbf{\Theta}^t, \mathbf{\Phi}^t) + n\min\pi_j^t\Delta^2/6$.

Proof: Since $\sum_i\sum_j(U_{ij} - \tau_{ij}^t)\max_{\mathbf{\Theta}}\Pr(\omega_j|\boldsymbol{x}_i) < n\min\pi_j^t\Delta^2/6$ by Theorem 3 and $L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) - L(\mathbf{\Theta}, \mathbf{\Phi}^t) \le \sum_i\sum_j(U_{ij} - \tau_{ij}^t)\max_{\mathbf{\Theta}}\Pr(\omega_j|\boldsymbol{x}_i)$, we have $L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^t) \le L(\mathbf{\Theta}, \Psi(\mathbf{\Theta})) - L(\mathbf{\Theta}, \mathbf{\Phi}^t) \le n\min\pi_j^t\Delta^2/6$. □

5. Algorithm

Theorem 3 provides an easy way to verify whether $R(\mathbf{\Theta}^t, \Delta)$ is a valid maximal region. On the other hand, Theorem 4 implies that a smaller Δ can lead to tighter bound on the likelihood function L. However, it is not necessary to get the tightest bound on local optimum in our algorithm, since the goal of our algorithm is estimating whether the current configuration can lead to better solution. Instead, we set Δ as $\min\left\{1, \sqrt{\frac{6(L^*-L(\mathbf{\Theta}^t,\mathbf{\Phi}^t))}{n\min\pi_j^t}}\right\}$, where L^* is the best result we have seen so far. This Δ is the maximal one of all Δ values, which are able to prune the current EM procedure by Theorem 4

The details of the algorithm are summarized in Algo 1. In this algorithm, conventional M-step and E-step

Algorithm 1 New Iteration(Data Set D, Current $\mathbf{\Theta}^{t-1}$, current $\mathbf{\Phi}^{t-1}$, component number k, sample number m, current best result L^*)

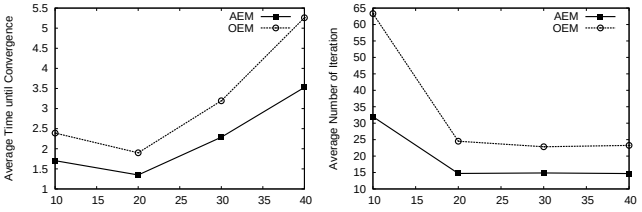
1: Compute new $\mathbf{\Theta}^t$ by M-Step.
2: Compute new $\mathbf{\Phi}^t$ by E-Step.
3: **if** $L(\mathbf{\Theta}^t, \mathbf{\Phi}^t) < L^*$ **then**
4: Let $\Delta = \min\left\{1, \sqrt{\frac{6(L^* - L(\mathbf{\Theta}^t, \mathbf{\Phi}^t))}{n \min \pi_j^t}}\right\}$
5: $S = X = 0$
6: **for** each $\boldsymbol{x}_i$ **do**
7: **for** each dimension j **do**
8: Get $l_{ij} = \max_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\theta_j)\pi_j$ by Lemma 3.
9: Get $s_{ij} = \min_{\mathbf{\Theta}} \Pr(\boldsymbol{x}_i|\theta_j)\pi_j$ by Lemma 4.
10: Get U_{ij} by Lemma 5.
11: $S+ = U_{ij} * l_{ij}$
12: $X+ = \tau_{ij}^{t-1} * l_{ij}$
13: **end for**
14: **end for**
15: **if** $\ln S - \ln X - n \min \pi_j \Delta^2/6 < L(\mathbf{\Theta}^t, \mathbf{\Phi}^t) - L(\mathbf{\Theta}^t, \mathbf{\Phi}^{t-1})$ **then**
16: Stop the current procedure of EM algorithm.
17: **end if**
18: **else**
19: Return $(\mathbf{\Theta}^t, \mathbf{\Phi}^t)$
20: **end if**

are invoked first. If the current configuration is better than the best solution we have seen before, there is no need to test the upper bound of the local optimum. Otherwise, the value of Δ is set according to $\min \pi_j^t$, L^* and $L(\mathbf{\Theta}^T, \mathbf{\Phi}^t)$. For each point and each component, l_{ij}, s_{ij} and U_{ij} are collected according to Lemma 3, Lemma 4 and Lemma 5 respectively. With the information collected from each point, the condition of Theorem 1 can be tested. If this condition is satisfied, we can assert that current local optimum can never be better than L^*, leading to the termination of the current procedure.

6. Experiments

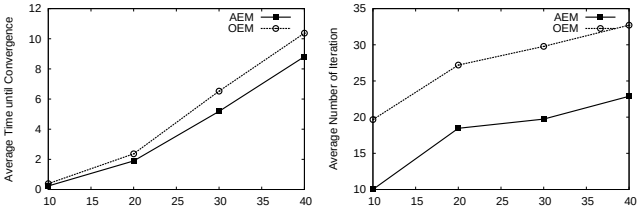
In this section, we report the experimental results on the comparison of our accelerated EM algorithm (AEM) and the conventional EM algorithm (OEM). We note that in our implementation, either AEM or OEM will be stopped if it does not converge after 100 iterations.

We employ both synthetic and real data sets in our empirical studies. The synthetic data sets are generated in a d-dimensional unit cube. There are k components in the space. Each component follows some Gaussian distribution. The center, size and covariance matrix



(a) CPU Time (b) Number of Iterations

Figure 1: Performance vs. varying dimensionality



(a) CPU Time (b) Number of Iterations

Figure 2: Performance vs. varying component number

of each component are randomly generated independently. Two real data sets are also tested, including *Cloud* and *Spam*, both of which are available on UCI Machine Learning Repository. The *Cloud* data set consists of 1024 points in 10-dimensional space, while *Spam* data set has 4601 points in 58 dimensions. Both of the real data set are normalized before being used in our experiments.

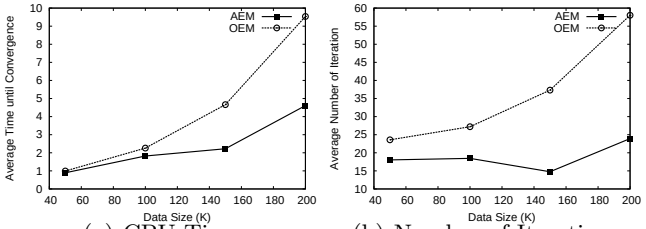
Two performance measurements are recorded in our experiments, including CPU time and number of iterations. An algorithm is supposed to be better if it spends less CPU time and invokes less time of iterations. All of the experiments are compiled and run on a Fedora Core 6 linux machine with 3.0 GHz Processor, 1GB of memory and GCC 4.1.2.

In the experiments on the data sets, we test the performances of the algorithms with varying dimensionality D, number of components k, and the number of points in the data S. The default setting of our experiments is $D = 20$, $k = 20$, and $S = 100$K. The time of EM restart is fixed at 100 in all tests. More experimental results are available in the technical report (Zhang et al., 2008).

6.1. Results on Synthetic Data

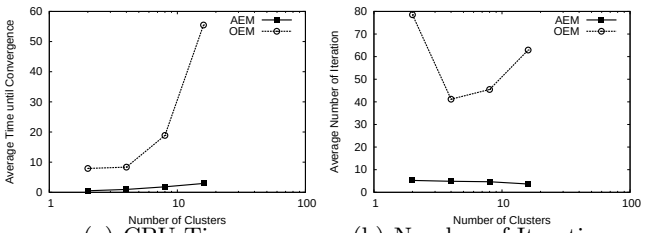
In Figure 1(a) and Figure 1(b), we present the experimental result by varying the dimensionality from 10 to 40. The results show that AEM is much more efficient than OEM. On data set with low dimensionality, AEM is almost two times faster than OEM, both on the CPU time and the number of iterations. The advantage is very obvious, even on high dimensional space.

The results of our experiments on varying component



(a) CPU Time (b) Number of Iterations

Figure 3: Performance vs. varying data size



(a) CPU Time (b) Number of Iterations

Figure 4: Performance vs. varying component number on *Spam* data

number are summarized in Figure 2(a) and Figure 2(b). From the figures, we can see the performance advantage of AEM is stable, with the increase of component number. The CPU time and number of iterations on AEM is only about half of those of OEM.

As is shown in Figure 3(a), Figure 3(b) AEM has much better performance than OEM when we increase the data size from 50K to 200K. AEM can detect those worse local optimums much earlier, if there are more data available. The number of iterations invoked by AEM is almost the same, even when the data has been doubled. The ratio of CPU time is more stable when the data size is larger.

6.2. Results on Real Data

On *Spam* data set, AEM also show great advantage over OEM, on CPU time (Figure 4(a)) and on the number of iterations (Figure 4(b)). AEM is more efficient than OEM by one magnitude, independent to the number of components k.

However, the experiments on *Cloud* data set show quite different results than the pervious results, where AEM has very limited advantage. We believe the difference on the results stems from normalization problem.

7. Conclusion

In this paper, we propose a new acceleration method for multiple restart EM algorithm over Gaussian Mixture Model. We derive an upper bound on the local optimum of the likelihood function in the solution space. This upper bound computation turns out to be both efficient and effective in pruning un-promising procedures of EM algorithm.

Abstract

This paper presents a *cutting plane* algorithm for multiclass *maximum margin clustering* (*MMC*). The proposed algorithm constructs a nested sequence of successively tighter relaxations of the original *MMC* problem, and each optimization problem in this sequence could be efficiently solved using the *constrained concave-convex procedure* (*CCCP*). Experimental evaluations on several real world datasets show that our algorithm converges much faster than existing *MMC* methods with guaranteed accuracy, and can thus handle much larger datasets efficiently.

1. Introduction

Clustering (Duda et al., 2001; Shi & Malik, 2000; Ding et al., 2001) aims at dividing data into groups of similar objects, *i.e.* clusters. Recently, motivated by the success of large margin methods in supervised learning, (Xu et al., 2004) proposed *maximum margin clustering* (*MMC*), which borrows the idea from the *support vector machine* theory and aims at finding the maximum margin hyperplane which can separate the data from different classes in an unsupervised way.

Technically, what *MMC* does is to find a way to label the samples by running an *SVM* implicitly, and the *SVM* margin obtained would be maximized over all possible labelings (Xu et al., 2004). However, unlike supervised large margin methods which are usually formulated as *convex optimization* problems, *maximum margin clustering* is a *non-convex integer optimization* problem, which is much more difficult to solve.

Several attempts have been made to solve the *maximum margin clustering* problem in polynomial time. (Xu et al., 2004) and (Valizadegan & Jin, 2007) made several relaxations to the original *MMC* problem and reformulated it as a *semi-definite programming* (*SDP*) problem. However, even with the recent advances in interior point methods, solving *SDP*s is still computationally very expensive. Consequently, the algorithms can only handle very small datasets containing several hundreds of samples. More recently, *Zhang et al.* utilized alternating optimization techniques to solve the *MMC* problem (Zhang et al., 2007), in which the *maximum margin clustering* result is obtained by solving a series of *SVM* training problems. However, there is no guarantee on how fast it can converge and the algorithm is still time demanding on large scale datasets. Moreover, the methods described above can only handle binary clustering problems (Zhao et al., 2008), and there are significant complications to deriving an effective *maximum margin clustering* approach for the multiclass scenario[1]. Therefore, how to efficiently solve the *multiclass MMC* problem to make it capable of clustering large scale dataset is a very challenging research topic.

In this paper, we propose a *cutting plane multiclass maximum margin clustering* algorithm *CPM3C*. Specifically, the algorithm constructs a nested sequence of successively tighter relaxations of the original *multiclass MMC* problem, and each optimization problem in this sequence could be efficiently solved using the *constrained concave-convex procedure* (*CCCP*). Moreover, we show that the computational time of *CPM3C* scales roughly linearly with the dataset size. Our experimental evaluations on several real world datasets show that *CPM3C* performs better than existing *MMC* methods, both in efficiency and accuracy.

[1] It should be noted that (Xu & Schuurmans, 2005) proposed a multiclass extension for *MMC*, however, their algorithm has a time complexity of $O(n^7)$, which renders it impractical for real world datasets.

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

The rest of this paper is organized as follows. Section 2 will show the *CPM3C* algorithm in detail, and the time complexity analysis of *CPM3C* will be presented in section 3. Section 4 presents the experimental results on several real world datasets, followed by the conclusions in section 5.

2. Cutting Plane Multiclass Maximum Margin Clustering

We will formally present the *cutting plane multiclass maximum margin clustering* (*CPM3C*) algorithm in this section.

2.1. Multiclass Maximum Margin Clustering

Maximum margin clustering (*MMC*) extends the theory of *support vector machine* (*SVM*) to the unsupervised scenario. Specifically, given a point set $\mathcal{X} = \{\mathbf{x}_1, \quad, \mathbf{x}_n\}$ and their labels $\mathbf{y} = (y_1, \ldots, y_n) \in \{1, \ldots, k\}^n$, *SVM* defines a weight vector $\mathbf{w}_p$ for each class $p \in \{1, \ldots, k\}$ and classifies sample $\mathbf{x}$ by $y^* = \arg\max_{y \in \{1,\ldots,k\}} \mathbf{w}_y^T \mathbf{x}$ with the weight vectors obtained as follows [2](Crammer & Singer, 2001)

$$\begin{aligned} \min_{\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi} \quad & \frac{1}{2} \sum_{p=1}^{k} ||\mathbf{w}_p||^2 + \sum_{i=1}^{n} \xi_i \\ s.t. \quad & \forall i = 1, \ldots, n, r = 1, \ldots, k \\ & \mathbf{w}_{y_i}^T \mathbf{x}_i + \ _{y_i,r} \quad \mathbf{w}_r^T \mathbf{x}_i \quad 1 \quad \xi_i \end{aligned} \tag{1}$$

where the data samples in $\mathcal{X}$ are mapped into a high (possibly infinite) dimensional feature space, and by using the kernel trick, this mapping could be done implicitly. However, in those cases where kernel trick cannot be applied, it is possible to compute the coordinates of each sample in the *kernel PCA basis* (Schölkopf et al., 1999) according to kernel K. Therefore, throughout the rest of this paper, we use $\mathbf{x}_i$ to denote the sample mapped by the kernel function.

Instead of finding a large margin classifier given labels on the data as in *SVM*, *MMC* targets to find a labeling that would result in a large margin classifier (Xu et al., 2004). That is to say, if we subsequently run an *SVM* with the labeling obtained from *MMC*, the margin would be maximal among all possible labelings. *multiclass MMC* could be formulated as follows:

$$\begin{aligned} \min_{\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi,\mathbf{y}} \quad & \frac{1}{2} \sum_{p=1}^{k} ||\mathbf{w}_p||^2 + \frac{1}{n} \sum_{i=1}^{n} \xi_i \\ s.t. \quad & \forall i = 1, \ldots, n, r = 1, \ldots, k \\ & \mathbf{w}_{y_i}^T \mathbf{x}_i + \ _{y_i,r} \quad \mathbf{w}_r^T \mathbf{x}_i \quad 1 \quad \xi_i \end{aligned} \tag{2}$$

[2]Although we focus on the *multiclass SVM* formulation of (Crammer & Singer, 2001), our method can be directly applied to other *multiclass SVM* formulations.

where $\sum_{i=1}^{n} \xi_i$ is divided by n to better capture how the regularization parameter scales with the dataset size. Different from *SVM*, where the class labels are given and the only variables are $(\mathbf{w}_1, \ldots, \mathbf{w}_k)$, *MMC* targets to find not only the optimal weight vectors, but also the optimal labeling vector $\mathbf{y}^*$.

2.2. Cutting Plane Algorithm

In this section, we will reformulate problem (2) to reduce the number of variables. Specifically,

Theorem 1 *Problem (2) is equivalent to*

$$\begin{aligned} \min_{\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi} \quad & \frac{1}{2} \sum_{p=1}^{k} ||\mathbf{w}_p||^2 + \frac{1}{n} \sum_{i=1}^{n} \xi_i \\ s.t. \quad & \forall i = 1, \ldots, n, r = 1, \ldots, k \\ & \sum_{p=1}^{k} \mathbf{w}_p^T \mathbf{x}_i \prod_{q=1,q\neq p}^{k} I_{(\mathbf{w}_p^T \mathbf{x}_i > \mathbf{w}_q^T \mathbf{x}_i)} \\ & + \prod_{q=1,q\neq r}^{k} I_{(\mathbf{w}_r^T \mathbf{x}_i > \mathbf{w}_q^T \mathbf{x}_i)} \quad \mathbf{w}_r^T \mathbf{x}_i \quad 1 \quad \xi_i \end{aligned} \tag{3}$$

where $I(\ )$ is the indicator function *and the label for sample $\mathbf{x}_i$ is determined as*

$$y_i = \sum_{p=1}^{k} p \prod_{q=1,q\neq p}^{k} I_{(\mathbf{w}_p^T \mathbf{x}_i > \mathbf{w}_q^T \mathbf{x}_i)} \tag{4}$$

Proof. We will show that for every $(\mathbf{w}_1, \ldots, \mathbf{w}_k)$ the smallest feasible $\sum_{i=1}^{n} \xi_i$ are identical for problem (2) and problem (3), and their corresponding labeling vectors are the same. For a given $(\mathbf{w}_1, \ldots, \mathbf{w}_k)$, the ξ_i in problem (2) can be optimized individually. According to the constraint in problem (2),

$$\xi_i \quad 1 \quad (\mathbf{w}_{y_i}^T \mathbf{x}_i + \ _{y_i,r} \quad \mathbf{w}_r^T \mathbf{x}_i), \ \forall r = 1, \ldots, k \tag{5}$$

As the objective is to minimize $\frac{1}{n} \sum_{i=1}^{n} \xi_i$, the optimal value for ξ_i is

$$\xi_i^{(1)} = \min_{y_i=1,\ldots,k} \max_{r=1,\ldots,k} \{1 \quad (\mathbf{w}_{y_i}^T \mathbf{x}_i + \ _{y_i,r} \quad \mathbf{w}_r^T \mathbf{x}_i)\} \tag{6}$$

and we denote the corresponding class label by $y_i^{(1)}$. Without loss of generality, we assume the following relationship

$$\mathbf{w}_{i_1}^T \mathbf{x}_i \quad \mathbf{w}_{i_2}^T \mathbf{x}_i \quad \ldots \quad \mathbf{w}_{i_k}^T \mathbf{x}_i \tag{7}$$

where $(i_1, i_2, \ldots, i_k)$ is a permutation of $(1, 2, \ldots, k)$. For $y_i \neq i_1$, $\max_{r=1,\ldots,k}\{1 \quad (\mathbf{w}_{y_i}^T \mathbf{x}_i + \delta_{y_i,r} \quad \mathbf{w}_r^T \mathbf{x}_i)\}$ 1, while for $y_i = i_1$, $\max_{r=1,\ldots,k}\{1 \quad (\mathbf{w}_{y_i}^T \mathbf{x}_i + \delta_{y_i,r} \quad \mathbf{w}_r^T \mathbf{x}_i)\} \leq 1$, therefore, $y_i^{(1)} = i_1$ and

$$\begin{aligned} \xi_i^{(1)} &= \max_{r=1,\ldots,k} \{1 \quad (\mathbf{w}_{i_1}^T \mathbf{x}_i + \ _{i_1,r} \quad \mathbf{w}_r^T \mathbf{x}_i)\} \\ &= \max\{0, 1 \quad (\mathbf{w}_{i_1}^T \mathbf{x}_i \quad \mathbf{w}_{i_2}^T \mathbf{x}_i)\} \end{aligned} \tag{8}$$

Similarly, for problem (3), the optimal value for ξ_i is

$$\begin{aligned}\xi_i^{(2)} &= \max_{r=1,\ldots,k}\left\{1 \quad \left[\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i\prod_{q=1,q\neq p}^{k}I_{(\mathbf{w}_p^T\mathbf{x}_i>\mathbf{w}_q^T\mathbf{x}_i)}\right.\right.\\ &\quad \left.\left.+\prod_{q=1,q\neq r}^{k}I_{(\mathbf{w}_r^T\mathbf{x}_i>\mathbf{w}_q^T\mathbf{x}_i)} \quad \mathbf{w}_r^T\mathbf{x}_i\right]\right\} \qquad (9)\\ &= \max_{r=1,\ldots,k}\{1 \quad (\mathbf{w}_{i_1}^T\mathbf{x}_i + \ _{i_1,r} \quad \mathbf{w}_r^T\mathbf{x}_i)\}\\ &= \max\{0,1 \quad (\mathbf{w}_{i_1}^T\mathbf{x}_i \quad \mathbf{w}_{i_2}^T\mathbf{x}_i)\}\end{aligned}$$

and the class label could be calculated as

$$y_i^{(2)} = \sum_{p=1}^{k} p\prod_{q=1,q\neq p}^{k}I_{(\mathbf{w}_p^T\mathbf{x}_i>\mathbf{w}_q^T\mathbf{x}_i)} = i_1 \qquad (10)$$

Therefore, the objective functions of both optimization problems are equivalent for any $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$ with the same optimal ξ_i, and consequently so are their optima. Moreover, their corresponding labeling vectors $\mathbf{y}$ are the same. Hence, we proved that problem (2) is equivalent to problem (3). □

By reformulating problem (2) as problem (3), the number of variables involved is reduced by n, but there are still n slack variables ξ_i in problem (3). Define $\mathbf{e}_p$ as the $k \quad 1$ vector with only the p-th element being 1 and others 0, $\mathbf{e}_0$ as the $k \quad 1$ zero vector and $\mathbf{e}$ as the all one vector. To further reduce the number of variables involved in the optimization problem, we have the following theorem

Theorem 2 *Problem (3) can be equivalently formulated as problem (11), with* $\xi^* = \frac{1}{n}\sum_{i=1}^{n}\xi_i^*$.

$$\begin{aligned}\min_{\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi\geq 0} \quad & \frac{1}{2} \quad \sum_{p=1}^{k}||\mathbf{w}_p||^2+\xi \qquad (11)\\ s.t. \quad & \forall \mathbf{c}_i \in \{\mathbf{e}_0,\mathbf{e}_1,\ldots,\mathbf{e}_k\},\ i=1,\ldots,n\\ & \frac{1}{n}\sum_{i=1}^{n}\left\{\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip}+\sum_{p=1}^{k}c_{ip}(z_{ip} \quad \mathbf{w}_p^T\mathbf{x}_i)\right\}\\ & \frac{1}{n}\sum_{i=1}^{n}\mathbf{c}_i^T\mathbf{e} \quad \xi\end{aligned}$$

where $z_{ip} = \prod_{q=1,q\neq p}^{k} I_{(\mathbf{w}_p^T\mathbf{x}_i>\mathbf{w}_q^T\mathbf{x}_i)}\ \forall i = 1,\ldots,n; p = 1\ldots,k$ *and each constraint* $\mathbf{c}$ *is represented as a* $k \quad n$ *matrix* $\mathbf{c} = (\mathbf{c}_1,\ldots,\mathbf{c}_n)$.

Proof. To justify the above theorem, we will show that problem (3) and problem (11) have the same objective value and an equivalent set of constraints. Specifically, we will prove that for every $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$, the smallest feasible ξ and $\sum_{i=1}^{n}\xi_i$ are related by $\xi = \frac{1}{n}\sum_{i=1}^{n}\xi_i$. This means, with $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$ fixed, $(\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi)$ and $(\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi_i)$ are optimal solutions to problem (3) and (11) respectively, and they result in the same objective function value.

For any given $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$, the ξ_i in problem (3) can be optimized individually and the optimum is achieved as

$$\xi_i^{(2)} = \max\{0,1 \quad (\mathbf{w}_{i_1}^T\mathbf{x}_i \quad \mathbf{w}_{i_2}^T\mathbf{x}_i)\} \qquad (12)$$

where we assume the relation in (7) holds.

Similarly for problem (11), the optimal ξ is

$$\begin{aligned}\xi^{(3)} = \max_{\mathbf{c}_1,\ldots,\mathbf{c}_n\in\{\mathbf{e}_0,\ldots,\mathbf{e}_k\}}\left\{\frac{1}{n}\sum_{i=1}^{n}\mathbf{c}_i^T\mathbf{e} \quad \frac{1}{n}\sum_{i=1}^{n}\left[\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip}\right.\right. \qquad (13)\\ \left.\left.+\sum_{p=1}^{k}c_{ip}(z_{ip} \quad \mathbf{w}_p^T\mathbf{x}_i)\right]\right\}\end{aligned}$$

Since each $\mathbf{c}_i$ are independent in Eq.(13), they can be optimized individually. Therefore,

$$\begin{aligned}\xi^{(3)} &= \frac{1}{n}\sum_{i=1}^{n}\max_{\mathbf{c}_i}\{\mathbf{c}_i^T\mathbf{e} \quad \mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip} \quad \sum_{p=1}^{k}c_{ip}(z_{ip} \quad \mathbf{w}_p^T\mathbf{x}_i)\}\\ &= \frac{1}{n}\sum_{i=1}^{n}\max \quad 0, \max_{p=1,\ldots,k}[1 \quad (\mathbf{w}_{i_1}^T\mathbf{x}_i + \ _{i_1,p} \quad \mathbf{w}_p^T\mathbf{x}_i)]\\ &= \frac{1}{n}\sum_{i=1}^{n}\max\left\{0,\max[0,1 \quad (\mathbf{w}_{i_1}^T\mathbf{x}_i \quad \mathbf{w}_{i_2}^T\mathbf{x}_i)]\right\}\\ &= \frac{1}{n}\sum_{i=1}^{n}\max\{0,1 \quad (\mathbf{w}_{i_1}^T\mathbf{x}_i \quad \mathbf{w}_{i_2}^T\mathbf{x}_i)\} = \frac{1}{n}\sum_{i=1}^{n}\xi_i^{(2)}\end{aligned}$$

Hence, for any $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$, the objective functions for problem (3) and problem (11) have the same value given the optimal ξ and ξ_i. Therefore, the optima of the two optimization problems are the same. □

Putting theorems 1 and 2 together, we could therefore solve problem (11) instead to find the same *maximum margin clustering* solution, with the number of variables reduced by $2n \quad 1$. Although the number of variables in problem (11) is greatly reduced, the number of constraints increases from nk to $(k+1)^n$. The algorithm we propose in this paper targets to find a small subset of constraints from the whole set of constraints in problem (11) that ensures a sufficiently accurate solution. Specifically, we employ an adaptation of the *cutting plane* algorithm (Kelley, 1960) to solve problem (11), where we construct a nested sequence of successively tighter relaxations of problem (11). Moreover, we can prove theoretically (see section 3) that we can always find a polynomially sized subset of constraints, with which the solution of the relaxed problem fulfills all constraints from problem (11) up to a precision of . That is to say, the remaining exponential number of constraints are guaranteed to be violated by no more than , without the need for explicitly adding them to the optimization problem (Tsochantaridis et al., 2005). Specifically, the *CPM3C* algorithm keeps a subset Ω of working constraints and

computes the optimal solution to problem (11) subject to the constraints in Ω. The algorithm then adds the most violated constraint in problem (11) into Ω. In this way, a successively strengthening approximation of the original *MMC* problem is constructed by a cutting plane that cuts off the current optimal solution from the feasible set (Kelley, 1960). The algorithm stops when no constraint in (11) is violated by more than . Here, the feasibility of a constraint is measured by the corresponding value of ξ, therefore, the most violated constraint is the one that results in the largest ξ. Since each constraint in problem (11) is represented by a k n matrix $\mathbf{c}$, then we have

Theorem 3 *Define* $p^* = \arg\max_p(\mathbf{w}_p^T\mathbf{x}_i)$ *and* $r^* = \arg\max_{r\neq p^*}(\mathbf{w}_r^T\mathbf{x}_i)$ *for* $i = 1,\ldots,n$, *the most violated constraint could be calculated as follows*

$$\mathbf{c}_i = \begin{array}{ll} \mathbf{e}_{r^*} & if\ (\mathbf{w}_{p^*}^T\mathbf{x}_i \quad \mathbf{w}_{r^*}^T\mathbf{x}_i) < 1 \\ \mathbf{0} & otherwise \end{array},\ i = 1,\ldots,n \qquad (14)$$

Proof. The most violated constraint is the one that would result in the largest ξ. As each $\mathbf{c}_i$ in the constraint is independent, in order to fulfill all constraints in problem (11), the value of ξ is as follows

$$\begin{aligned}\xi^* &= \frac{1}{n}\sum_{i=1}^{n}\max_{\mathbf{c}_i}\{\mathbf{c}_i^T\mathbf{e} \quad \mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip} \quad \sum_{p=1}^{k}c_{ip}(z_{ip} \quad \mathbf{w}_p^T\mathbf{x}_i)\} \\ &= \frac{1}{n}\sum_{i=1}^{n}\max_{\mathbf{c}_i}\{\mathbf{c}_i^T[\mathbf{e} \quad \mathbf{w}_{p^*}^T\mathbf{x}_i\mathbf{e} \quad \mathbf{z}_i + \mathbf{t}_i]\}\end{aligned}$$

where $\mathbf{t}_i = (\mathbf{w}_1^T\mathbf{x}_i,\ldots,\mathbf{w}_k^T\mathbf{x}_i)^T$. Since $\mathbf{c}_i \in \{\mathbf{e}_0,\ldots,\mathbf{e}_k\}$, $\mathbf{c}_i$ selects the largest element of the vector $\mathbf{e}$ $\mathbf{w}_{p^*}^T\mathbf{x}_i\mathbf{e}$ $\mathbf{z}_i + \mathbf{t}_i$, which could be calculated as 1 $(\mathbf{w}_{p^*}^T\mathbf{x}_i \quad \mathbf{w}_{r^*}^T\mathbf{x}_i)$. Therefore, the most violated constraint $\mathbf{c}$ that results in the largest ξ^* could be calculated as in Eq.(14). □

The *CPM3C* algorithm iteratively selects the most violated constraint under the current weight vectors and adds it into the working constraint set Ω until no violation of constraints is detected. Moreover, if a point $(\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi)$ fulfills all constraints up to precision

$$\begin{aligned}&\forall \mathbf{c}_i \in \{\mathbf{e}_0,\mathbf{e}_1,\ldots,\mathbf{e}_k\}^n,\ i = 1,\ldots,n \qquad (15)\\ &\frac{1}{n}\sum_{i=1}^{n}\left\{\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip} + \sum_{p=1}^{k}c_{ip}(z_{ip} \quad \mathbf{w}_p^T\mathbf{x}_i)\right\} \quad \frac{1}{n}\sum_{i=1}^{n}\mathbf{c}_i^T\mathbf{e} \quad \xi\end{aligned}$$

then the point $(\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi + \ )$ is feasible. Furthermore, as in the objective function of problem (11), there is a single slack variable ξ that measures the clustering loss. Hence, we could simply select the stopping criterion as all samples satisfying the inequality (15). Then, the approximation accuracy of this approximate solution is directly related to the training loss.

2.3. Enforcing the Class Balance Constraint

In 2-class *maximum margin clustering*, a trivially "optimal" solution is to assign all patterns to the same class, and the resultant margin will be infinite (Xu et al., 2004). Similarly, for the multiclass scenario, a large margin can always be achieved by eliminating classes (Xu & Schuurmans, 2005). Therefore, we add the following class balance constraints to avoid the trivially "optimal" solutions

$$l \quad \sum_{i=1}^{n}\mathbf{w}_p^T\mathbf{x}_i \quad \sum_{i=1}^{n}\mathbf{w}_q^T\mathbf{x}_i \quad l,\ \forall p,q = 1,\ldots,k \qquad (16)$$

where l 0 controls the class imbalance. Therefore, *multiclass maximum margin clustering* with working constraint set Ω could be formulated as follows

$$\begin{aligned}\min_{\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi\geq 0} \quad & \frac{1}{2} \quad \sum_{p=1}^{k}||\mathbf{w}_p||^2 + \xi \qquad (17)\\ s.t. \quad & \frac{1}{n}\sum_{i=1}^{n}\left\{\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip} + \sum_{p=1}^{k}c_{ip}(z_{ip} \quad \mathbf{w}_p^T\mathbf{x}_i)\right\}\\ & \frac{1}{n}\sum_{i=1}^{n}\mathbf{c}_i^T\mathbf{e} \quad \xi,\ \forall[\mathbf{c}_1,\ldots,\mathbf{c}_n] \in \Omega\\ & l \quad \sum_{i=1}^{n}\mathbf{w}_p^T\mathbf{x}_i \quad \sum_{i=1}^{n}\mathbf{w}_q^T\mathbf{x}_i \quad l,\ \forall p,q = 1,\ldots,k\end{aligned}$$

Before getting into details of solving problem (17), we first present the *CPM3C* approach in Algorithm 1.

Algorithm 1 Cutting Plane Multiclass MMC

Initialize $\Omega = \phi$
repeat
  Solve problem (17) for $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$ under the current working constraint set Ω and select the most violated constraint $\mathbf{c}$ with Eq.(14). Set $\Omega = \Omega \cup \{\mathbf{c}\}$.
until $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$ satisfies $\mathbf{c}$ up to precision

2.4. Optimization via the *CCCP*

In each iteration of the *CPM3C* algorithm, we need to solve problem (17) to obtain the optimal classifying hyperplanes under the current working constraint set Ω. Although the objective function in (17) is convex, the constraints are not, and this makes problem (17) difficult to solve. Fortunately, the *constrained concave-convex procedure (CCCP)* is just designed to solve those optimization problems with a concave-convex objective function under concave-convex constraints (Smola et al., 2005). In the following, we will show how to utilize *CCCP* to solve problem (17).

The objective function in (17) and the second constraint are convex. Moreover, the first constraint is, although non-convex, the difference of two convex functions. Hence, we can solve (17) with *CCCP*. Notice that while $\frac{1}{n}\sum_{i=1}^{n}\left[\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip}+\sum_{p=1}^{k}c_{ip}z_{ip}\right]$ is convex, it is a non-smooth function of $(\mathbf{w}_1,\ldots,\mathbf{w}_k)$. To use *CCCP*, we need to calculate the *subgradients*:

$$\partial_{\mathbf{w}_r}\left\{\frac{1}{n}\sum_{i=1}^{n}\left[\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip}+\sum_{p=1}^{k}c_{ip}z_{ip}\right]\right\}_{\mathbf{w}=\mathbf{w}^{(t)}} \quad (18)$$
$$= \frac{1}{n}\sum_{i=1}^{n}\mathbf{c}_i^T\mathbf{e}z_{ip}^{(t)}\mathbf{x}_i \qquad \forall r=1,\ldots,k$$

Given an initial point $(\mathbf{w}_1^{(0)},\ldots,\mathbf{w}_k^{(0)})$, *CCCP* computes $(\mathbf{w}_1^{(t+1)},\ldots,\mathbf{w}_k^{(t+1)})$ from $(\mathbf{w}_1^{(t)},\ldots,\mathbf{w}_k^{(t)})$ by replacing $\frac{1}{n}\sum_{i=1}^{n}\left[\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip}+\sum_{p=1}^{k}c_{ip}z_{ip}\right]$ in the constraint with its first order Taylor expansion at $(\mathbf{w}_1^{(t)},\ldots,\mathbf{w}_k^{(t)})$, i.e.

$$\frac{1}{n}\sum_{i=1}^{n}\left\{\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}{\mathbf{w}_p^{(t)}}^T\mathbf{x}_i z_{ip}^{(t)}+\sum_{p=1}^{k}c_{ip}z_{ip}^{(t)}\right\} \quad (19)$$
$$+\frac{1}{n}\sum_{i=1}^{n}\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}(\mathbf{w}_p \quad \mathbf{w}_p^{(t)})^T\mathbf{x}_i z_{ip}^{(t)}$$
$$= \frac{1}{n}\sum_{i=1}^{n}\left\{\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip}^{(t)}+\sum_{p=1}^{k}c_{ip}z_{ip}^{(t)}\right\}$$

By substituting the above first-order Taylor expansion into problem (11), we obtain the following *quadratic programming (QP)* problem:

$$\min_{\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi\geq 0} \ \frac{1}{2}\sum_{p=1}^{k}||\mathbf{w}_p||^2+\xi \quad (20)$$
$$s.t. \ \forall[\mathbf{c}_1,\ldots,\mathbf{c}_n]\in\Omega$$
$$\frac{1}{n}\sum_{i=1}^{n}\mathbf{c}_i^T\mathbf{e} \quad \xi+\frac{1}{n}\sum_{i=1}^{n}\sum_{p=1}^{k}c_{ip}\mathbf{w}_p^T\mathbf{x}_i$$
$$\frac{1}{n}\sum_{i=1}^{n}\left\{\mathbf{c}_i^T\mathbf{e}\sum_{p=1}^{k}\mathbf{w}_p^T\mathbf{x}_i z_{ip}^{(t)}+\sum_{p=1}^{k}c_{ip}z_{ip}^{(t)}\right\} \quad 0$$
$$l \quad \sum_{i=1}^{n}\mathbf{w}_p^T\mathbf{x}_i \quad \sum_{i=1}^{n}\mathbf{w}_q^T\mathbf{x}_i \quad l, \forall p,q=1,\ldots,k$$

Moreover, the dual problem of (20) is a *QP* problem with $|\Omega|+2$ variables and could be solved in polynomial time, where $|\Omega|$ denotes the total number of constraints in Ω. Putting everything together, according to the formulation of the *CCCP* (Smola et al., 2005), we solve problem (17) with the approach presented in Algorithm 2, where we set the stopping criterion in *CCCP* as the difference between two iterations less than % and set % = 0.01, which means the current objective function is larger than 1 % of the objective function in last iteration, since *CCCP* decreases the objective function monotonically.

Algorithm 2 Solve problem (17) with CCCP

Initialize $\mathbf{w}_p=\mathbf{w}_p^0$ for $p=1,\ldots,k$.
repeat
  Find $(\mathbf{w}_1^{t+1},\ldots,\mathbf{w}_k^{t+1})$ as the solution to the *quadratic programming* problem (20).
  Set $\mathbf{w}_p=\mathbf{w}_p^{t+1}, p=1,\ldots,k$
until stopping criterion satisfied.

2.5. Theoretical Analysis

We provide the following theorem regarding the correctness of the *CPM3C* algorithm.

Theorem 4 *For any dataset* $\mathcal{X}=(\mathbf{x}_1,\ldots,\mathbf{x}_n)$ *and any* >0, *if* $(\mathbf{w}_1^*,\ldots,\mathbf{w}_k^*,\xi^*)$ *is the optimal solution to problem (11) with the class balance constraint, then our* CPM3C *algorithm returns a point* $(\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi)$ *for which* $(\mathbf{w}_1,\ldots,\mathbf{w}_k,\xi+\ )$ *is feasible in problem (11) and satisfies the class balance constraint. Moreover, the corresponding objective value is better than the one corresponds to* $(\mathbf{w}_1^*,\ldots,\mathbf{w}_k^*,\xi^*)$.

Based on the above theorem, indicates how close one wants to be to the error rate of the best classifying hyperplanes and can thus be used as the stopping criterion (Joachims, 2006).

3. Time Complexity Analysis

In this section, we will provide analysis on the time complexity of *CPM3C*. For the high-dimensional *(say, d-dimensional)* sparse data commonly encountered in applications like text mining and bioinformatics, we assume each sample has only $s \ll d$ non-zero features, *i.e.*, s implies the sparsity, while for non-sparse data, by simply setting $s=d$, all our theorems still hold.

Theorem 5 *Each iteration of* CPM3C *takes time* $O(snk)$ *for a constant working set size* $|\Omega|$.

Moreover, for the binary clustering scenario, we have the following theorem

Theorem 6 *For any* >0, >0, *and any dataset* $\mathcal{X}=\{\mathbf{x}_1,\ldots,\mathbf{x}_n\}$ *with samples belonging to two different classes, the* CPM3C *algorithm terminates after adding at most* $\frac{R}{2}$ *constraints, where* R *is a constant number independent of* n *and* s.

It is true that the number of constraints can potentially explode for small values of , however, experi-

ence with *CPM3C* shows that relatively large values of are sufficient without loss of clustering accuracy. Since the number of iterations in *CPM3C* (with $k = 2$) is bounded by $\frac{R}{2}$, a constant independent of n and s, and each iteration of the algorithm takes time $O(snk)$ ($O(sn)$ for the binary clustering scenario), we arrive at the following theorem

Theorem 7 *For any dataset $\mathcal{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$ with n samples belonging to 2 classes and sparsity of s, and any fixed value of > 0 and > 0, the* CPM3C *algorithm takes time $O(sn)$ to converge.*

For the multiclass scenario, experimental results shown in section 4 also demonstrate that the computational time of *CPM3C* scales roughly linearly with the dataset size n.

4. Experiments

In this section, we will validate the accuracy and efficiency of the *CPM3C* algorithm on several real world datasets. Moreover, we will also analyze the scaling behavior of *CPM3C* with the dataset size and the sensitivity of *CPM3C* to , both in accuracy and efficiency. All the experiments are performed with MATLAB 7.0 on a 1.66GHZ Intel Core$^{\text{TM}}$2 Duo PC running Windows XP with 1.5GB main memory.

4.1. Datasets

We use eight datasets in our experiments, which are selected to cover a wide range of properties: **Digits, Letter** and **Satellite** from the **UCI** repository, **MNIST**[3], **20 newsgroup**[4], **WebKB**[5], **Cora** (McCallum et al., 2000) and **RCVI** (Lewis et al., 2004). In order to compare *CPM3C* with other *MMC* algorithms which can only perform binary clustering, we choose the first two classes from **Letter** and **Satellite**. For the **20 newsgroup** dataset, we choose the topic *rec* which contains *autos, motorcycles, baseball* and *hockey* from the version 20-news-18828. For **WebKB**, we select a subset consists of about 6000 web pages from computer science departments of four schools (Cornell, Texas, Washington, and Wisconsin). For **Cora**, we select a subset containing the research paper of subfield data structure (DS), hardware and architecture (HA), machine learning (ML), operating system (OS) and programming language (PL). For **RCVI**, we use the data samples with the highest four topic codes (CCAT, ECAT, GCAT and MCAT) in the "Topic Codes" hierarchy in the training set.

4.2. Comparisons and Clustering Results

Besides our *CPM3C* algorithm, we also implements some other competitive algorithms and present their results for comparison. Specifically, we use **K-Means (KM)** and **Normalized Cut (NC)** as baselines, and also compared with **Maximum Margin Clustering (MMC)** (Xu et al., 2004), **Generalized Maximum Margin Clustering (GMC)** (Valizadegan & Jin, 2007) and **Iterative Support Vector Regression (SVR)** (Zhang et al., 2007) which all aim at clustering data with the maximum margin hyperplane. Technically, for **k-means**, the cluster centers are initialized randomly. For **NC**, the implementation is the same as in (Shi & Malik, 2000), and the width of the Gaussian kernel is set by exhaustive search from the grid $\{0.1\sigma_0, 0.2\sigma_0, \ldots, \sigma_0\}$, where σ_0 is the range of distance between any two data points in the dataset. Moreover, for **MMC** and **GMC**, the implementation is the same as in (Xu et al., 2004; Xu & Schuurmans, 2005) and (Valizadegan & Jin, 2007) respectively. Furthermore, the implementation code for **SVR** is downloaded from http://www.cse.ust.hk/ twinsen and the initialization is based on *k-means* with randomly selected initial data centers, and the width of the Gaussian kernel is set in the same way as in **NC**.

In the experiments, we set the number of clusters equal to the true number of classes k for all the clustering algorithms. To assess clustering accuracy, we follow the strategy used in (Xu et al., 2004) where we first take a set of labeled data, remove the labels for all data samples and run the clustering algorithms, then we label each of the resulting clusters with the majority class according to the original training labels, and finally measure the number of correct classifications made by each clustering. Moreover, we also calculate the *Rand Index* (Rand, 1971) for each clustering result. The *clustering accuracy* and *Rand index* results are summarized in table 2 and table 3 respectively,

Table 2. Clustering accuracy(%) comparisons.

where the results for *k-means* and *iterative SVR* are averaged over 50 independent runs and '-' means the corresponding algorithm cannot handle the dataset in reasonable time. Since *GMC* and *iterative SVR* can only handle binary clustering problems, we also provide experiments on several 2-class problems: **Letters**, **Satellite**, **autos vs. motorcycles (Text-1)** and **baseball vs. hockey (Text-2)**. Moreover, for the **UCI-Digits** and **MNIST** datasets, we enumerate all 45 possible class pairs, and report the average clustering results. Furthermore, as the *MMC* and *GMC* algorithms can only handle datasets with no more than a few hundred samples, we perform experiments on **UCI Digits** and focus on those pairs (3 vs 8, 1 vs 7, 2 vs 7, 8 vs 9, 0689 and 1279) that are difficult to differentiate. From the tables we can clearly observe

that our *CPM3C* algorithm can beat other competitive algorithms on almost all the datasets.

4.3. Speed of CPM3C

Table 4 compares the CPU-time of *CPM3C* with other competitive algorithms. According to the table, *CPM3C* is at least 18 times faster than *SVR*, 200 times faster than *GMC*. As reported in (Valizadegan & Jin, 2007), *GMC* is about 100 times faster than *MMC*. Hence, *CPM3C* is still faster than *MMC* by about four orders of magnitude. Moreover, as the sample size increases, the CPU-time of *CPM3C* grows much slower than that of *iterative SVR*, which indicates *CPM3C* has much better scaling property with the sample size than *SVR*. Finally, *CPM3C* also performs much faster than conventional *kmeans*, which is a very appealing result. As for the *Ncut* method, since the calculation of the similarity matrix is very time consuming and usually takes several hours on the text datasets, we do not report the time it spends here.

Table 4. CPU-time (seconds) comparisons.

4.4. Dataset size n vs. Speed

In the theoretical analysis section, we state that the computational time of *CPM3C* scales linearly with the number of samples. We present numerical demonstra-

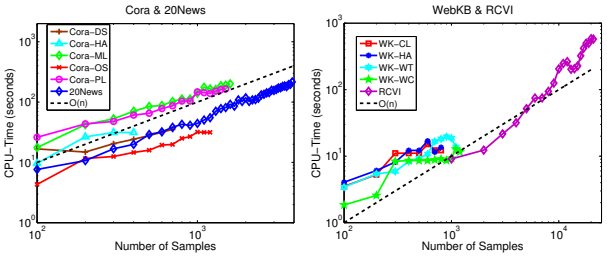

Figure 1. CPU-Time (seconds) of *CPM3C* as a function of dataset size n.

tion for this statement in figure 1, where a log-log plot of how computational time increases with the size of the data set is shown. Specifically, lines in the log-log plot correspond to polynomial growth $O(n^d)$, where d is the slope of the line. Figure 1 shows that the CPU-time of *CPM3C* scales roughly $O(n)$, which is consistent with the statement in section 3.

4.5. vs. Accuracy & Speed

Theorem 6 states that the total number of iterations involved in *CPM3C* is at most $\frac{R}{2}$, and this means with higher , the algorithm might converge fast. However, as is directly related to the training loss in *CPM3C*, we need to determine how small should be to guarantee sufficient accuracy. We present in figure 2 and figure 3 how clustering accuracy and computational time scale with . According to figure 2, = 0.01

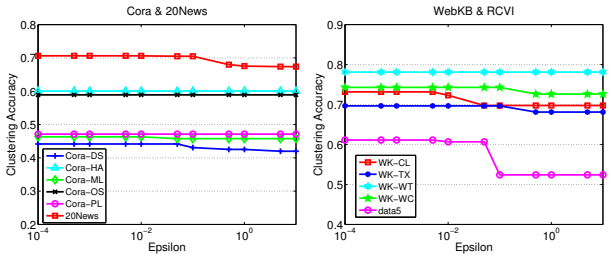

Figure 2. Clustering accuracy of *CPM3C* vs. .

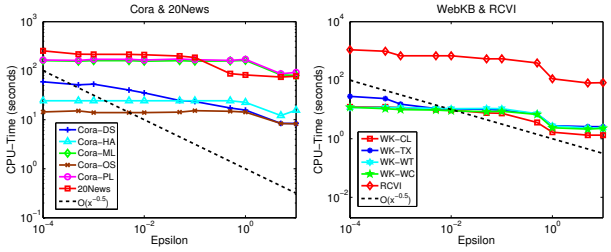

Figure 3. CPU-time (seconds) of *CPM3C* vs. .

is small enough to guarantee clustering accuracy. The log-log plot in figure 3 verifies that the CPU-time of *CPM3C* decreases as increases. Moreover, the empirical scaling of roughly $O(\frac{1}{0.5})$ is much better than $O(\frac{1}{2})$ in the bound from theorem 6.

5. Conclusions

We propose the *cutting plane multiclass maximum margin clustering* (*CPM3C*) algorithm in this paper, to cluster data samples with the maximum margin hyperplane. Preliminary theoretical analysis of the algorithm is provided, where we show that the computational time of *CPM3C* scales linearly with the sample size n with guaranteed accuracy. Moreover, experimental evaluations on several real world datasets show that *CPM3C* performs better than existing *MMC* methods, both in efficiency and accuracy.

Abstract

We propose Laplace max-margin Markov networks (LapM^{3}N), and a general class of Bayesian M^{3}N (BM^{3}N) of which the LapM^{3}N is a special case with sparse structural bias, for robust structured prediction. BM^{3}N generalizes extant structured prediction rules based on point estimator to a Bayes-predictor using a learnt distribution of rules. We present a novel *Structured Maximum Entropy Discrimination* (SMED) formalism for combining Bayesian and max-margin learning of Markov networks for structured prediction, and our approach subsumes the conventional M^{3}N as a special case. An efficient learning algorithm based on variational inference and standard convex-optimization solvers for M^{3}N, and a generalization bound are offered. Our method outperforms competing ones on both synthetic and real OCR data.

1. Introduction

In recent years, log-linear models based on composite features that explicitly exploit the structural dependencies among elements in high-dimensional inputs (e.g., DNA strings, text sequences, image lattices) and structured interpretational outputs (e.g., gene segmentation, natural language parsing, scene description) have gained substantial popularity in learning structured predictions from complex data. Major instances of such models include the conditional random fields (CRFs) (Lafferty et al., 2001), Markov networks (MNs) (Taskar et al., 2003), and other specialized graphical models (Altun et al., 2003). Adding to the flexibilities and expressive power of such models, different learning paradigms have been explored, such as maximum likelihood estimation (Lafferty et al., 2001), and max-margin learning (Altun et al., 2003; Taskar et al., 2003; Tsochantaridis et al., 2004).

For domains with complex feature space, it is often desirable to pursue a "sparse" representation of the model that leaves out irrelevant features. Learning such a sparse model is key to reduce the rick of overfitting and achieve good generalizability. In likelihood-based estimation, sparse model fitting has been extensively studied. A commonly used strategy is to add an L_1-penalty to the likelihood function, which can also be viewed as a MAP estimation under a Laplace prior. Recent work along this line includes (Lee et al., 2006; Wainwright et al., 2006; Andrew & Gao, 2007).

This progress notwithstanding, little progress has been made so far on learning sparse MNs or log-linear models in general based on the max-margin principle, which is arguably a more desirable paradigm for training highly discriminative structured prediction models in a number of application contexts. While sparsity has been pursued in maximum margin learning of certain discriminative models such as SVM that are "unstructured" (i.e., with a univariate output), by using L_1-regularization (Bennett & Mangasarian, 1992) or by adding a cardinality constraint (Chan et al., 2007), generalization of these techniques to structured output space turns out to be extremely non-trivial. For example, although it appears possible to formulate sparse max-margin learning as a convex optimization problem as for SVM, both the primal and dual problems are hard to solve since there is no obvious way to exploit the conditional independence structures within a regularized MN to efficiently deal with the typically exponential number of margin constraints. Another empirical insight as we will show in this paper is that the L_1-regularized estimation is not so robust. Discarding the features that are not completely irrelevant can potentially hurt generalization ability.

In this paper, we propose a new formalism called *Structured Maximum Entropy Discrimination*

Appearing in *Proceedings of the 25th International Conference on Machine Learning*, Helsinki, Finland, 2008.

(SMED), which offers a general framework to combine Bayesian learning and max-margin learning of log-linear models for structured prediction. SMED is a generalization of the maximum entropy discrimination (Jaakkola et al., 1999) methods originally developed for classification to the broader problem of structured learning. It facilitates posterior inference of a full distribution of feature coefficients (i.e., weights), rather than a point-estimate as in the standard max-margin Markov network (M^3N) (Taskar et al., 2003), under a user-specified prior distribution of the coefficients and generalized maximum margin constraints. One can use the learned posterior distribution of coefficients to form a Bayesian max-margin Markov network (BM^3N) that is equivalent to a weighted sum of differentially parameterized M^3Ns, or one can obtain a MAP BM^3N. We show that, by using a Laplace prior for the feature coefficients, the resulting BM^3N is effectively a "sparse" max-margin Markov network, which we refer to as a Laplace M^3N ($LapM^3N$). But unlike the L_1-regularized maximum likelihood estimation, where sparsity is due to a hard threshold introduced by the Laplace prior (Kaban, 2007), the effect of Laplace prior in $LapM^3N$ is a biased posterior weighting of the parameters. Smaller parameters are shrunk more and thus robust estimation is achieved when the data have irrelevant features. The Bayesian formalism also makes the $LapM^3N$ less sensitive to regularization constants. Interestingly, a trivial assumption on the prior distribution of the coefficients, i.e., a standard (zero-mean and identity covariance) normal, reduces BM^3N to the standard M^3N, as shown in Theorem 3.

The paper is structured as follows. The next section reviews the basic structured prediction formalism and sets the stage for our model. Sec. 3 presents the SMED formalism and basic results on BM^3N. Sec. 4 presents $LapM^3N$ and a novel learning algorithm. Sec. 5 presents a generalization bound of BM^3N. Sec. 6 shows empirical results. Sec. 7 concludes this paper.

2. Preliminaries

Consider a structured prediction problem such as natural language parsing, image understanding, or DNA decoding. The objective is to learn a predictive function $h : \mathcal{X} \mapsto \mathcal{Y}$ from a structured input $\mathbf{x} \in \mathcal{X}$ (e.g., a sentence or an image) to a structured output $\mathbf{y} \in \mathcal{Y}$ (e.g., a sentence parsing or a scene annotation), where $\mathcal{Y} = \mathcal{Y}_1 \times \cdots \times \mathcal{Y}_l$ with $\mathcal{Y}_i = \{y_1, \ldots, y_{m_i}\}$ represents a combinatorial space of structured interpretations of multi-facet objects. For example, $\mathcal{Y}$ could correspond to the space of all possible instantiations of the part-of-speech (POS) tagging in the parse tree of a sentence, or the space of all possible ways of labeling entities over some segmentation of an image. The prediction $\mathbf{y} \equiv (y_1, \ldots, y_l)$ is *structured* because each individual label $y_i \in \mathcal{Y}_i$ within $\mathbf{y}$ must be determined in the context of other labels $y_{j \neq i}$, rather than independently as in a standard classification problem.

Let $F : \mathcal{X} \times \mathcal{Y} \mapsto \mathbb{R}$ represent a discriminant function over the input-output pairs from which one can define the predictive function h. A common choice of F is a linear model, which is based on a set of feature functions $f_k : \mathcal{X} \times \mathcal{Y} \mapsto \mathbb{R}$ and their weights w_k, i.e., $F(\mathbf{x}, \mathbf{y}; \mathbf{w}) = \mathbf{w}^\top \mathbf{f}(\mathbf{x}, \mathbf{y})$. Given F, the prediction function h is typically defined in terms of an optimization problem that maximizes F over the response variable $\mathbf{y}$ given input $\mathbf{x}$:

$$h_0(\mathbf{x}; \mathbf{w}) = \arg \max_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} F(\mathbf{x}, \mathbf{y}; \mathbf{w}). \quad (1)$$

Depending on the specific choice of the objective function $C(\mathbf{w})$ for estimating the parameter $\mathbf{w}$ (e.g., likelihood, or margin), incarnations of the general structured prediction formalism described above can be seen in models such as the CRFs (Lafferty et al., 2001), where $C(\mathbf{w})$ is the conditional likelihood of the true structured label; and the M^3N (Taskar et al., 2003), where $C(\mathbf{w})$ is the margin between the true label and any other label. Recent advances in structured prediction has introduced regularizations of $C(\mathbf{w})$ in the CRF context, so that a *sparse* $\mathbf{w}$ can be learned (Andrew & Gao, 2007). To the best of our knowledge, existing max-margin structured prediction methods utilize a single discriminant function $F(\,\cdot\,; \mathbf{w})$ defined by the "optimum" estimate of $\mathbf{w}$, similar to a practice in Frequentist statistics. In this paper, we propose a Bayesian version of the predictive rule in Eq. (1) so that the prediction function h can be obtained from a posterior mean over multiple (indeed infinitely many) $F(\,\cdot\,; \mathbf{w})$; and we also propose a new formalism and objective $C(\mathbf{w})$ that lead to a **Bayesian M^3N**, which subsumes the standard M^3N as a special case, and can achieve a posterior shrinkage effect on $\mathbf{w}$ that resembles L_1-regulatiztion. To our knowledge, although sparse graphical model learning based on various likelihood-based principles has recently received substantial attention (Lee et al., 2006; Wainwright et al., 2006), learning sparse networks based on the maximum margin principle has not yet been successfully explored. Our proposed method represents an initial foray in this important direction.

Before dwelling into exposition of the proposed approach, we end this section with a brief recapitulation of the basic M^3N that motivates this work, and provides a useful baseline that grounds the proposed approach. Under a max-margin framework, given training data $\mathcal{D} = \{\langle \mathbf{x}^i, \mathbf{y}^i \rangle\}_{i=1}^N$, we obtain a point estimate

of the weight vector $\mathbf{w}$ by solving the following max-margin problem P0 (Taskar et al., 2003):

$$\text{P0 (M}^3\text{N)}: \quad \min_{\mathbf{w},\xi} \ \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{N}\xi_i$$

$$\text{s.t. } \forall i, \forall \mathbf{y} \neq \mathbf{y}^i: \quad \mathbf{w}^\top \Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i,\ \xi_i \geq 0\ ,$$

where $\Delta\mathbf{f}_i(\mathbf{y}) = \mathbf{f}(\mathbf{x}^i, \mathbf{y}^i) - \mathbf{f}(\mathbf{x}^i, \mathbf{y})$ and $\mathbf{w}^\top\Delta\mathbf{f}_i(\mathbf{y})$ is the "margin" between the true label $\mathbf{y}^i$ and a prediction $\mathbf{y}$, $\Delta\ell_i(\mathbf{y})$ is a loss function with respect to $\mathbf{y}^i$, and ξ_i is a slack variable that absorbs errors in the training data. Various loss functions have been proposed in the literature (Tsochantaridis et al., 2004). In this paper, we adopt the *hamming loss* used in (Taskar et al., 2003): $\Delta\ell_i(\mathbf{y}) = \sum_{j=1}^{|\mathbf{x}^i|}\mathbb{I}(y_j \neq y_j^i)$, where $\mathbb{I}(\cdot)$ is an indicator function that equals to one if the argument is true and zero otherwise. The optimization problem P0 is intractable because the feasible space for $\mathbf{w}$, $\mathcal{F}_0 = \{\mathbf{w} : \mathbf{w}^\top\Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i;\ \forall i, \forall\mathbf{y} \neq \mathbf{y}^i\}$, is defined by $O(N|\mathcal{Y}|)$ number of constraints, and $\mathcal{Y}$ itself is exponential to the size of the input $\mathbf{x}$. Exploring sparse dependencies among individual labels y_i in $\mathbf{y}$, as reflected in the specific design of the feature functions (e.g., based on pair-wise labeling potentials), and convex duality of the objective, efficient algorithms based on cutting-plane (Tsochantaridis et al., 2004) or message-passing (Taskar et al., 2003) have been proposed to obtain an approximate optimum solution. As described shortly, these algorithms can be directly employed as subroutines in solving our proposed model.

3. Bayesian Maximum Margin Markov Networks

In this paper, we take a Bayesian approach and learn a distribution $p(\mathbf{w})$, rather than a point estimate of $\mathbf{w}$, in a max-margin manner. For prediction, we take the average over all the possible models, that is:

$$h_1(\mathbf{x}) = \arg\max_{\mathbf{y}\in\mathcal{Y}(\mathbf{x})} \int p(\mathbf{w})F(\mathbf{x},\mathbf{y};\mathbf{w})\,\mathrm{d}\mathbf{w}\,. \quad (2)$$

Now, the open question is how we can devise an appropriate objective function over $p(\mathbf{w})$, in a similar spirit as the L_2-norm cost over $\mathbf{w}$ in P0, that leads to an optimum estimate of $p(\mathbf{w})$. Below, we present a structured maximum entropy discrimination (SMED) framework that facilitates the estimation of a Bayesian M^{3}N defined by $p(\mathbf{w})$. As we show in the sequel, our Bayesian max-margin learning formalism offers several advantages like the PAC-Bayes generalization guarantee and estimation robustness.

3.1. SMED and the Bayesian M^{3}N

Given a training set $\mathcal{D}$, analogous to the feasible space $\mathcal{F}_0$ for weight vector $\mathbf{w}$ in an M^{3}N (i.e., problem P0), the feasible subspace $\mathcal{F}_1$ of weight distribution $p(\mathbf{w})$ is defined by a set of *expected* margin constraints:

$$\mathcal{F}_1 = \{p(\mathbf{w}) : \langle\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})\rangle_{p(\mathbf{w})} \geq -\xi_i,\ \forall i, \mathbf{y} \neq \mathbf{y}^i\},$$

where $\Delta F_i(\mathbf{y};\mathbf{w}) = F(\mathbf{x}^i,\mathbf{y}^i;\mathbf{w}) - F(\mathbf{x}^i,\mathbf{y};\mathbf{w})$ and $\langle\cdot\rangle_p$ denotes the expectations with respect to p.

To choose the best distribution $p(\mathbf{w})$ from $\mathcal{F}_1$, the *maximum entropy principle* suggests that one can consider the distribution that minimizes its relative entropy with respect to some chosen prior p_0, as measured by the Kullback-Leibler divergence, $KL(p||p_0) = \langle\log(p/p_0)\rangle_p$. To accommodate the discriminative prediction problem we concern, instead of minimizing the usual KL, we optimize the generalized entropy (Dudík et al., 2007; Lebanon & Lafferty, 2001), or a regularized KL-divergence, $KL(p(\mathbf{w})||p_0(\mathbf{w})) + U(\xi)$, where $U(\xi)$ is a closed proper convex function over the slack variables. This leads to the following Structured Maximum Entropy Discrimination Model:

Definition 1 (The Structured Maximum Entropy Discrimination Model) *Given training data $\mathcal{D} = \{\langle\mathbf{x}^i,\mathbf{y}^i\rangle\}_{i=1}^N$, a discriminant function $F(\mathbf{x},\mathbf{y};\mathbf{w})$, a loss function $\Delta\ell_{\mathbf{x}}(\mathbf{y})$, and an ensuing feasible subspace $\mathcal{F}_1$ (defined above) for parameter distribution $p(\mathbf{w})$, the SMED model that leads to a prediction function of the form of Eq. (2) is defined by the following generalized relative entropy minimization with respect to a parameter prior $p_0(\mathbf{w})$:*

$$\text{P1}: \quad \min_{p(\mathbf{w}),\xi} \ KL(p(\mathbf{w})||p_0(\mathbf{w})) + U(\xi)$$
$$\text{s.t. } \ p(\mathbf{w}) \in \mathcal{F}_1,\ \xi_i \geq 0, \forall i.$$

The P1 defined above is a variational optimization problem over $p(\mathbf{w})$ in a subspace of valid parameter distributions. Since both the KL and the function U in P1 are convex, and the constraints in $\mathcal{F}_1$ are linear, P1 is a convex program, which can be solved via applying the calculus of variations to the Lagrangian to obtain a variational extremum, followed by a dual transformation of P1. Due to space limit, a detailed derivation is given in an extended version of this paper, and below we state the main results as a theorem.

Theorem 2 (Solution to SMED) *The variational optimization problem P1 underlying the SMED model gives rise to the following optimum distribution of Markov network parameters $\mathbf{w}$:*

$$p(\mathbf{w}) = \frac{1}{Z(\alpha)}p_0(\mathbf{w})\exp\{\sum_{i,\mathbf{y}}\alpha_i(\mathbf{y})[\Delta F_i(\mathbf{y};\mathbf{w}) - \Delta\ell_i(\mathbf{y})]\}, \quad (3)$$

where the Lagrangian multipliers $\alpha_i(\mathbf{y})$ (corresponding to constraints in $\mathcal{F}_1$) can be obtained by solving the dual problem of P1:

$$\text{D1}: \quad \max_{\alpha} \ -\log Z(\alpha) - U^\star(\alpha)$$
$$\text{s.t. } \ \alpha_i(\mathbf{y}) \geq 0,\ \forall i,\ \forall\mathbf{y},$$

where $U^\star(\cdot)$ represents the conjugate of the slack function $U(\cdot)$, i.e., $U^\star(\alpha) = \sup_\xi\big(\sum_{i,\mathrm{y}}\alpha_i(\mathrm{y})\xi_i - U(\xi)\big)$.

For a closed proper convex function $\phi(\mu)$, its conjugate is defined as $\phi^\star(\nu) = \sup_\mu[\nu^\top\mu - \phi(\mu)]$. In problem D1, by convex duality, the log normalizer $\log Z(\alpha)$ can be shown to be the conjugate of the KL-divergence. If the slack function is $U(\xi) = C\|\xi\| = C\sum_i \xi_i$, it is easy to show that $U^\star(\alpha) = \mathbb{I}_\infty(\sum_{\mathbf{y}} \alpha_i(\mathbf{y}) \leq C,\ \forall i)$, where $\mathbb{I}_\infty(\cdot)$ is a function that equals to zero when its argument holds true and infinity otherwise. Here, the inequality corresponds to the trivial solution $\xi = 0$, that is, the training data are perfectly separative. Ignoring this inequality does not affect the solution since the special case $\xi = 0$ is still included. Thus, the Lagrangian multipliers $\alpha_i(\mathbf{y})$ in the dual problem D1 comply with the set of constraints that $\sum_{\mathbf{y}} \alpha_i(\mathbf{y}) = C,\ \forall i$. Another example is $U(\xi) = KL(p(\xi)||p_0(\xi))$ by introducing uncertainty on the slack variables (Jaakkola et al., 1999). Some other U functions and their dual functions are studied in (Lebanon & Lafferty, 2001; Dudík et al., 2007).

The optimum parameter distribution $p(\mathbf{w})$ defined by Eq. (3), along with the predictive function $h_1(x;\mathbf{w})$ given by Eq. (2), jointly form what we would like to call a **Bayesian M^{3}N** (BM^{3}N). The close connection of BM^{3}N and M^{3}N is suggested by the striking isomorphisms of the opt-problem P1, the feasible space $\mathcal{F}_1$, and the predictive function h_1 underlying an BM^{3}N, to their counterparts P0, $\mathcal{F}_0$, and h_0, respectively, underlying an M^{3}N. Indeed, by making a special choice of a parameter prior in Eq. (3), based on the above discussion of conjugate functions in D1, we arrive at a reduction of D1 to an M^{3}N optimization problem. The following theorem makes this explicit.

Theorem 3 (Reduction of BM^{3}N to M^{3}N) *Assuming $F(\mathbf{x},\mathbf{y};\mathbf{w}) = \mathbf{w}^\top\mathbf{f}(\mathbf{x},\mathbf{y})$, $U(\xi) = \sum_i \xi_i$, and $p_0(\mathbf{w}) = \mathcal{N}(\mathbf{w}|0,I)$, where I denotes an identity matrix, then the Lagrangian multipliers $\alpha_i(\mathbf{y})$ are obtained by solving the following dual problem:*

$$\max_{\alpha} \sum_{i,\mathbf{y}} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}) - \frac{1}{2}\|\sum_{i,\mathbf{y}} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})\|^2$$
$$\text{s.t.} \sum_{\mathbf{y}} \alpha_i(\mathbf{y}) = C;\ \alpha_i(\mathbf{y}) \geq 0,\ \forall i,\ \forall \mathbf{y},$$

which, when applied to h_1, lead to a predictive function that is identical to $h_0(\mathbf{x};\mathbf{w})$ given by Eq. (1).

Proof: (sketch) Replacing $p_0(\mathbf{w})$ in Eq. (3) with $\mathcal{N}(\mathbf{w}|0,I)$, we can obtain the following closed-form expression of the $Z(\alpha)$ in $p(\mathbf{w})$:

$$\int \frac{1}{(2\pi)^{\frac{K}{2}}} \exp\{-\frac{\mathbf{w}^\top\mathbf{w}}{2} + \sum_{i,\mathbf{y}} \alpha_i(\mathbf{y})[\mathbf{w}^\top\Delta\mathbf{f}_i(\mathbf{y}) - \Delta\ell_i(\mathbf{y})]\}\,\mathrm{d}\mathbf{w}$$
$$= \exp\Big(-\sum_{i,\mathbf{y}} \alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}) + \frac{1}{2}\|\sum_{i,\mathbf{y}} \alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})\|^2\Big).$$

As we have stated, the constraints $\sum_{\mathbf{y}} \alpha_i(\mathbf{y}) = C$ are due to the conjugate of $U(\xi) = \sum_i \xi_i$. □

Theorem 3 shows that in the supervised learning setting, M^{3}N is subsumed by the SMED model, and can be viewed as a special case of a Bayesian M^{3}N when the slack function is linear and the parameter prior is a standard normal. As described later, this connection renders many existing techniques for solving the M^{3}N directly applicable for solving the BM^{3}N. Note that although the distribution $p(\mathbf{w})$ in Eq. (3) has the same form as that of Bayesian CRFs (Qi et al., 2005), the underlying principles are fundamentally different.

Recent trend in pursuing "sparse" graphical models has led to the emergence of regularized version of CRFs (Andrew & Gao, 2007) and Markov networks (Lee et al., 2006; Wainwright et al., 2006). Interestingly, while such extensions have been successfully implemented by several authors in maximum likelihood learning of various sparse graphical models, they have not yet been explored in the context of maximum margin learning. Such a gap is not merely due to a negligence. Indeed, learning a sparse M^{3}N can be significantly harder as we discuss below.

As Theorem 3 reveals, an M^{3}N corresponds to a BM^{3}N with a standard normal prior for the weight vector $\mathbf{w}$. To encourage a sparse model, when using zero-mean normal prior, the weights of irrelevant features should peak around zero with very small variances. However, the isotropy of the variances in all dimensions in the standard normal prior makes M^{3}N infeasible to adjust the variances in different dimensions to fit sparse data. One way to learn a sparse model is to adopt the strategy of L_1-SVM to use L_1-norm instead of L_2-norm (a detailed description of this formulation and the duality derivation is available in the extended version of this paper). However, in both the primal and dual of an L_1-regularized M^{3}N, there is no obvious way to exploit the sparse dependencies among variables of the MN in order to efficiently deal with typically exponential number of constraints, which makes direct optimization or LP-formulation expensive. In this paper, we adopt the SMED framework that directly leads to a Bayesian M^{3}N, and employ a Laplace prior for $\mathbf{w}$ to learn a Laplace M^{3}N. When fitted to training data, the parameter posterior $p(\mathbf{w})$ under a Laplace M^{3}N has a shrinkage effect on small weights, which is similar to the L_1-regularizer in an M^{3}N. Although exact learning of a Laplace M^{3}N is still very hard, we show that it can be efficiently approximated by a variational inference procedure based on existing methods.

4. Laplace M^{3}N

The Laplace prior is $p_0(\mathbf{w}) = \prod_{k=1}^K \frac{\sqrt{\lambda}}{2} e^{-\sqrt{\lambda}|w_k|} = \big(\frac{\sqrt{\lambda}}{2}\big)^K e^{-\sqrt{\lambda}\|\mathbf{w}\|}$. The Laplace density is heavy tailed

and peaked at zero. Thus, it encodes the prior belief that the distribution of $\mathbf{w}$ is strongly peaked around zero. Another nice property is that the Laplace density is log-convex, which can be exploited to get convex estimation problems like LASSO (Tibshirani, 1996).

4.1. Variational Learning with Laplace Prior

Although in principle we have a closed-form solution of $p(\mathbf{w})$ in Theorem 2, the parameters $\alpha_i(\mathbf{y})$ are hard to estimate when using the Laplace prior. As we shall see in Section 4.2, exact integration will lead to a dual function that is difficult to maximize. Thus, we present a variational approximate learning approach.

Our approach is based on the hierarchical interpretation (Figueiredo, 2003) of the Laplace prior, that is, each w_k has a zero-mean Gaussian distribution $p(w_k|\tau_k) = \mathcal{N}(w_k|0, \tau_k)$ and the variance τ_k has an exponential hyper-prior density,

$$p(\tau_k|\lambda) = \frac{\lambda}{2}\exp\big\{-\frac{\lambda}{2}\tau_k\big\}, \quad \text{for } \tau_k \geq 0.$$

Let $p(\mathbf{w}|\tau) = \prod_{k=1}^K p(w_k|\tau_k)$, $p(\tau|\lambda) = \prod_{k=1}^K p(\tau_k|\lambda)$, then, $p_0(\mathbf{w}) = \int p(\mathbf{w}|\tau)p(\tau|\lambda)\,\mathrm{d}\tau$. Using the hierarchical representation and applying the Jensen's inequality, we get the following upper bound:

$$\begin{aligned} KL(p||p_0) &= -H(p) - \langle \log \int p(\mathbf{w}|\tau)p(\tau|\lambda)\,\mathrm{d}\tau \rangle_p \\ &\leq -H(p) - \langle \int q(\tau)\log\frac{p(\mathbf{w}|\tau)p(\tau|\lambda)}{q(\tau)}\,\mathrm{d}\tau \rangle_p \\ &\triangleq \mathcal{L}(p(\mathbf{w}), q(\tau)), \end{aligned}$$

where $q(\tau)$ is a variational distribution which is used to approximate $p(\tau|\lambda)$.

Substituting this upper bound for the KL in P1, we now solve the following problem,

$$\min_{p(\mathbf{w})\in\mathcal{F}_1; q(\tau); \xi} \mathcal{L}(p(\mathbf{w}), q(\tau)) + U(\xi). \tag{4}$$

This problem can be solved with an iterative minimization algorithm alternating between $p(\mathbf{w})$ and $q(\tau)$, as outlined in Algorithm 1, and detailed below.

Algorithm 1 Variational Bayesian Learning

Input: data $\mathcal{D} = \{\langle \mathbf{x}^i, \mathbf{y}^i\rangle\}_{i=1}^N$, constants C and λ, iteration number T
Output: posterior mean $\langle \mathbf{w}\rangle_p^T$
Initialize $\langle \mathbf{w}\rangle_p^1 \leftarrow 0$, $\Sigma_{\mathbf{w}}^1 \leftarrow I$
for $t = 1$ **to** $T-1$ **do**
  Step 1: solve (5) or (6) for $\langle \mathbf{w}\rangle_p^{t+1} = \Sigma_{\mathbf{w}}^t\eta$; update $\langle \mathbf{w}\mathbf{w}^\top\rangle_p^{t+1} \leftarrow \Sigma_{\mathbf{w}}^t + \langle \mathbf{w}\rangle_p^{t+1}(\langle \mathbf{w}\rangle_p^{t+1})^\top$.
  Step 2: use (7) to update $\Sigma_{\mathbf{w}}^{t+1} \leftarrow \mathrm{diag}(\sqrt{\frac{\langle w_k^2\rangle_p^{t+1}}{\lambda}})$.
end for

Step 1: Keep $q(\tau)$ fixed, we optimize (4) with respect to $p(\mathbf{w})$. Taking the same procedure as in solving P1, we get the posterior distribution $p(\mathbf{w})$ as follows,

$$\begin{aligned} p(\mathbf{w}) &\propto \exp\{\int q(\tau)\log p(\mathbf{w}|\tau)\,\mathrm{d}\tau - b\}\cdot\exp\{\mathbf{w}^\top\eta - L\} \\ &\propto \exp\{-\frac{1}{2}\mathbf{w}^\top\langle A^{-1}\rangle_q\mathbf{w} - b + \mathbf{w}^\top\eta - L\} \\ &= \mathcal{N}(\mathbf{w}|\mu_{\mathbf{w}}, \Sigma_{\mathbf{w}}), \end{aligned}$$

where $\eta = \sum_{i,\mathbf{y}}\alpha_i(\mathbf{y})\Delta\mathbf{f}_i(\mathbf{y})$, $L = \sum_{i,\mathbf{y}}\alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y})$, $A = \mathrm{diag}(\tau_k)$, and $b = KL(q(\tau)||p(\tau|\lambda))$ is a constant. The posterior mean and variance are $\langle \mathbf{w}\rangle_p = \mu_{\mathbf{w}} = \Sigma_{\mathbf{w}}\eta$ and $\Sigma_{\mathbf{w}} = (\langle A^{-1}\rangle_q)^{-1} = \langle \mathbf{w}\mathbf{w}^\top\rangle_p - \langle \mathbf{w}\rangle_p\langle \mathbf{w}\rangle_p^\top$, respectively. The dual parameters α are estimated by solving the following dual problem:

$$\begin{aligned} \max_{\alpha}\ & \sum_{i,\mathbf{y}}\alpha_i(\mathbf{y})\Delta\ell_i(\mathbf{y}) - \frac{1}{2}\eta^\top\Sigma_{\mathbf{w}}\eta \\ \text{s.t.}\ & \sum_{\mathbf{y}}\alpha_i(\mathbf{y}) = C;\ \alpha_i(\mathbf{y}) \geq 0,\ \forall i,\ \forall\mathbf{y}. \end{aligned} \tag{5}$$

This dual problem can be directly solved using existing algorithms developed for M^{3}N, such as (Taskar et al., 2003; Bartlett et al., 2004). Alternatively, we can solve the following primal problem:

$$\begin{aligned} \min_{\mathbf{w},\xi}\ & \frac{1}{2}\mathbf{w}^\top\Sigma_{\mathbf{w}}^{-1}\mathbf{w} + C\sum_{i=1}^N\xi_i \\ \text{s.t.}\ & \mathbf{w}^\top\Delta\mathbf{f}_i(\mathbf{y}) \geq \Delta\ell_i(\mathbf{y}) - \xi_i;\ \xi_i \geq 0,\ \ \forall i,\ \forall\mathbf{y} \neq \mathbf{y}^i. \end{aligned} \tag{6}$$

It is easy to show that the solution of problem (6) leads to the posterior mean of $\mathbf{w}$ under $p(\mathbf{w})$. The primal problem can be solved with subgradient (Ratliff et al., 2007) or extragradient (Taskar et al., 2006) methods.

Step 2: Keep $p(\mathbf{w})$ fixed, we optimize (4) with respect to $q(\tau)$. Take the derivative of $\mathcal{L}$ with respect to $q(\tau)$ and set it to zero, then we get $q(\tau) = \prod_{k=1}^K q(\tau_k)$. Each $q(\tau_k)$ is computed as follows:

$$\begin{aligned} \forall k: \quad q(\tau_k) &\propto p(\tau_k|\lambda)\exp\big\{\langle \log p(w_k|\tau_k)\rangle_p\big\} \\ &\propto \mathcal{N}(\sqrt{\langle w_k^2\rangle_p}|0,\tau_k)\exp(-\frac{1}{2}\lambda\tau_k). \end{aligned}$$

The normalization factor is $\int\mathcal{N}(\sqrt{\langle w_k^2\rangle_p}|0,\tau_k)\cdot\frac{\lambda}{2}\exp(-\frac{1}{2}\lambda\tau_k)\,\mathrm{d}\tau_k = \frac{\sqrt{\lambda}}{2}\exp(-\sqrt{\lambda\langle w_k^2\rangle_p})$. The expectations $\langle\tau_k^{-1}\rangle_q$ required in calculating $\langle A^{-1}\rangle_q$ are calculated as follows,

$$\langle\frac{1}{\tau_k}\rangle_q = \int\frac{1}{\tau_k}q(\tau_k)\,\mathrm{d}\tau_k = \sqrt{\frac{\lambda}{\langle w_k^2\rangle_p}}. \tag{7}$$

We iterate between the above two steps until convergence. Then, we use the posterior distribution $p(\mathbf{w})$ to make prediction. For irrelevant features, the variances should converge to zeros and thus lead to a sparse estimation. The intuition behind this iterative minimization algorithm is as follows. First, we use a Gaussian distribution to approximate the Laplace distribution and thus get a QP problem that is analogous to that of M^{3}N; then, the second step updates the covariance matrix in the QP problem with an exponential hyper-prior on the variance.

4.2. Insights

To see how the Laplace prior affects the posterior distribution, we do the following calculations. Substitute the hierarchical representation of the Laplace prior into $p(\mathbf{w})$ in Theorem 2, and we get:

$$\begin{aligned} Z(\alpha) &= \int\int p(\mathbf{w}|\tau)p(\tau|\lambda)\,\mathrm{d}\tau \cdot \exp\{\mathbf{w}^\top\eta - L\}\,\mathrm{d}\mathbf{w} \\ &= \int p(\tau|\lambda)\int p(\mathbf{w}|\tau)\cdot\exp\{\mathbf{w}^\top\eta - L\}\,\mathrm{d}\mathbf{w}\;\mathrm{d}\tau \\ &= \exp\{-L\}\prod_{k=1}^{K}\frac{\lambda}{\lambda-\eta_k^2}, \end{aligned} \tag{8}$$

where $\eta_k = \sum_{i,\mathbf{y}}\alpha_i(\mathbf{y})(f_k(\mathbf{x}^i,\mathbf{y}^i) - f_k(\mathbf{x}^i,\mathbf{y}))$ and an additional constraint is $\forall k,\ \eta_k^2 < \lambda$. Otherwise, the integration is infinity. Using the result (8), we can get:

$$\frac{\partial \log Z}{\partial \alpha_i(\mathbf{y})} = \mu^\top\Delta\mathbf{f}_i(\mathbf{y}) - \Delta\ell_i(\mathbf{y}), \tag{9}$$

where μ is a column vector and $\mu_k = \frac{2\eta_k}{\lambda-\eta_k^2}$, $\forall 1 \le k \le K$. An alternative way is using the definition of Z : $Z = \int p_0(\mathbf{w})\cdot\exp\{\mathbf{w}^\top\eta - L\}\,\mathrm{d}\mathbf{w}$. We can get:

$$\frac{\partial \log Z}{\partial \alpha_i(\mathbf{y})} = \langle\mathbf{w}\rangle_p^\top\Delta\mathbf{f}_i(\mathbf{y}) - \Delta\ell_i(\mathbf{y}). \tag{10}$$

Comparing Eqs. (9) and (10), we get $\langle\mathbf{w}\rangle_p = \mu$, that is, $\langle w_k\rangle_p = \frac{2\eta_k}{\lambda-\eta_k^2}$, $\forall 1 \le k \le K$. Similar calculation can lead to the result that in M^{3}N (standard normal prior) $\langle\mathbf{w}\rangle_p = \eta$. Figure 1 shows the posterior means (any dimension) when the priors are standard normal, Laplace with $\lambda = 4$, and Laplace with $\lambda = 6$. We can see that with a Laplace prior, the parameters are shrunk around zero. The larger the λ value is, the greater the shrinkage effect. For a fixed λ, the shape of the posterior mean is smoothly nonlinear but no component is explicitly discarded, that is, no weight is set to zero. This is different from the shape of a L_1-regularized maximum likelihood estimation (Kaban, 2007) where an interval exists around the origin and parameters falling into this interval are set to zeros.

Note that if we use the exact integration as in Eq. (8), the dual problem D1 will maximize $L - \sum_{k=1}^{K}\log\frac{\lambda}{\lambda-\eta_k^2}$. Since η_k^2 appears within a logarithm, the optimization problem would be very hard to solve. Thus, we turn to a variational approximation method.

5. Generalization bound

The PAC-Bayes bound (Langford et al., 2001) provides a theoretical motivation to learn an averaging model as in P1 which minimizes the KL-divergence and simultaneously satisfies the discriminative classification constraints. To apply it to our structured learning setting, we assume that the discriminant functions are bounded, that is, $F \in \mathcal{H} : \mathcal{X}\times\mathcal{Y} \to [-c, c]$ for all $\mathbf{w}$,

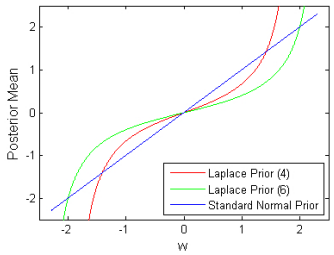

Figure 1. Posterior mean with different priors against the estimation of M^{3}N (i.e. with the standard normal prior).

where c is a positive constant. Recall that our averaging model is $h(\mathbf{x},\mathbf{y}) = \langle F(\mathbf{x},\mathbf{y};\mathbf{w})\rangle_{p(\mathbf{w})}$. We define the margin of an example $(\mathbf{x},\mathbf{y})$ for such a function h as $M(h,\mathbf{x},\mathbf{y}) = h(\mathbf{x},\mathbf{y}) - \max_{\mathbf{y}'\neq\mathbf{y}} h(\mathbf{x},\mathbf{y}')$. Clearly, the model h makes a wrong prediction on $(\mathbf{x},\mathbf{y})$ only if $M(h,\mathbf{x},\mathbf{y}) \le 0$. Let Q be a distribution over $\mathcal{X}\times\mathcal{Y}$, and let $\mathcal{D}$ be a sample of N examples randomly drawn from Q. We have the following PAC-Bayes theorem.

Theorem 4 (PAC-Bayes Bound of BM^{3}N) *Let p_0 be any continuous probability distribution over $\mathcal{H}$ and let $\delta \in (0,1)$. If $F \in \mathcal{H} : \mathcal{X}\times\mathcal{Y} \to [-c,c]$ for all $\mathbf{w}$, then with probability at least $1-\delta$ over random samples $\mathcal{D}$ of Q, for very distribution p over $\mathcal{H}$ and for all margin thresholds $\gamma > 0$:*

$$\begin{aligned} &\Pr_Q(M(h,\mathbf{x},\mathbf{y}) \le 0) \le \Pr_{\mathcal{D}}(M(h,\mathbf{x},\mathbf{y}) \le \gamma) \\ &\quad + O\left(\sqrt{\frac{\gamma^{-2}KL(p||p_0)\ln(N|\mathcal{Y}|) + \ln N + \ln\delta^{-1}}{N}}\right). \end{aligned}$$

Here, $\Pr_Q(.)$ stands for $\langle.\rangle_Q$ and $\Pr_{\mathcal{D}}(.)$ stands for the empirical average on $\mathcal{D}$. The proof follows the same structure as the original PAC-Bayes bound proof, with consideration of the margins. Due to space limit, details of the proof are given in the extended paper.

6. Experiments

In this section, we present some empirical results of LapM^{3}N on both synthetic and real data sets. We compare LapM^{3}N with M^{3}N, CRFs, L_1-regularized CRFs (L_1-CRFs), and L_2-regularized CRFs (L_2-CRFs). We use the quasi-Newton method (Andrew & Gao, 2007) to learn L_1-CRFs.

6.1. Synthetic Data Sets

6.1.1. I.I.D Features

The first experiment is conducted on synthetic sequence data with 100 i.i.d features. We generate three types of data sets with 10, 30, and 50 relevant features. For each setting, we randomly generate 10 linear-chain CRFs with 8 binary labeling states. The feature functions include: a real valued state-feature function over a one dimensional input feature and a class label; and

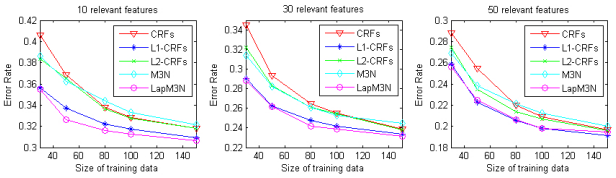

Figure 2. Evaluation results on data sets with i.i.d features.

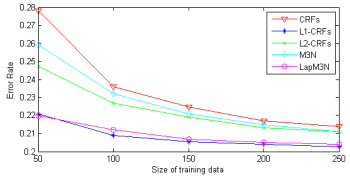

Figure 3. Results on data sets with 30 relevant features.

4 (2×2) binary transition-feature functions capturing pairwise label dependencies. For each model we generate a data set of 1000 samples. For each sample, we first *independently* draw the 100 features from a standard normal distribution, and then apply a Gibbs sampler to assign a label sequence with 5000 iterations.

For each data set, we randomly draw a part as training data and use the rest for testing. The numbers of training data are 30, 50, 80, 100, and 150. The QP problem is solved with the exponentiated gradient method (Bartlett et al., 2004). In all the following experiments, the regularization constant of L_1-CRFs and L_2-CRFs is chosen from $\{0.01, 0.1, 1, 4, 9, 16\}$ by a 5-fold cross-validation in training. For LapM^{3}N, we use the same method to choose λ from 20 roughly evenly spaced values between 1 and 268. For each setting, the average over 10 data sets is the final performance.

The results are shown in Figure 2. All the results of LapM^{3}N are achieved with 3 iterations of the variational learning. Under different settings LapM^{3}N consistently outperforms M^{3}N and performs comparably with L_1-CRFs. But note that the synthetic data come from simulated CRFs. Both L_1-CRFs and L_2-CRFs outperform the un-regularized CRFs. One interesting result is that M^{3}N and L_2-CRFs perform comparably. This is reasonable because as derived by Lebanon and Lafferty (2001) and noted by Globerson et al. (2007) the L_2-regularized MLE of CRFs has a similar convex dual as that of M^{3}N. The only difference is the loss they try to optimize. CRFs optimize the log-loss while M^{3}N optimizes the hinge-loss. As the number of training data increase, all the algorithms consistently get higher performance. The advantage of LapM^{3}N is more obvious when there are fewer relevant features.

6.1.2. Correlated Features

In reality, most data sets contain redundancy and the features are usually correlated. So, we evaluate our models on synthetic data sets with correlated features. We take the similar procedure as in generating the data sets with i.i.d features to first generate one linear-chain CRF model. Then, we use the CRF model to generate 10 data sets of which each sample has 30 relevant features. The 30 relevant features are partitioned into 10 groups. For the features in each group, we first draw a real-value from a standard normal distribution and then 'spoil' the feature with a random Gaussian noise to get 3 correlated features. The noise Gaussian has a zero mean and standard variance 0.05. Here and in all the remaining experiments, we use the sub-gradient method (Ratliff et al., 2007) to solve the QP problem in both M^{3}N and LapM^{3}N. We use the learning rate and complexity constant that are suggested by the authors, that is, $\alpha_t = \frac{1}{2\beta\sqrt{t}}$ and $C = 200\beta$, where β is a parameter we introduced to adjust α_t and C. We do K-fold CV on each data set and take the average over the 10 data sets as the final results. Like (Taskar et al., 2003), in each run we choose one part to do training and test on the rest K-1 parts. We vary K from 20, 10, 7, 5, to 4. In other words, we use 50, 100, about 150, 200, and 250 samples during the training. We use the same grid search to choose λ and β from $\{9, 16, 25, 36, 49, 64\}$ and $\{1, 10, 20, 30, 40, 50, 60\}$ respectively. Results are shown in Figure 3. We can get the same conclusions as in the previous results.

6.2. Real-World OCR Data Set

The OCR data set is partitioned into 10 subsets for 10-fold CV (Taskar et al., 2003; Ratliff et al., 2007). We randomly select N samples from each fold for our experiments. We vary N from 100, 150, 200, to 250, and denote the selected data sets by OCR100, OCR150, OCR200, and OCR250 respectively. When $\beta = 4$ on OCR100 and OCR150, $\beta = 2$ on OCR200 and OCR250, and $\lambda = 36$, results are shown in Figure 4.

Overall, as the number of training data increases, all algorithms achieve lower error rates and smaller variances. Generally, LapM^{3}N consistently outperforms all the other models. M^{3}N outperforms the standard, non-regularized, CRFs and the L_1-CRFs. Again, L_2-CRFs perform comparably to M^{3}N. This is a bit surprising but still reasonable due to the understanding of their only difference on loss functions (Globerson et al., 2007). By examining the prediction accuracy, we can see an obvious over-fitting in CRFs and L_1-CRFs. In contrast, L_2-CRFs are very robust. This is because unlike the synthetic data sets, features in real-world data are usually not completely irrelevant. In this case, putting small weights to zero as in L_1-CRFs will hurt generalization ability and also lead to instability to regularization constants as shown later. Instead, L_2-CRFs do not put small weights to zero but

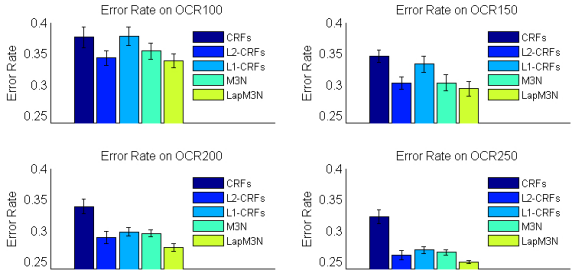

Figure 4. Evaluation results on OCR data set with different numbers of selected data.

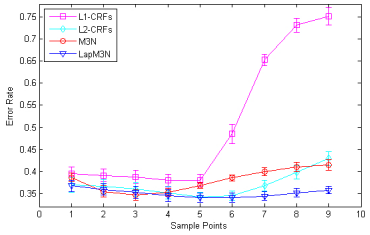

Figure 5. Error rates of different models on OCR100 with different regularization constants. From left to right, the regularization constants are 0.0001, 0.001, 0.01, 0.1, 1, 4, 9, 16, and 25 for L_1-CRFs and L_2-CRFs, and for M^{3}N and LapM^{3}N they are 1, 4, 9, 16, 25, 36, 49, 64, and 81.

shrink them towards zero as in LapM^{3}N. The non-regularized MLE can also easily lead to over-fitting.

6.3. Sensitivity to Regularization Constants

Figure 5 shows the error rates of different models on OCR100. From the results, we can see that the L_1-CRFs are much sensitive to the regularization constants. However, L_2-CRFs, M^{3}N, and LapM^{3}N are much less sensitive. Among all the models, LapM^{3}N is the most stable one. The stability of LapM^{3}N is due to the posterior weighting instead of hard-thresholding to set small weights to zero as in L_1-CRFs.

7. Conclusions

We proposed a *Structured Maximum Entropy Discrimination* formalism for Bayesian max-margin learning in structured prediction. This formalism gives rise to a general class of Bayesian M^{3}Ns and subsumes the standard M^{3}N as a spacial case where the predictive model is assumed to be linear and the parameter prior is a standard normal. We show that the adoption of a Laplace prior of the parameter leads to a Laplace M^{3}N that enjoys properties expected from a sparsified Bayesian M^{3}N. Unlike the L_1-regularized MLE which sets small weights to zeros to achieve sparsity, LapM^{3}N weights the parameters *a posteriori*. Features with smaller weights are shrunk more. This posterior weighting effect makes LapM^{3}N more stable with respect to the magnitudes of the regularization coefficients and more generalizable.

Acknowledgements

We thank Ivor Tsang for inspiring discussions. This work was conceived and completed while J.Z. was a visiting researcher at CMU under a State Scholarship from China, and supports from NSF DBI-0546594 and DBI-0640543 awarded to Eric Xing.
